LIST OF CONTRIBUTORS

TO VOLUME II.

- Dr. E. F. ARMSTRONG (*Messrs. Huntley and Palmers, Reading*). [DEXTRINS; DIASTASE; EMULSIN; GLUCOSIDES; GLUTEN.]
- Dr. WILLIAM A. BONE, F.R.S., *Professor of Fuel and Refractory Materials, Imperial College of Science and Technology, London*. [FUEL.]
- JOSEPH BURTON, Esq., *Pilkington Tile and Pottery Co., Clifton Junction, Manchester*. [CLAY.]
- ERNEST BURY, Esq., M.Sc., *The Skinningrove Iron Co., Ltd., Carlin How, Yorkshire*. [COKE MANUFACTURE AND THE RECOVERY OF BY-PRODUCTS.]
- Dr. J. C. CAIN, F.I.C., *Editor of the Journal of the Chemical Society, London*. [DISAZO- AND TETRAZO- COLOURING MATTERS.]
- ARTHUR CAREY, Esq., B.Sc., *United Alkali Company, Ltd., Liverpool*. [CHLORINE.]
- DUGALD CLERK, Esq., F.R.S., *Consulting Engineer, London*. [EVAPORATION; EXPLOSION OF GASEOUS MIXTURES.]
- T. C. CLOUD, Esq., A.R.S.M., M.I.M.M., *Consulting Metallurgical Engineer, London*. [COPPER.]
- Dr. JULIUS B. COHEN, F.R.S., *Professor of Organic Chemistry in the University of Leeds*. [DIPHENYLAMINE; DIPHENYLMETHANE.]
- W. H. COLEMAN, Esq., *Tar Works Chemist (Messrs. Hardman and Holden, Manchester)*. [CREOSOTE.]
- Dr. HAROLD G. COLMAN, F.I.C., *Consulting and Analytical Chemist, London*. [COAL GAS.]
- JAMES CONNAH, Esq., B.A., B.Sc., F.I.C., *The Government Laboratory, Custom House, London, E.* [CHOCOLATE; COCOA; COFFEE; CORDIALS AND LIQUEURS; DENATURANTS; FUSEL OIL; GEN.]
- CECIL H. CRIBB, Esq., B.Sc., F.I.C., *Consulting and Analytical Chemist, London*. [GINGER.]
- Dr. BERNARD DYER, F.I.C., *Consulting and Analytical Chemist, London*. [FEEDING STUFFS; FERTILISERS OR MANURES.]
- Dr. THOMAS EWAN (*Cassel Cyanide Co., Glasgow*). [CYANIDES.]
- THOMAS FAIRLEY, Esq., F.I.C., *Analytical and Consulting Chemist, Leeds*. [FILTER PUMPS.]
- SAMUEL FIELD, Esq., *Northampton Polytechnic Institute, Clerkenwell, London*. [ELECTRO-DEPOSITION AND ELECTRO-PLATING.]
- W. M. GARDNER, Esq., M.Sc., *Director of the Dyeing Department in the Technical College, Bradford, Yorkshire*. [DYEING; DYE STUFFS, IDENTIFICATION OF, ON FABRICS.]
- Dr. ERNEST GOULDING, F.I.C., *Imperial Institute, South Kensington*. [COTTON.]
- Dr. A. D. HALL, M.A., F.R.S., *Rothamsted Experimental Station, Harpenden, Herts*. [CROPS.]
- Dr. ARTHUR HARDEN, F.R.S., *The Lister Institute, London*. [FERMENTATION.]
- NOEL HEATON, Esq., B.Sc., *Consulting and Analytical Chemist, London*. [GLASS.]
- Dr. JOHN T. HEWITT, M.A., F.R.S., *Professor of Chemistry in the East London College*. [CHROMOPHORES AND CHROMOGENS.]
- J. W. HINCHLEY, Esq., A.R.S.M., *Lecturer on Chemical Engineering, Imperial College of Science and Technology, South Kensington*. [CRYSTALLISATION; FILTRATION.]
- GEORGE T. HOLLOWAY, Esq., A.R.C.S., F.I.C., *Metallurgical Chemist, London*. [COLUMBIUM.]
- Dr. HARRY INGLE, F.I.C., *Consulting and Analytical Chemist, Leeds*. [CORK; GLUE AND GLUE TESTING.]

- HERBERT INGLE, Esq., B.Sc., F.I.C., *late Chief Chemist to the Transvaal Agricultural Department.* [CHICK PEA; CHICORY; CHOLINE; CLOVER; CRANBERRY; CUCUMBER; DATE; EGG FRUIT; ELDERBERRY; ENDIVE; FENUGREEK; FIG; FILBERT; GARLIC; GOOSEBERRY; GORSE.]
- Dr. RUDOLPH LESSING, *Consulting Chemist, London.* [FORMALDEHYDE.]
- VIVIAN B. LEWES, Esq., F.I.C., *Professor of Chemistry in the Royal Naval College, Greenwich, S.E.* [CORROSION OF IRON; CORROSION AND FOULING OF STEEL AND IRON SHIPS AND ITS PREVENTION; FIRE EXTINCTION AND PREVENTION; AIR GAS; GAS MANTLES; OIL GAS; WATER GAS.]
- Dr. JULIUS LEWKOWITSCH, M.A., F.I.C., *Consulting and Analytical Chemist, London.* [CHINESE VEGETABLE TALLOW; CHOCOLATE FATS; COCOA-NUT OIL GROUP; COD-LIVER OIL; COTTON SEED OIL; CROTON OIL; CURCAS OIL; DÉGRAS OR SOD OIL; DIKA FAT GROUP; DRIERS; EDIBLE OILS AND FATS; GARBAGE FATS; GLYCERIN.]
- WILLIAM D. MCCREATH, Esq., *The Quantock Vale Cider Co., Ltd., North Petherton, Bridgewater.* [CIDER.]
- Dr. G. T. MORGAN, A.R.C.S., F.I.C., *Professor of Chemistry in the Faculty of Applied Chemistry, Royal College of Science for Ireland, Dublin.* [DIAZO-COMPOUNDS; DYSPROSIUM; ERBIUM; EUROPIUM; GADOLINIUM.]
- G. S. NEWTH, Esq., F.I.C. [FLASH LIGHTS.]
- A. G. PERKIN, Esq., F.R.S., F.I.C., *Clothworkers' Research Laboratory, University of Leeds.* [CHICA RED; COCHINEAL; COTTON FLOWERS; CYANELLAGIC ACID; DAPHNETIN; DATISCA CANNABINA; DIVI-DIVI; DROSERA WHITTAKERI; DYER'S BROOM; ELLAGIC ACID; ERYTHRIN; EVERNIC ACID AND EVERNICINIC ACID; EVODIA MELLEFOPIA; FLAVELLAGIC ACID; FLAVONE; FLAVONOL; FUKUGI; GALANGA ROOT; GENTIAN ROOT.]
- GEORGE H. PERRY, Esq., B.Sc., *The Laboratory, Woolwich Arsenal.* [EXPLOSIVES.]
- Dr. J. C. PHILIP, M.A., *Assistant Professor and Lecturer on Physical Chemistry, Imperial College of Science and Technology, South Kensington, London.* [COLLOIDS; CRYOSCOPY; DIFFUSION.]
- Dr. SAMUEL RIDEAL, F.I.C., *Analytical and Consulting Chemist, London.* [DISINFECTANTS.]
- H. H. ROBINSON, Esq., M.A., F.I.C., *Imperial Institute, London.* [EXTRACTION APPARATUS.]
- Dr. THOMAS K. ROSE, A.R.S.M., *The Royal Mint, London.* [GOLD.]
- Dr. F. W. RUDLER, I.S.O., *late of the Museum of Economic Geology, Jermyn St., London.* [CHINA-STONE; DATOLITE; DOLONITE; ENAMELS; FIRE-CLAY; FLAGSTONE; FREE-STONE.]
- Dr. ALFRED SENIER, F.I.C., *Professor of Chemistry, University College, Galway.* [CHLOROFORM; COLCHICUM; COLOCYNTH; CUBARA; CUSPARIA BARK; DANDELION ROOT; DATURA STRAMONIUM; DIGITALIS; DULCAMARA; ELATERIUM; ERGOT OF RYE; FILIX MAS.; GENTIAN.]
- CHARLES SIMMONDS, Esq., B.Sc., F.I.C., *The Government Laboratory, London.* [FRITTS AND GLAZES.]
- Dr. IDA SMEDLEY, *Beit Research Fellow.* [FLUORENE.]
- ARTHUR SMITHELLS, Esq., B.Sc., F.R.S., F.I.C., *Professor of Chemistry in the University of Leeds.* [FLAME.]
- L. J. SPENCER, Esq., M.A., *Mineralogical Department, British Museum, London.* [CHLOANTHITE; CHROMITE; CINNABAR; CINNAMON-STONE; COLEMANITE; COLUMBITE; COPPER-GLANCE; COPPER-PYRITES; CORUNDUM; COVELLITE; CROCIDOLITE; CRYOLITE; CUPRITE; DESCLOZITE; DIAMOND; DOMEYKITE; EMBOLITE; EMERY; ENARGITE; EUXENITE; FAHLORE; FEATHER ALUM; FEATHER ORE; FELSPAR; FERGUSONITE; FERRITE; FICHELITE; FLINT; FLUORSPAR; FRANKLINITE; FREIBERGITE; FULLER'S EARTH; GADOLINITE; GALENA; GARNET; GARNIERITE; GEMS, ARTIFICIAL; GEMS, IMITATION AND COUNTERFEIT.]
- Dr. J. J. SUDBOROUGH, F.I.C., *Professor of Chemistry in the Indian Institute of Science, Bangalore.* [ESTERIFICATION.]
- Dr. JOCELYN F. THORPE, F.R.S., *Sorby Research Fellow, University of Sheffield.* [DIPHENYL.]
- Dr. MARTHA A. WHITELEY, A.R.C.S., *Demonstrator in Chemistry, Imperial College of Science and Technology, South Kensington.* [CREATINE; CREATININE; CYSTINE; DIALURIC ACID; DILITURIC ACID; GLUTAMIC ACID; GLUTAMINE; GLUTANIC ACID.]
- Dr. SYDNEY YOUNG, F.R.S., F.I.C., *Professor of Chemistry, Trinity College, Dublin.* [DISTILLATION.]

A

DICTIONARY

OF

APPLIED CHEMISTRY.

CHIAN TURPENTINE *v.* OLEO-RESINS.

CHICA RED. *Chica red* or *chica, carneru, Vermillon americanum, carajura* is a red pigment, produced by the Indians of Central America from *Bignonia chica* (Humb. et Bonpl.). The leaves of this plant are extracted with boiling water, and the extract is allowed to ferment, or, according to Crookes (Dyeing and Calico-printing), some particles of the bark of a tree called 'aryane' are added to the liquid, and cause the precipitation of the colouring matter.

Chica red came into commerce in the form of small red cakes under the name of 'carneru,' or 'vermillion americanum,' and sometimes as a red powder; but is now extremely difficult, if not impossible, to procure. It is insoluble in water, somewhat soluble in boiling dilute alcohol, and soluble in solutions of the alkali hydroxides, with a brown-red or orange-red colour.

Boussingault (Ann. Chim. Phys. [2] 27, 315) extracted from this material, by means of alcohol, a red colouring matter. Erdmann (J. 1857, 487) employed alcoholic sulphuric acid, and precipitated the dye with ammonium carbonate. According to the latter author, this product has the composition $C_8H_8O_4$, and is decomposed by nitric acid with formation of anisic acid, picric acid, oxalic acid, and hydrocyanic acid.

Chica red is in reality a lake, and when this is decomposed with hot dilute hydrochloric acid, a comparatively small quantity of a residue remains, which consists of a mixture of the free colouring matter with plant *debris*. After purification the colouring matter consists of a pale-red power, soluble in alkaline solutions, with a red-violet colouration; which rapidly becomes brown on contact with air. It dyes mordanted calico shades which are of a similar type to those given by alizarin. *Carajura*, which is also a lake, appears to yield the same dyestuff as chica red, and is probably identical with it (Perkin, private communication). A. G. P.

CHICAGO BLUE, -ORANGE, *v.* AZO-COLOURING MATTERS.

CHICK PEA. *Cicer arietinum*, L. A leguminous annual, growing to a height of about 2 feet,
VOL. II.—T.

largely cultivated in India, where its seeds are used as food for cattle and horses, and, after the removal of the husks, for man.

In some cases the young leaves, fried in oil, are also eaten. Church (The Food Grains of India, 1886) gives, as the average composition:

	Water	Protein	Fat	Sol. carbo-	Fibre	Ash
With husk	11.2	19.5	4.6	53.8	7.8	3.1
Husked	11.5	21.7	4.2	59.0	1.0	2.6

Analyses of various parts of the fresh plant were made by Passerini (Staz. Sper. Agrar. 21, 20; Chem. Soc. Abstr. 1893, ii. 226).

The fresh substance of the stems, leaves, and entire pods contained 27.54 p.c., 24.39 p.c., and 19.85 p.c. of dry matter respectively.

The dry matter of the stems, leaves, and seeds contained:

	Protein	Fat	Cellu-	Other	carbo-	Nitrogen
			lose	hydrates	Ash	
Stems	6.35	1.8	35.0	49.0	7.81	1.62
Leaves	14.21	4.1	13.9	58.9	8.83	2.27
Seeds	26.20	5.2	1.7	63.6	3.30	4.19

The ash contained:

	K ₂ O	Na ₂ O	CaO	MgO	Fe ₂ O ₃	Mn ₂ O ₄	P ₂ O ₅	SO ₃	SiO ₂	Cl
Stems	48.4	0.5	23.6	4.4	2.1	0.03	5.35	8.6	2.3	7
Leaves	29.6	0.9	40.6	3.3	3.0	—	6.04	4.1	3.1	8
Seeds	24.6	1.3	4.5	20.0	2.4	—	39.63	4.0	7.2	9

Traces of boron, lithium, and copper were also present in the ash.

H. I.

CHICORY or **SUCCORY.** *Cichorium Intybus* (Linn.). A perennial plant belonging to the *Compositae*, growing to a height of about 3 feet, bearing blue flowers and having a long tap root. It is sometimes grown as cattle food, the foliage being thus used, but more generally it is cultivated for the sake of its root, which, when dried, roasted, and ground, is largely used for mixing with coffee.

According to Lethby's analysis (quoted by Wynter Blyth, Foods, 359, 1909), fresh chicory root contains:

Water	Gummy matter	Glucose	Bitter extractive	Fat	Cellulose, inulin, and fibre	Ash
77.0	7.5	1.1	4.0	0.6	9.0	0.8

Analyses by Mayer (Bied. Zentr. 1885, 828) gave:

	Albu- minoids	Fat	Inulin	Fibre	Sugar	Bitter extract	Ash
72	1.1	0.2	12.0	1.4	5.6	0.5	1.4
to			to	to	to	to	to
77			17.3	1.8	6.0	0.15	1.9

Wolff (Chem. Zentr. 1899, ii. 211) also found that chicory root contains from 13 to 15 p.c. of inulin, and an optically inactive sugar, synanthrose. He states that drying the roots has little or no effect upon the sugars, but during roasting the reducing sugars are increased, and a large portion of the inulin is changed, and caramel and dextrin are formed.

Petermann (Bied. Zentr. 1883, 843) found pure roasted chicory to contain:

Soluble in water, 74.2 p.c.

Water	Glucose	Dextrin and inulin	Protein	Colouring matter	Ash
16.3	26.1	9.6	3.2	16.4	2.6

Insoluble in water, 25.8 p.c.

Protein	Fat	Cellulose	Ash
3.2	5.7	12.3	4.6

The ash of chicory root and leaves, according to Wolff, contain:

	K ₂ O	Na ₂ O	MgO	CaO	Fe ₂ O ₃	P ₂ O ₅	SO ₃	SiO ₂	Cl
Root	40.4	7.7	6.3	8.7	3.0	14.2	9.0	6.0	3.7
Leaves	60.0	0.7	3.2	14.3	—	9.0	9.0	1.0	1.7

Wynter Blyth (Foods, 359, 1909) gives as the main differences between the ashes of coffee and chicory, the following:—

	Coffee ash	Chicory ash
Silica and sand	—	10.7–35.9 p.c.
Carbon dioxide	14.9	1.8–3.2 "
Ferrie oxide	0.44–0.98	3.1–5.3 "
Chlorine	0.26–1.1	3.3–4.9 "
Phosphorus pentoxide	10.0–11.0	5.0–6.0 "

The soluble ash of chicory may be taken as about 1.74 p.c., that of coffee as about 3.0 p.c.

Chicory has about three times the tinctorial power of ordinary coffee, and this has been proposed as the basis for a rough estimation of the amount of chicory present in a mixture of coffee and chicory (Leebody, Chem. News, 30, 243).

The sp. gr. at 15.5° of a solution, made by boiling a quantity of the substance with ten times its weight of water, affords a ready method of approximately determining the amount of adulteration. The following table gives the specific gravities of infusions made in this way from the various substances:—

Spent tan	1.00214
Acorns	1.00730
Peas	1.00730
Mocha coffee	1.00800
Ceylon coffee	1.00870
Java coffee	1.00870
Costa Rica coffee	1.00900
Native Ceylon coffee	1.00900
Brown malt	1.01090
Black malt	1.02120
Dandelion root	1.02190
Red beet	1.02210
Yorkshire chicory	1.01910
Foreign chicory	1.02260
Guernsey chicory	1.02326
Maize	1.02530
Bread raspings	1.02630

(quoted by Wynter Blyth, Foods, 360).

Hehner and Skertchly propose a determination of furfural (a measure of pentosans) as a means of examining suspected coffee. Coffee gives about 5–5.5 p.c., chicory about 2.5 p.c. of pentosans (Analyst, 24, 178). H. I.

CHILE SALTPETRE. *Sodium nitrate* (v. SODIUM).

CHINA BLUE. Syn. *Water Blue, Cotton Blue, Opal Blue* v. TRIPHENYLMETHANE COLOURING MATTERS.

CHINA CLAY or **KAOLIN** v. CLAY.

CHINA GRASS. *Rhea Ramie fibre.* This substance is the fibre of two (or perhaps more) species or varieties of the genus *Boehmeria*, nat. ord. *Urticaceæ*, shrubs allied to the nettle (*Urtica*), but possessing no stings, namely, *Boehmeria nivea* (Hook and Arn.) with a white hairy under surface to the leaf, and *B. utilis* [*B. tenacissima* (Gaud.)] with a green (Blume) under surface (more or less hairy only on the nerves) to the leaf. It is the Tchou-ma of China and the Rhea of Assam. The plants grow to a height of from three to five feet, throwing up numerous straight shoots as thick as the little finger, and covered with short soft hairs. Its leaves grow upon long foot-stalks and are broadly heart-shaped, about six inches long by four broad. It is a native of China and Sumatra, where, as in India, it has long been cultivated.

Its manufacture into mats used for making sails, foot-mats, &c., is carried on in Southern China, where three crops of Tchou-ma are taken each year, of which the second is the best. For this purpose the grass is sorted into bundles, which are soaked in water for two or three days and then dried in the sun. If a red colour is desired, the grass is steeped in a decoction of sapan wood; if yellow, in a decoction of the seeds and flowers of the common Chinese plant *mi-fa*, or in one of *Sophora japonica*, to which a little alum is added as a mordant. Other vegetable dyes are also employed; but of late years aniline colours have in a measure taken their place.

By processes of manufacture an exceedingly fine fibre is produced on separating the filaments of the stalk—a fibre distinguished by its strength, which is nearly three times that of Russian hemp; by its length, which is greater than that of any bast product; and by its lustrous, silky appearance. Great efforts have been made, with more or less success, to render the use of the fibre in European textile manufactures commercially profitable. It will be seen from the following remarks that there are difficulties in the way. In the first place, the method of separating the bast by hand was tedious, and could only be performed whilst the stems were quite fresh, thus limiting its production to the immediate neighbourhood of the plant's growth. In China the bark is stripped from the stems and the fibre seraped off with a knife, a process which removes the whole so-called grass if performed while the stem is still quite fresh, but leaves a large portion if it has become at all dry. Even under the best conditions a very skilful operator can collect only two pounds of grass per day, the average quantity obtained being only half a pound to one pound. It is further found that, owing to the large amount of pectinic substances

contained in these *Urticaceæ*, the long steeping or retting processes used with flax and hemp cannot be practised on account of the ensuing excessive fermentation, which injures the fibre. Experiments made in India with unskilled workers gave about four ounces per day each as the result of their labour. Attention has consequently been given to mechanical processes for separating the fibres from the bark in the green and in the dry state. With this in view, the India Office some years ago submitted samples of the dried article to Dr. Forbes Watson, who reported that he did not find it at all difficult to obtain the fibre from stems which were quite dry. The difficulty in the case of India is that the best crops are obtained during the rainy season, when it is all but impossible to dry the stems except by expensive artificial means; while, as above pointed out, the liability of the plant to ferment resulted in the spoiling of the crops when its treatment was delayed. The Government of India has followed up its inquiries and encouraged inventors to competition in producing a machine capable of dealing with the green crop. It may be said that this encouragement has resulted in an approximation to success; thus, in one instance of a machine consisting of a cylinder with beaters revolving at a high speed against the stems upon which meanwhile a jet of water is poured, Dr. Watson estimated the cost of producing the fibre to average 4*l.* to 5*l.* per ton. The yield from the machine was from 1 to 2 tons of green stalks per day, estimated to produce about 100 lbs. of cleaned fibre.

In the treatment of green stalks by hand the Favier's process consists in subjecting the plants to the action of steam for 15 to 30 minutes, after which the bark is easily stripped. Those stems also which have been standing some time after being cut can also be treated without leaving any appreciable amount of fibre on the stalks.

The operation of scutching the dried stems presents no difficulty when steam power is applicable and when the quantity of material to be treated is sufficiently large. The next process, however, of 'ungumming' has given a little trouble. Since China grass contains from 22 to 28 or, in some cases, up to 35 p.c. of gum, it is necessary to remove this constituent of the fibre before it can be spun into yarn. For this purpose many partly mechanical and partly chemical processes have been devised. It may sufficiently describe the lines which these various systems take to say that they resemble generally the processes adopted in the scouring and bleaching of cotton goods—that is to say, by subjecting the material to pressure under the application of steam, and to alternate treatment of alkaline and acid agents.

China grass has little or no attraction for dyes, and consequently the methods adopted in the dyeing of cotton or of jute are applicable to it. It is found that mineral colours, such as chrome yellow and orange, destroy the peculiar lustre of China grass; the yellow dye obtained with cadmium sulphide, however, is not open to this objection. Alizarin mordanted with Turkey-red oil destroys the lustre, whilst aniline colours fixed with the same mordant do not. Rosaniline derivatives and azo-colouring matters may be

used satisfactorily. It is recommended that the grass should be dyed immediately after retting and before spinning, to preserve the characteristic sheen.

The textiles formerly associated with China grass were such articles as handkerchiefs and 'grass cloths,' imported direct from China; but recent efforts to introduce the manufacture as well as the growth of China grass into Europe have led to other developments. Thus at the manufactory of Zittau in Saxony, the fibre has found application in tapestry and dress goods, table-cloths, damasks, lace, fancy knitting yarns, &c. It is also used in the manufacture of incandescent gas-mantles.

A number of other species of *Boehmeria* also supply bast fibres.

CHINA INK v. INDIAN INK.

CHINA-STONE. A granitic rock, having its felspathic constituent more or less decomposed, but not completely kaolinised. As the felspar still retains part of its alkali, and as some micaceous mineral is generally present, the stone is fusible; hence it is largely used in the manufacture of porcelain, and when free felspar is not introduced it forms the only vitrifiable constituent of the paste. China-stone is sometimes known as 'Cornish stone' in consequence of its being largely quarried in Cornwall, where it was discovered by W. Cookworthy, of Plymouth, about 1750. He first noticed it at Tregonning Hill, near Breage, and described it under the local name of 'growan' or 'moor-stone.' It is now obtained principally from the neighbourhood of St. Stebbens, near St. Austell. The rock requires no preparation, but is sent direct from the quarry to the potteries. Notwithstanding the altered condition of the felspar, it is used locally as a building stone, and found to be durable.

The conditions under which the china-stone has been formed are obscure. Its occurrence sometimes in narrow bands, and its altered character at great depths, render it improbable that the decomposition has been due to the superficial action of meteoric agents, such as water and carbon dioxide. Daubrée, Smyth, Le Neve Foster, Collins, and other observers in Cornwall, have held that the granite has been decomposed probably by means of compounds containing fluorine rising from below; a view supported by the fact that the china-stone and kaolin occur in association with veins of tin ore and various fluorine-bearing minerals (Daubrée, Geol. Expt. 1879, 64).

Cornish stone consists usually of quartz, altered orthoclase, kaolinite, and gilbertite, frequently associated with lepidolite, or lithiamica, known to the Cornish quarrymen as 'shell,' and occasionally as schorl, or black tourmaline, and fluor-spar as accessory constituents. The gilbertite (hydrated silicate of aluminium and potassium) seems to have been mistaken by some observers for talc (hydrated silicate of magnesium), as the china-stone has been frequently described as an altered talcose granite. The following analyses of the china-stone of St. Stephens, Cornwall, are given by J. H. Collins (Hensbarrow Granite District, Truro, 1878, 31):—

Silica	73.39	69.50	71.66
Alumina	16.50	17.85	18.79
Lime	0.50	2.66	1.70
Magnesia	0.31	0.12	0.35
Potash (with a little soda)	7.66	7.98	6.60
Iron	trace	trace	trace
Manganese	—	trace	trace
Fluorine	0.74	0.71	0.14
Water	1.25	1.30	0.91
	100.35	100.12	100.15

It has been proposed by Collins to distinguish china-stone under the name *petunzite*, a word suggested by the Chinese *pe-tun-tse*. In the early part of the 18th century a Jesuit missionary named D'Entrecolles, residing at King-te-chin, sent to Réaumur, in Paris, samples of the raw materials used in China. These were the first specimens of their kind that had ever reached Europe, and they led to the foundation of the manufacture of porcelain at Sèvres. The china-stone was described by D'Entrecolles as *pe-tun-tse*, and the china-clay as kaolin; but it appears that the former name, if not both, must have been erroneously applied. According to the Chinese scholar, Stanislas Julien (*Hist. et Fabric. de la Porcel. Chin. Paris, 1856, preface xx.*), *pe-tun* signifies 'white paste,' while *tse* is merely a diminutive applied to the material when worked up into small cakes. Hence, *pe-tun-tse* is really the name of small blocks of white clay or prepared paste, and not of the granitic rock. Nevertheless, custom in this country has justified the use of the term *pe-tun-tse* as synonymous with china-stone.

(For an account of the occurrence of china-stone in Cornwall, see *Mem. Geol. Survey, Bodmin and St. Austell District, 1909.*) The amount of china-stone raised in Cornwall in 1908, and sent as such to the potteries, was 75,473 tons, valued at 37,315*l.*; while the amount of china-clay washed from china-stone at the pits amounted during the same period in Cornwall and Devon to 721,416 tons, valued at 484,305*l.*

F. W. R.

CHINESE BLUE. (*Porzellanblau*, Ger.) Several compounds are sold under this name, of which the following are examples: ultramarine and flake white; cobalt blue and white lead; and a double cyanide of iron (Prussian blue) (*v. PIGMENTS*).

CHINESE GREEN or **LOKAO.** This colouring matter is obtained in China from different varieties of buckthorn (*Rhamnus*), and is brought into commerce in the form of thin blue slabs, easily broken, but difficult to pulverise. It is a lake containing the colouring matter lokaïn, with from 26 p.c. (Cloez and Guignet, *Ber. 5, 338*) to 47 p.c. of clay and chalk (Kayser, *ibid.* 18, 3417). To obtain the pure colouring matter, lokaïo is extracted with ammonium carbonate solution; on the addition of alcohol to the filtrate a deep-blue precipitate of the ammonia compound of lokaïn $C_{42}H_{46}O_{27}$ is formed. From the solution of this compound in water, oxalic acid precipitates lokaïn, which, when dried, is a pulverulent bluish-black substance insoluble in water, alcohol, ether, chloroform, and benzene. Friction imparts to it metallic lustre. The monammonium salt forms small crystals with bronze-like lustre, from which the diammonium salt

$C_{42}H_{46}O_{27}(NH_4)_2$ is obtained by moistening them with ammonia and subsequently drying over sulphuric acid. The barium salt $C_{42}H_{46}BaO_{27}$ is insoluble in water and alcohol. The potassium salt $C_{42}H_{46}K_2O_{27}$ forms a dark-blue amorphous precipitate from alcohol. Soluble compounds of lokaïn show perfect absorption of the spectrum in the red and yellow portions only. Boiling dilute acids decompose lokaïn into a carbohydrate lokaose $C_6H_{12}O_6$, and lokanic acid $C_{36}H_{34}O_{21}$; the latter is a bluish-violet crystalline powder insoluble in water, alcohol, and ether, containing 1 molecule of water, which is given off at 120°. The ammonium salt $C_{36}H_{35}O_{21}NH_4$ is a deep-blue powder soluble in water, with a violet colour; the barium and lead salts are dark-blue powders insoluble in water and alcohol. Soluble compounds of lokaïn in very dilute solution show a characteristic perfect absorption in the yellow and yellow-green portions of the spectrum. Lokaose reduces Fehling's solution with half the power of glucose, from which it also differs by its optical inactivity. The decomposition of the lokaïn is expressed by the equation $C_{42}H_{46}O_{27} = C_{36}H_{36}O_{21} + C_6H_{12}O_6$. Reducing agents convert blue solutions of lokaïn and lokanic acids into blood-red solutions, which become green on exposure to the air.

Lokanic acid is decomposed by cold concentrated sulphuric acid according to the equation $C_{36}H_{36}O_{21} - 5H_2O = C_{36}H_{26}O_{16}$. This latter substance forms a red-brown powder; its barium compound $C_{36}H_{24}BaO_{16}$ is also a red-brown substance. Concentrated potassium hydroxide solution (50 p.c.) decomposes lokanic acid into a brown powder and phloroglucinol; the former body is termed delokanic acid $C_{15}H_8O_6$ (R. Kayser, *l.c.*; *J. Soc. Chem. Ind.* 5, 162) (*v. LOKAW*).

CHINESE LAKE or **SCARLET LAKE** *v. PIGMENTS*.

CHINESE VEGETABLE TALLOW is the hard fat which coats the seeds of the Chinese tallow tree, *Stillingia sebifera* (Willd.), *Stillingia sinensis*, *Croton sebiferum*, *Sapium sebiferum*, (Roxb.), *Excoecaria sebifera* (F. Müll), *Carumbium sebiferum*, a tree growing wild in China, and largely cultivated there, as also in Indo-China and the North of India, where the tree thrives luxuriantly. In China the stillingia tree is exploited for both its leaves and seeds. In Tonkin the tree is only cultivated for the sake of its leaves, a decoction of which furnishes a colouring matter used for dyeing silk. In China the fat is only a by-product. The tree commences to produce at the age of 4-5 years, and when it has reached its full development it yields about 24-30 kilos. of seeds a year. The fruit yields about 30 p.c. of a mixture of vegetable tallow and of stillingia oil; half of this quantity consists of vegetable tallow alone, and the other half of stillingia oil. The fruit consists of three oval seeds surrounded by a thick tallow-like mass, the true vegetable tallow. This is recovered by placing the seeds in perforated cylinders and steaming them, so that the fat melts and runs off. Another method is to pass the seeds between fluted rollers, which scrape off the outer fat coating without breaking the seed proper. The scraped-off mass is pressed in the hot in primitive wedge presses, and sold under

the Chinese name of 'pi-icou' or 'pi-yu'; it is known in Europe as 'prima' vegetable tallow. The seeds which have been bared from their fat coating, are then crushed separately and yield the stillingia oil, a drying oil known in China as 'tsé-ticou' or 'ting-yu.' In another process, the seeds, together with their coating of fat, are crushed, and thus a mixture of vegetable tallow and stillingia oil is obtained. The product thus prepared is naturally much softer than the true vegetable tallow, and has therefore a lower melting-point and a much higher iodine value. This second quality is sold in Europe as 'secunda' vegetable tallow, and represents a mixture of 'pi-yu' and 'ting-yu.' It is sold in China under the name 'mou-icou.'

The saponification value of commercial samples of vegetable fat varies, therefore, according to the mode of preparation, from 179 to 203. Similarly, the iodine value varies considerably, and numbers ranging from 19 to 32 have been recorded. The composition of vegetable tallow has not yet been definitely ascertained. From the absence of stearic acid, it may be concluded that the fat consists of palmitin and olein only.

Vegetable tallow plays, in China, an important rôle as an article of commerce; it is largely used in the manufacture of candles. During recent years considerable quantities have been exported; thus during 1907 the United Kingdom imported 4000 tons, France 2500 tons, and Italy 1700 tons. The bulk of the vegetable tallow is used in the candle and soap industries. J. L.

CHINESE WAX or **INSECT WAX** v. **WAXES.**

CHINESE YELLOW (*King's yellow*) v. **PIGMENTS.**

CHINOFORM. Trade name for quinine formate.

CHINOLINE v. **QUINOLINE.**

CHINOSOL. Trade name for *o*-hydroxyquinoline sulphate, a pale-yellow crystalline powder with a saffron-like smell and a burning taste; m.p. 175°-177.5°; readily soluble in water, sparingly soluble in alcohol, insoluble in ether; with ferric chloride gives an intense green colour, and a white precipitate with barium chloride. Used as an antiseptic.

CHINOVOSE v. **CARBOHYDRATES.**

CHIOLITE. A double fluoride of aluminium and sodium 3AlF₃·5NaF, closely akin to cryolite AlF₃·3NaF. Found at Miask (Brandl, Jahrb. Min. 1882; 2nd Ref. 201; Chem. Soc. Abstr. 44, 29).

The following analysis is given by Brandl (Annalen, 213, 1):—

Al	Na	F
17.66	24.97	57.30 = 99.93
17.64	25.00	57.30 = 99.94

CHITIN, CHITOSE v. **CARBOHYDRATES.**

CHLOANTHITE. Native nickel arsenide, NiAs₂, isomorphous with smaltite (CoAs₂), there being no sharp line of demarcation between the two species. Found as cubic crystals and compact masses at Schneeberg in Saxony and Riechelsdorf in Hesse, where it was formerly mined as an ore of nickel. L. J. S.

CHLORACETIC ACIDS v. **HALOGEN ACETIC ACIDS.**

CHLORAL *Trichloroacetaldehyde* CCl₃·CHO.

Chloral was first prepared by Liebig, who obtained it by the continuous chlorination of absolute alcohol (Annalen, 1, 189). It was further examined by Dumas (Ann. Chim. Phys. [2] 56, 125), who determined its composition, and by Städeler (Annalen, 61, 101). Although a chlorinated aldehyde, it cannot be prepared by treating acetaldehyde with chlorine, unless water is present together with calcium carbonate to neutralise the hydrogen chloride formed, since butyric chloral results when dry materials are employed (Pinner, Ber. 4, 256).

Industrial preparation. The process by which chloral is manufactured is divided into three stages: the preparation of chloral alcoholate; conversion of this into chloral; and the formation of chloral hydrate.

In a large glass balloon 60 kilos. of alcohol, as completely dehydrated as possible, are subjected to the action of a current of chlorine, the escaping hydrochloric acid being absorbed by water. The introduction of the chlorine lasts a considerable time, in some works 10 to 14 days. At first the balloon must be cooled, for, if the temperature is not properly regulated, the yield is much reduced. After a time the reaction becomes less violent; the mixture is then warmed to 60°, and finally to 100°. When the liquid is completely soluble in water, the current of chlorine is stopped, and on cooling, a white mass of the alcoholate is obtained. In this operation Springmühl recommends the use of iodine as a chlorine carrier; Page, the addition of crystallised ferric chloride (Annalen, 1884, 225, 209); and in either case the ethyl halide is easily recovered.

In the ordinary process the chlorinated liquid is not allowed to cool, and is transferred to an enamelled still holding 150-200 kilos., where an equal volume of strong sulphuric acid is added in small quantities. The temperature is raised to boiling, the condensed vapours being returned to the still. During the ebullition there is an evolution of hydrochloric acid gas, the cessation of which indicates the termination of the decomposition of the alcoholate. Fractional distillation follows, this ceasing when the thermometer has reached 100°. The distillate is again rectified, the portion coming over above 94° being pure chloral. In some works the final purification is carried out by distilling over chalk or sodium bicarbonate. Ethylene dichloride, ethylidene chloride, and chlorinated ethylene dichloride (b.p. 115°) are also formed as by-products in this reaction (Krämer, Ber. 3, 257).

The chloral is shaken with the theoretical quantity of water and the product of the reaction at once poured over a smooth surface, when it solidifies; in this state it is sent into commerce. To obtain crystals the warm mass (heat is disengaged in this reaction) is mixed with one-third of its volume of chloroform, and the mixture allowed to cool in closed vessels; crystallisation is complete in a week. The mother liquors serve for a second crystallisation, and the crystals are dried at the ordinary temperature. Flickiger (Zeitsch. Chem. [2] 6, 432) recommends crystallisation from

warm carbon disulphide or turpentine, and Martius from benzene. Other methods, which have been described, differ from the preceding in that the chlorinated mixture, after solidification and pressure, is sublimed or distilled with calcium chloride (Detsényi, *Dingl. polyt. J.* 209, 224; Trillat, *J. Pharm. Chim.* 5, 218).

The following method has been devised for the continuous production of chloral. Chloral and its hydrate are the most volatile products of the action of chlorine on alcohol, and may therefore be removed by continuous distillation. A special apparatus is described; chlorine and chlorinated alcohol are introduced into a vessel heated in a water-bath, from which the vapours pass into a second and then into a third heated vessel. The residual chlorine is absorbed in a cylinder provided with baffle plates. The rectifier, which also acts continuously, is provided with baffle plates; it is fed at the middle with chloral, and at the top with sulphuric acid (60°B.). The final rectification is carried out as already described. The same apparatus may be used for converting chloral into chloroform (Besson, *Eng. Pat.* 17202; *U.S. Pat.* 774151; *J. Soc. Chem. Ind.* 1901, 1139).

Theories to explain the action of chlorine on alcohol and the subsequent production of chloral have been proposed by Lieben (*Ber.* 3, 910); Wurtz and Vogt (*Compt. rend.* 74, 777); Jacobsen (*Ber.* 15, 601); and Brochet (*Bull. Soc. chim.* 17, [3] 228).

Chloral is a colourless pungent liquid, which solidifies at -75° (Berthelot, *Ann. Chim. Phys.* [5], 12, 536), at -57.5° (Van Rossem, *Zeitsch. physikal. Chem.* 1908, 62, 681); and is readily soluble in water, alcohol, and ether. Its b.p. is 97.7° (corr.) and sp.gr. 1.54175 at 0° (Passavant, *Chem. Soc. Trans.* 39, 55; Thorpe, *ibid.* 37, 191); b.p. 96° – 97° at 750 mm., and sp.gr. 1.5121 at $20^{\circ}/4^{\circ}$ (Brühl, *Annalen*, 203, 11); b.p. 97° at 740 mm. (Van Rossem, *l.c.*). Three hydrates exist: (1) a semi-hydrate $2C_2H_3Cl_3O \cdot H_2O$; true m.p. is about 49° , the highest observed 80° ; (2) the ordinary monohydrate existing in two pseudo-symmetrical modifications: true m.p. 47.4° , highest observed 54° ; (3) a heptahydrate, m.p. -14° (Pope, *Chem. Soc. Proc.* 1896, 142; and Van Rossem, *l.c.*). According to Wolf (*J. Phys. Chem.* 4, 21); there is only one modification, the difference in melting-points being due to dissociation. Nascent hydrogen reduces it to aldehyde (Personne, *Annalen*, 157, 113), which it closely resembles in reducing ammoniacal silver nitrate solution (Städeler, *Annalen*, 106, 253), and in forming crystalline compounds with sodium disulphite (*ibid.*); with ammonia (*v.* chloral ammonium); with hydrogen cyanide (Bischoff and Pinner, *Ber.* 5, 113; *Annalen*, 179, 77); with amides (Wallach, *Ber.* 5, 251; Sulzberg, *D. R. P.* 198715; *J. Soc. Chem. Ind.* 1908, 958); and with amines (Wallach, *l.c.*; Rügheimer, *Ber.* 1906, 1653; Wheeler, *Amer. Chem. J.* 1902, 1063; 1908, 136; 1909, 937).

When heated with aqueous alkalis it decomposes into chloroform and an alkaline formate, and a similar reaction occurs when alcoholic potash or soda is employed (Kekulé, *Annalen*, 119, 188). Chlorine, bromine, or iodine and aluminium chloride convert chloral into hexachlorethane (Mouneyrat, *Bull. Soc. chim.* 17, [3] 796). Fuming nitric acid converts it into trichlor-

acetic acid, and, according to Grabowski (*Ber.* 6, 225), fuming sulphuric acid combines with it in the cold, but on heating converts it into chloralide $C_2H_3Cl_3O_3$ (compare Grabowski, *Ber.* 8, 1433; Städeler, *Annalen*, 61, 114; Wallach, *ibid.* 193, 1). Chloral condenses with succinic acid by means of acetic anhydride to form trichloromethylparaconic acid (Fittig and Miller, *ibid.* 255, 43).

Derivatives. Chloral ammonium $C_2H_3Cl_3NO$ is prepared by the action of ammonia on a solution of chloral in chloroform (Schiff, *Ber.* 10, 167). It is a white crystalline solid, resembling chloral hydrate in taste and colour; it melts at 64° , and is slightly soluble in water, more readily soluble in alcohol (Personne, *Annalen*, 157, 113; *Compt. rend.* 71, 228). Nesbit recommends the use of chloral ammonium instead of urethane and chloral hydrate, since the action of chloral hydrate on the respiration centres and the heart is retarded by the introduction into that compound of an amino-group (*J. Soc. Chem. Ind.* 1889, 413; 1890, 889). By heating chloral ammonium on the water-bath, chloroform and ammonia distil off, and the residue consists of formamide and chloralimide $C_2H_3Cl_3N$, the latter of which is extracted with alcohol. Isochloralimide is also formed, and according to Schiff (*Gazz. chim. ital.* 21, 490), dimolecular and trimolecular -imides exist. Chloralimide can also be prepared by heating chloral and chloral ammonium until chloroform is no longer evolved, and by the reaction between chloral hydrate and ammonium acetate (Schiff, *l.c.*; Pinner and Fuchs, *Ber.* 10, 1068; Arends, *Chem. Ind.* 16, 78; Béhal and Choaz, *Compt. rend.* 109, 817; 110, 1270). It has remarkable antipyretic and analgesic properties. Other chloralimide compounds have been described by Moschelles (*Ber.* 24, 1803).

Chloralimide or chloral formamide $C_2H_3Cl_3NO_2$ is produced by gently heating chloral and formamide in molecular proportions (*J. F. von Mering, Eng. Pat.* 7391; *D. R. P.* 50586; *J. Soc. Chem. Ind.* 1890, 413). When recrystallised, it forms colourless crystals melting at 115° – 116° ; it is soluble in 9 parts of water, or in $1\frac{1}{2}$ parts of 96 p.c. alcohol. It is without smell, and has a slightly bitter taste; when heated above 60° , it is decomposed; aqueous or alcoholic solutions are unaffected by weak acids or by silver nitrate, but are rapidly decomposed by alkali hydroxides, more slowly by alkali carbonates. As a hypnotic it has been proved superior to chloral hydrate, and is of most value in cases of nervous insomnia and similar disorders (Hagner and Hübner, *Weiner Med. Presse*, 1899, 1361). It has no corroding action, does not affect the digestion, nor disturb the heart. It may be taken internally as a powder, prepared by triturating 1–3 grams of the amide with 1 gram of feñnel-ol sugar (*Ellæosaccharum Feniculi*) (*Merck's Bull.* 1889, 85).

Chloralose (${}^1_8H_{11}Cl_3O_6$) is obtained by heating equal parts of chloral and glucose, both anhydrous, on the water-bath. The vitreous mass is boiled with water to remove the chloral, and the concentrated aqueous solution deposits a crystalline compound, from which chloralose is extracted by alcohol. On treating the residue with ether, a compound isomeric with chloralose, termed *para-chloralose*, is obtained. Chloralose

melts at 187°, and is a powerful hypnotic; whilst parachloralose melts at 227°, and possesses no hypnotic properties. By oxidising these compounds with nitric acid, followed by potassium permanganate, the corresponding chloralic acids are obtained; m.p. 212° and 202° respectively (Hanriot and Richet, Bull. Soc. chim. [3] 11, 37; 12, 303; Compt. rend. 116, 63; 122, 1127; 148, 1265; Meunier, *ibid.* 122, 142; Petit and Polonovski, Bull. Soc. chim. 3, [3] 861).

Chloral-acetonechloroform $C_6H_8O_2Cl_6$ is prepared by heating molecular quantities of chloral and acetonechloroform. It melts at 65°, and has a faint odour and taste resembling camphor (Hoffmann-Laroche, U.S. Pat. 778277; J. Soc. Chem. Ind. 1905, 150).

Chloral-bromal-carbamide is obtained by mixing urea with molecular quantities of chloral and bromal, or equivalent quantities of their hydrates in the presence of concentrated hydrochloric or sulphuric acid (Kalle & Co. D. R. P. 128462; Chem. Zentr. 1902, i. 547).

The following condensation products of chloral have been prepared: chloralacetone, chloralacetophenone, and chloralal (Gigli, Gazz. chim. ital. 28, [2] 83; Königs, Ber. 1892, 792; 1893, 554; Wislicenus, Kireheisen, and Sattler, *ibid.* 1893, 908); carbonylchloraldehydes (Farb. vorm. F. Bayer & Co. D. R. P. 121223, Chem. Zentr. 1901, ii. 69); chloral nitrite (Bertoni, Gazz. chim. ital. 24, ii. 20); the compounds with aminoazobenzene (Betti, *ibid.* 28, 241); with amidooxybenzoic esters (Kalle & Co. D. R. P. 112216; Chem. Zentr. 1900, ii. 791); with aromatic hydrocarbons (Biltz, Ber. 1893, 1952; Dinesmann, Compt. rend. 1905, 141, 201); with hexamethylenetetramine (Lederer, Eng. Pat. 17693; J. Soc. Chem. Ind. 1897, 1039); with hydroveratine (Frankforter, Amer. Chem. J. 20, 358); with methylpropanaldialkaminic acids (Poulenc Frères & Fourneau, Fr. Pat. 382787; D. R. P. 203643; J. Soc. Chem. Ind. 1908, 246); with menthol and terpinol (Wagnitz, Eng. Pat. 19103; J. Soc. Chem. Ind. 1899, 856; Schmitt, Compt. rend. Soc. Biol. 1890, 678); and with resorcinol (Causse, Bull. Soc. chim. 3, [3] 861; Hewitt and Pope, Chem. Soc. Trans. 1896, 1265).

Polymerides. Two polymerides of chloral are known, an insoluble and a soluble substance. When pure, chloral is perfectly stable, but traces of impurities, and particularly of sulphuric acid (Byasson, Compt. rend. 91, 1071) convert it into *metachloral*, a white amorphous solid. It may be prepared by leaving chloral hydrate in contact with half its weight of concentrated sulphuric acid for several hours, until a pasty mass is formed. After pouring off the acid, the residue is introduced into a well-cooled solution of hydrochloric acid, and the product, which now becomes solid, is washed and dried over sulphuric acid. Chloral alcoholate may be substituted for chloral hydrate in this preparation (Gärtner, D. R. P. 170534; Chem. Soc. Abstr. 1906, i. 628). Another method is to add 7 parts of anhydrous aluminium chloride to 100 parts of well-cooled anhydrous chloral, the temperature being kept below 40°. In the course of an hour the whole mass solidifies. After 24 hours the hard mass is broken up, extracted with dilute hydrochloric acid, washed

with alcohol, and dried at a moderate temperature (Erdmann, D. R. P. 139392; Chem. Zeit. 27, [20] 223). It is insoluble in alcohol, ether, water, and acids, but soluble in sodium carbonate solution. On warming with alcohol, it yields chloroform, and on distillation at 180°–250° is reconverted into chloral (Kolbe, Annalen, 54, 183 [footnote]). It is tasteless, and can be employed as an anæsthetic; unlike chloral hydrate, it has no irritating effect on the mucous membrane of the stomach.

The soluble polymeride is obtained by treating chloral with pyridine or any other amine in the cold, and then acidifying. It is a slightly volatile anæsthetic substance, volatilising without melting, converted by hot water or hot alcohol into chloral hydrate and chloral alcoholate respectively, and decomposed by alkalis into chloroform and formic acid. It is soluble in water (Gärtner, D. R. P. 165984; U.S. Pat. 768744; Chem. Soc. Abstr. 1906, i. 481).

Chloral hydrate $CCl_3 \cdot CHO + H_2O$ or $CCl_3 \cdot CH(OH)_2$.

Properties.—Chloral hydrate crystallises in monoclinic tables (Groth, Ber. 5, 676), and has a peculiar odour and sharp taste. Its m.p. is 57° (Meyer and Dulk, Annalen, 171, 75), 47·4° (Van Rossem, Zeitsch. physikal. Chem. 1908, 62, 681); b.p. 97·5°; and sp.gr. 1·818 (in powder) and 1·848 (crystallised) (Schröder, Ber. 12, 562). It dissolves readily in water, 1 part of water dissolving 4·7 parts of chloral hydrate at 17·5° (Mauch, Arch. Pharm. 240, 113), alcohol, ether, chloroform, turpentine, and light petroleum; and its solubility in carbon disulphide is given by Flückiger (*l.c.*) as 1 in 45 at 15°–18°, and 1 in 4·5 at the boiling-point. Concentrated sulphuric acid decomposes it into chloral and water, and alkalis act upon it as upon chloral. A modification of the hydrate, melting at 80°, is obtained by rapidly evaporating an acetic acid solution of anhydrous chloral over sulphuric acid (Meyer and Dulk, *l.c.*); this is probably the semihydrate described by Van Rossem (*l.c.*). Under the influence of light and air, chloral hydrate is decomposed, the decomposition products being hydrochloric acid and carbon dioxide or monoxide, or water, chlorine, and carbon dioxide, the amount of available oxygen determining the products (School and Van den Berg, Ph. Weekblad. 43, 42).

Chloral hydrate should be free from alcoholate, which has not the same physiological properties; and when warmed with twice its volume of water it should give a clear solution, free from oily drops and not precipitated by silver nitrate. When carefully heated, it should volatilise completely, and the vapours should not be inflammable; when gently warmed with 3 vols. of strong sulphuric acid the mixture should remain clear. On warming chloral hydrate with potassium hydroxide, turbidity is caused through the separation of chloroform; the clear portion is decanted, and iodine dissolved in potassium iodide added. So soon as the liquid begins to turn yellow, it is cooled, when the presence of alcohol and consequently of chloral alcoholate, is indicated by the formation of a precipitate of iodoform (Trillat, J. Pharm. Chim. 5, 218). Chloral alcoholate may also be detected by the Zeisel method for the estimation of ethoxyl (Schmidinger,

Monatsh. 21, 36). Chloral hydrate is converted into alcoholate when dissolved in alcohol, and similarly, chloral alcoholate is very slightly soluble in water, dissolving slowly to form chloral hydrate. Potassium carbonate is a good antidote to chloral poisoning, if it has not reached the blood (Klar, J. Soc. Chem. Ind. 1896, 555).

Physiological Action.—Compare Liebreich (Ber. 2, 269); Personne (Compt. rend. 78, 129); Byasson (*ibid.* 78, 649); Tomaszewicz (abstracted, Chem. Soc. Trans. 1874, S14); Tanret (J. Pharm. Chim. [4] 20, 355); and Trillat (*l.c.*).

Estimation.—4 grams of the sample are treated with 30 c.c. of normal caustic soda in a stoppered bottle, and shaken vigorously for a few minutes without the application of heat. On titrating back with normal sulphuric acid, using litmus as an indicator, 5.8 c.c. should be required for complete neutralisation (Alcock and Thomas, Pharm. J. 63, 236; and Sargeant, *ibid.*). Owing to the secondary reaction $\text{CHCl}_3 + 3\text{NaOH} = 3\text{NaCl} + \text{CO} + 2\text{H}_2\text{O}$, this titration with acid is slightly inaccurate. Modifications of the method have been devised by Trillat (*l.c.*); Hinrichs (Pharm. J. 70, 530); Desgrez (Compt. rend. 125, 780; Analyst, 23, 76); Self (Pharm. J. 79, 4); and Garnier (Chem. Zentr. 1908, i. 1492). Another method is to heat 0.3 gram of the sample with 1 gram of aluminium powder, or 2.5 grams of zinc filings, 15 c.c. of glacial acetic acid, and 40 c.c. of water under a reflux condenser for half an hour. The mixture is filtered and washed, and the chlorine estimated volumetrically or gravimetrically as silver chloride (Self, *l.c.*). Wallis (Pharm. J. 76, 162) treats the chloral hydrate with caustic soda in a bottle, and then estimates the chlorine as silver chloride. It may also be determined iodometrically (Rupp, Arch. Pharm. 241, [5] 326).

Chloral hydrate may be detected by means of the green colour formed on the addition of antimony trichloride to a solution in castor oil (Covelli, Chem. Zeit. 31, 342); or by the colours formed when it reacts with resorcinol in the presence of sulphuric acid (Jaworowski, Zeitsch. anal. Chem. 37, 60). Another method is to add a solution of ammonium sulphide, when a pinkish or yellow precipitate is obtained, and an oil having the odour of walnuts (Lesinsky and Grundlich, Amer. Chem. J. 19, 603). Chloral hydrate is valuable for extracting alkaloids from plants containing much resin, essential oils, &c. (Schaer, Zeitsch. anal. Chem. 38, 469); it is used in rubber analysis (Weber, J. Soc. Chem. Ind. 1903, 576); in microchemical investigations (Schaer, Chem. Soc. Abst. 1908, i. 62); and in qualitative analysis (Mauch, Arch. Pharm. 240, 166).

Derivatives.—Chloral antipyrine is obtained by the condensation of chloral hydrate with antipyrine (Béthel and Choaz, Ann. Chim. Phys. 27, 319).

Chloral caffeine is formed when chloral hydrate and caffeine are brought together in aqueous or alcoholic solutions in molecular proportions. It is recrystallised from warm water at 30°, and, owing to its easy solubility as opposed to the difficult solubility of caffeine, is of medicinal value (Chem. Fab. auf Act. vorm. E. Schering,

D. R. P. 75847; J. Soc. Chem. Ind. 1895, 987).

Chloral tannin is prepared by the condensation of chloral hydrate with tannin in the presence of sulphuric acid. It is a greyish-brown amorphous powder, having valuable dermatological properties (Farb. vorm. Fried. Bayer & Co. D. R. P. 98273; Eng. Pat. 2882; J. Soc. Chem. Ind. 1899, 172).

Chloraldoxime is prepared by treating chloral hydrate (1 mol.) with hydroxylamine hydrochloride (4 mols.) and a little water; m.p. 39°–40° (Meyer, Annalen, 264, 116; Tarugi, Gazz. chim. ital. 21, ii. 6).

Chloralhydroxylamine is obtained by triturating molecular quantities of chloral hydrate, sodium carbonate, and hydroxylamine hydrochloride, dissolving the mass in a little water, and extracting with ether; m.p. 98° (Hantzsch, Ber. 1892, 701).

Compounds with formaldehyde are described by Pinner (Ber. 1898, 1926).

Chloral alcoholates. The preparation of chloral ethylalcoholate has already been described. It may also be obtained by the action of chloral on absolute alcohol (Martius and Mendelssohn, Ber. 3, 444). It crystallises in needles, melts at 44°–46° (Meyer and Dulk, Annalen, 171, 78), at 46° (Lieben, Ber. 3, 907); boils at 115°; is sparingly soluble in water, more soluble in absolute alcohol, 1 part of alcohol dissolving 4.4 parts of chloral alcoholate at 17.5° (Mauch, Arch. Pharm. 240, 113). Sulphuric acid decomposes it into chloral and alcohol. Chloral propylalcoholate, b.p. 120°–122°, and chloral isopropylalcoholate, m.p. 47°, and b.p. 108°, have been described by Gabutti (Gazz. chim. ital. 31, i. 86), and Vitoria (Chem. Soc. Abst. 1905, i. 110); chloral amylalcoholate by Gradamer (Arch. Pharm. 243, 30), and Kalle & Co. (D. R. P. 115251; Chem. Zentr. 1900, ii. 1141). Other alcoholates have been prepared by Jacobsen (Annalen, 157, 224), and Kuntze (Arch. Pharm. 246, 91).

Butyl chloral $\text{CH}_3\text{-CHCl-CCl}_2\text{-CHO}$; more correctly, tri-chlor-butyril-aldehyde; b.p. 164°–165° at 760 mm.; sp.gr. 1.3956 at 20°/4° (Brühl, Annalen, 203, 20). It is a colourless oil, having a characteristic chloral odour, formed by the action of chlorine upon ordinary aldehyde or paraldehyde (Krämer and Pinner, Ber. 3, 383). Chloroacetaldehyde $\text{CH}_2\text{Cl-CHO}$ is first formed, and this condenses with another molecule of acetaldehyde, forming α -chlorocrotonaldehyde $\text{CH}_3\text{-CH:CCl-CHO}$ and water, and this, by the action of more chlorine, forms the butyl chloral.

Preparation.—Chlorine is led through cooled paraldehyde (or aldehyde cooled by a freezing mixture); water is then added, and the liquid neutralised with calcium carbonate. The mixture is then distilled on the oil-bath in a current of steam, and the hydrate is thus obtained. This is then purified by recrystallisation from water, and decomposed by distillation in a stream of hydrochloric acid gas (Pinner, Annalen, 179, 26).

Butyl chloral is converted by fuming nitric acid into $\alpha\beta$ -trichlorbutyric acid. Phosphorus pentachloride converts it into a body $\text{C}_4\text{H}_2\text{Cl}_4$, which boils at 200°. It combines with zinc-ethyl to form a compound which is decomposed

by water with formation of trichlorobutyl alcohol.

The ammonia compound

m.p. 62°, is formed by leading ammonia into a cooled mixture of 1 part of butylchloral, and 1½ parts of chloroform (Schiff and Tassinari, Ber. 10, 1783). It forms a solid mass, insoluble in water, soluble in ether, alcohol, and chloroform. Is readily decomposed on heating.

Butyl chloral has a strong affinity for water, and readily forms

Butylchloral hydrate $\text{CH}_3\text{-CHCl-CCl}_2\text{-CHO} + \text{H}_2\text{O}$. This compound, which is also known as butyl chloral, is prepared by passing chlorine into paracetaldehyde (Freundler, Compt. rend. 143, 682). It forms white crystalline trimetric plates of a peculiar odour, with difficulty soluble in cold, more readily in hot water; very readily soluble in alcohol; m.p. 78°, with partial dissociation, and sp.gr. 1.694 (Schröder, Ber. 12, 562). For some years after its discovery in 1870, it was regarded as croton-chloralhydrate. It is decomposed by distillation into the chloral and water. Alcohol and potassium cyanide convert the hydrate into ethyl α -chlorocrotonate. Zinc and hydrochloric acid, or zinc-dust and water, produce mono-chlorocrotonaldehyde, and finally crotonaldehyde (Sarnow, Annalen, 164, 108). With acetic acid and iron filings, butyraldehyde, normal butyl alcohol, and crotonyl alcohol are produced (Lieben and Zeisel, Monatsh. 1, 840). It is a valuable anodyne in cases of neuralgia, facial rheumatism, periostitis, &c. The following composition is recommended: butyl chloral hydrate, 2-5 grams; alcohol, 10 grams; glycerol, 20 grams; and distilled water, 120 grams (J. Soc. Chem. Ind. 1889, 476; 1890, 889). It is frequently adulterated with the cheaper chloral hydrate, from which it may be distinguished by the following reaction: A solution of pyrogallol in pure 65 p.c. sulphuric acid gives, when gently and carefully warmed, a blue colour with chloral, a ruby colour with butyl chloral and a more or less violet-to-blue colour with mixtures of the two compounds. On addition of a large quantity of water, the blue colour obtained with chloral changes to yellowish-brown, and the ruby colour obtained with butyl chloral to a more or less deep-violet colour (Galbutti, J. Soc. Chem. Ind. 1894, 273).

Derivatives.—Butylchloralantipyrine, yellow crystals, m.p. 70°-71° (Calderato, Chem. Zentr. 1902, ii. 1387); butylchloraldoxime (Tarugi, Gazz. chim. ital. 21, ii. 6).

CHLORALUM *v.* DISINFECTANTS.

CHLORAMINE-BLUE, -GREEN, *v.* AZO-COLOURING MATTERS.

CHLORAMINE-YELLOW *v.* PRIMULINE AND ITS DERIVATIVES.

CHLORANIL *v.* QUINONES.

CHLORATE OF POTASH, SODA *v.* CHLORINE.

CHLORAZIDE. N_3Cl . A gas obtained by mixing solutions of sodium azide N_3Na , and sodium hypochlorite, and acidifying with acetic acid. Chlorazide is highly explosive, slightly soluble in water, and insoluble in caustic alkalis (Raschig, Ber. 1908, 4194).

CHLORAZOL-BROWN, -DEEP BROWN, -BLUE, -VIOLET *v.* AZO-COLOURING MATTERS.

CHLORETONE *v.* ACETONECHLOROFORM.

CHLORIDE OF LIME, POTASH, SODA *v.* CHLORINE.

CHLORINE. Symbol Cl. At. wt. 35.46.

Chlorine was first obtained by Scheele in 1774 by the action of hydrochloric acid upon manganese dioxide, and was termed by him 'dephlogisticated marine acid air.' The idea that it was a compound substance prevailed until 1809, when Gay-Lussac and Thénard suggested that it was probably an elementary body, a supposition confirmed by the investigations of Davy in 1810 (Phil. Trans. 1811, 1, 32). Davy gave it its present name, from $\chi\lambda\omega\rho\acute{o}s$, greenish-yellow, in allusion to its characteristic colour.

Chlorine is never found free in nature; it exists mainly in combination with sodium, potassium, calcium, magnesium, &c. Sodium chloride occurs as *rock salt* in large quantities in Galicia, Tyrol, Transylvania, Spain, and in England (particularly in Cheshire) (*v.* *Sodium Chloride*, art. SODIUM). Potassium chloride is found as *sylvine* (*q.v.*), and in association with magnesium chloride as *carrollite* $\text{KCl-MgCl}_2\cdot 6\text{H}_2\text{O}$ (*q.v.*) in the salt-beds of Staßfurt. Other naturally occurring chlorides are *matlockite* $\text{PbCl}_2\cdot \text{PbO}$, *horn silver* AgCl , *atacamite* $\text{Cu}_2\text{Cl(OH)}_3$, *calomel* Hg_2Cl_2 , &c. Ferric chloride Fe_2Cl_6 and sal ammoniac are occasionally found native as products of volcanic action. Alkaline chlorides are also found in considerable quantity in sea-water and in many natural waters.

Sodium and potassium chlorides are present in most animal secretions, and free hydrochloric acid is met with in the gastric juice. Many plants, especially those growing in proximity to the sea, contain notable quantities of chlorides.

The readiest mode of preparing chlorine for laboratory purposes consists in heating manganese dioxide with hydrochloric acid, or by heating a mixture of manganese dioxide, common salt, and sulphuric acid:

Both these processes are used on the large scale for the preparation of chlorine (*v. infra*).

Many other peroxides and certain oxy-salts may also be used for the preparation of chlorine; thus red lead or potassium dichromate generate the gas when heated with hydrochloric acid.

Chlorine is also formed when the heated vapours of nitric and hydrochloric acid react upon each other: $2\text{HCl} + 2\text{HNO}_3 = \text{Cl}_2 + \text{N}_2\text{O}_4 + 2\text{H}_2\text{O}$.

Certain chlorides, *e.g.* MgCl_2 , PbCl_2 , AuCl_3 , &c., evolve chlorine when heated in air.

(For other processes, *v. infra*.)

At ordinary temperatures and pressures chlorine is a greenish-yellow gas, which becomes darker in colour as it is warmed; under strong pressures the colour becomes orange-yellow. Even when largely diluted with air, the gas possesses a characteristic pungent and irritating smell; it cannot be respired, as it rapidly

attacks the membranes. The gas is incom-
bustible in air, although it may be made to
burn in hydrogen; ordinary illuminating flames,
e.g. of coal gas, tallow, wax, &c., burn in chlor-
ine with separation of carbon and formation of
hydrochloric acid gas.

The sp.gr. of chlorine shows a gradual
diminution up to 240°, when its density
becomes normal, viz. 2.4502 (Jahns, Ber. 15,
1242).

40°	80°	120°	160°	200°	240°
2.4844	2.4776	2.4708	2.4641	2.4572	2.4504

The absorption spectrum of chlorine shows
numerous dark lines in addition to complete
absorption in the blue and violet.

Chlorine is readily liquefied to a dark greenish-
yellow liquid of sp.gr. 1.33, b.p. -33.6°. It
can be solidified at a low temperature. Liquid
chlorine is not miscible with water; its refractive
index is lower than that of water, and it is a
non-conductor of electricity.

Chlorine gas is readily soluble in water, its
absorption coefficient between 10° and 41.5°,
according to Schönfeld (Annalen, 93, 26; 96, 8),
is

$$3.0361 - 0.046196t + 0.0001107t^2$$

by means of which the following table showing
the volume of chlorine at 0° and 760 mm. ab-
sorbed by 1 vol. of water at varying tempera-
tures is calculated:—

10°	15°	20°	25°	30°	35°
2.5852	2.3681	2.1565	1.9504	1.7499	1.5550

(*v.* also Pickering, Chem. Soc. Trans. 1880,
139).

The volume of chlorine absorbed from a
mixture of that gas with an indifferent gas, as
hydrogen or carbon dioxide, is greater than that
calculated from the law of partial pressures
(Roseco, Chem. Soc. Trans. 8, 14).

Chlorine acts as an active germicide on
account of its affinity for hydrogen, and the con-
sequent release of nascent oxygen when it
comes into contact with micro-organisms in a
moist condition. A summary of work done on
gaseous chlorine as a disinfectant is given by
Clayton (J. Soc. Chem. Ind. 1896, 320).

Chlorine-water has the characteristic
smell and colour of the gas; in daylight, and
especially when exposed to sunshine, it gradually
loses its colour owing to the action of the chlor-
ine on the water, the main reaction being

On cooling a saturated solution to 0°, it de-
posits crystals of so-called chlorine hydrate
of a light-yellow colour, which become almost
white when cooled to -50°. By gently heating
the crystals in a sealed tube, they are readily
resolved into water and free chlorine, which may
be thus obtained as a liquid.

Chlorine is an active chemical agent, and
combines with many substances even at the
ordinary temperature. Phosphorus ignites
spontaneously in the gas, forming phosphorus
trichloride, which, in contact with excess of
chlorine, is ultimately converted into phos-
phorus pentachloride. Finely divided arsenic,
antimony, copper, tin, lead, and iron burn in
chlorine, forming the respective chlorides. Cer-

tain of these reactions are modified if the chlor-
ine is absolutely free from moisture. Wanklyn
(Chem. News, 20, 271) found that sodium might be
melted in dry chlorine without action, although
the metal readily burns in chlorine as ordinarily
prepared. Cowper (Chem. Soc. Trans. 43, 153)
found that Dutch metal, zinc, and magnesium
were unacted upon by dry chlorine; silver and
bismuth were only slowly attacked.

Sulphur dioxide, ethylene, and carbon mon-
oxide readily unite with chlorine. Chlorine
rapidly attacks many organic substances, form-
ing *addition products* as in the case of ethylene,
or *substitution products* as in that of marsh gas.
Chlorine has, indeed, a very strong affinity for
hydrogen; a lighted taper plunged into an atmo-
sphere of chlorine continues to burn with a dull
lurid flame accompanied by much soot. If a
piece of paper moistened with oil of turpentine
 $\text{C}_{10}\text{H}_{16}$ be thrust into a jar of the gas, it takes
fire and burns with a cloud of smoke. By reason
of its tendency to unite with hydrogen, chlorine
acts indirectly as an oxidising agent in presence
of moisture. Many metallic protoxides are con-
verted into peroxides by the action of the gas
in presence of water, the hydrogen of which
combines with the chlorine to form hydrochloric
acid, whilst the liberated oxygen attacks the
metallic oxide. If a stream of chlorine is led
into an alkaline solution containing sulphur, or
a sulphur compound in solution or suspension,
the sulphur, in presence of water, is rapidly
oxidised by the nascent oxygen to the state of
sulphuric acid. The oxidising action of chlorine
is frequently made use of in chemical analysis.
By virtue of its oxidising action, chlorine de-
stroys many organic colouring matters, and is
hence used directly or indirectly for bleaching.

INDUSTRIAL PREPARATION OF CHLORINE.

Chlorine is prepared industrially by :

(a) The action of hydrochloric acid on
substances capable of oxidising the hydrogen,
thus setting the chlorine at liberty.

(b) The electrolysis of metallic chlorides.

(c) Chlorine can be prepared and has been
prepared on the small industrial scale by the
direct action of sulphuric acid on a mixture of
sodium chloride and manganese peroxide. It is,
however, usually obtained by the oxidation of
the free HCl obtained by the decomposition of
common salt with sulphuric acid in the manufac-
ture of sulphate of soda.

The methods of oxidation adopted are:—

(1) By the action of MnO_2 .

(2) By the direct action of atmospheric
oxygen aided by the presence of a catalyst or
carrier.

To deal with the oxidation by MnO_2
first.

The raw materials used are :

A solution of hydrochloric acid in water or
muriatic acid usually obtained as mentioned
above in the manufacture of sodium sul-
phate.

The solution used should be as strong as
possible, because complete exhaustion of the
acid by manganese peroxide is impracticable,
and a residual liquor containing a considerable
amount of unavailable acid is always left. The

stronger the hydrochloric acid solution to start with the smaller the percentage of the total HCl which is lost (for actual figures, see below).

The only impurity occurring in sufficient quantities in ordinary commercial hydrochloric acid to have any serious effect is sulphuric acid. The liquid hydrochloric acid obtained by condensation of the salt cake (sodium sulphate) roaster gas may contain anything up to 3 p.c. of sulphuric acid, and, as calcium chloride, is always present in the chlorine generators and in the final neutralising wells, calcium sulphate is thrown down in the form of a voluminous precipitate, which entails labour and expense in filter pressing and handling, and always results in loss of manganese.

Manganese ore (peroxide).—Originally, native manganese ore was the only form of peroxide used for the generation of chlorine from HCl, and it is still the source from which the manganese in use is actually derived. Formerly the solution of manganese chloride obtained by the action of HCl on MnO_2 was a waste product, and after neutralising with limestone dust was run away. The invention and working out of the 'Weldon' process enabled the manganese in these waste liquors to be cheaply recovered in the form of peroxide, and the manganese ore is now used in large scale manufacture only to make up the inevitable losses of the recovery process.

The manganese ore used for the generation of chlorine should contain a high percentage of MnO_2 . The lower oxides of manganese also liberate chlorine, but only a smaller proportion of the total as shown by the following equations:—

Pyrolusite is the manganese ore generally used. This mineral is found in rhombic prisms, usually occurring in distinctly crystalline masses of a fibrous structure; its sp.gr. is 4.7–5, and its colour iron-black to dark steel-grey with a metallic lustre. It is soft and soils the fingers.

The ore is widely distributed, occurring in Germany at Elgersburg, and Giessen, in Bohemia, Transylvania, Russia, India, Australia, Japan, and the United States of America.

The chief source of the industrial pyrolusite used in this country is Southern Russia.

The ore varies usually from 75 p.c. to 85 p.c. MnO_2 .

An average analysis of the Russian ore is: 80 p.c. MnO_2 ; 1 p.c. MnO ; 3 p.c. H_2O .

It is customary to buy and sell manganese ore on the percentage of MnO_2 only.

The higher the percentage of MnO_2 , the more valuable the ore, as the impurities, even if substances such as $BaSO_4$ and SiO_2 , do harm by coating the particles of MnO_2 and preventing the action of the HCl, and also by adding to the amount of waste material to be handled, filtered, washed, and deposited. If the impurities are carbonates ($CaCO_3$, $BaCO_3$, &c.), they not only waste hydrochloric acid, but the CO_2 evolved on their solution harms the bleaching powder into which the bulk of industrial chlorine is made.

The physical condition of the manganese is also important, the softer ores being preferable to the harder ones, which are more slowly acted on by the hydrochloric acid.

The manufacture of chlorine from manganese and liquid hydrochloric acid is carried out usually in 'stills' made of acid-proof stone, such as Yorkshire flag, and occasionally on a small scale in stoneware vessels. *Stoneware stills* can be made only of moderate size, and hence are mostly used for producing chlorine on a small scale, not for manufacturing bleaching powder. Fig. 1 shows one of the best-known forms of stoneware

FIG. 1.

stills, intended for heating from the outside in a water- or steam-bath, made of wood or masonry. The manganese is placed in the perforated cylinder, which holds about 1 cwt., and is put in and out by means of specially shaped tongs, through the large opening. The small necks serve for introducing the acid and taking away the gas. At the end of the operation the still liquor is drawn off by a siphon, or by a discharge pipe passing through the steam-jacket. Since the acid is not diluted by steam-water, it is much better exhausted than in the large stone stills described below. Such small stills permit of careful and economical working so far as materials are concerned, and they necessitate hardly more labour than large ones.

These stoneware stills are sometimes heated by blowing steam into them, but this plan cannot be recommended, as the above-mentioned advantage is thus sacrificed, and, moreover, such stills easily crack.

Fig. 2 shows a contrivance which allows the chlorine pipes and the main pipe to be instantly connected or disconnected,

FIG. 2.

and which, at the same time, shows how stop-cocks can be dispensed with for such purposes. There is a Y-shaped lead pipe *a*, the upper arms of which are converted into hydraulic lutes by 'burning' an outer pipe, *bb*, on to them. The ends of the gas pipes, both that leading from the stills *c*, and that leading to the gas main *d*, are widened out into cups dipping into the water which fills the annular space at *b*.

Stone stills must be made of silicious sandstone or other stone not acted upon by acids, and not liable to crack by rapid changes of temperature. Such stone is found at Southowram, and is known as 'Yorkshire flag.' A variety of stone superior to it in resisting changes of temperature is found at Heworth, near Newcastle-on-Tyne, but this requires boiling in tar for several days to make it impermeable to acids. In Germany there are also several stones adapted to this purpose, but none equals in excellence the volcanic lava from the department of Puy-de-Dôme (France). This lava can be

had in thick blocks or thin slabs, and requires no boiling in tar to make it acid- and heat-proof.

It should be noticed that prolonged submersion in boiling tar is certainly an excellent way of toughening both stones and earthenware (fire clay), provided they possess a certain degree of porosity. It makes them resist both acids and changes of temperature, and at the same time hardens them very much, so that they must be worked into shape previous to the treatment.

Sometimes chlorine stills and acid tanks are hewn out of a block of stone (especially volcanic lava); but this is a costly operation, and in case a single crack occurs, the whole vessel is lost. It is, therefore, more usual (in England universal) to build up chlorine stills (like acid tanks, condensers, &c.) from stone slabs joined in a suitable manner and held together by iron binders. Such a still is shown in Fig. 3, which represents it cut through in the middle. The bottom is formed by a stone, 10 to 12 inches thick, with grooves for the sides to fit in. The sides are stone slabs, 5 to 6, or even 8 inches thick, and joined at the corners either 'on the bevel,' or on the 'feather and groove' principle. In the former case the stones are all dressed in the same way, and are held together by cast-iron

FIG. 3.

corner pieces, drawn together by long screw bolts; in the latter case, the end stones must project both ways over the sides, the latter fitting into grooves of the end stones (as is shown in the figure). The lid consists of one or more stones laid in a rebate. The joints are made tight by dressing a small groove into the two adjoining faces, and placing a $\frac{5}{8}$ -inch india-rubber cord in the channel thus formed. Temporary joints, not intended to harden, can be made with a putty of linseed oil and china-clay.

The diagram shows how the still is fitted with the following parts. A false bottom *a*; a pipe *b*, for the introduction of hydrochloric acid, sealed at the bottom by the acid itself; a leaden steam pipe, *c*, connected at the bottom with a stone or stoneware steam column *d*, and at the top by

the loop *e* with a tap *f* (the loop protecting the tap to some extent against the action of the chlorine); the earthenware or leaden gas pipe *g*, the connection of which with the gas main *h* can be opened or shut off at will by putting more or less water into the pot *i*. The man hole for charging the still and the discharging hole must be assumed to be provided in that half of the still not shown in the diagram.

These stills are made from 7×5×3 feet, inside measurement, and upwards.

Fig. 4 shows a still of the bevel-joint type,

FIG. 4.

seen from above, with the cover removed; *a, a* are the flags forming the false bottom, one of which, *a'*, is made to stand up; *c* is the steam stone; *A, B, C, D* are the rods binding the stones together by means of the cast-iron corner pieces *b, b*.

In order to work the stills, those of smaller sizes, where the manganese is contained in a sieve, are usually first charged with the requisite quantity of acid. The sieve containing the manganese (about 1 cwt.) is then put in, the cover is at once put on and made tight by water-luting or cementing, and the evolution of chlorine begins forthwith. When it slackens, heat is gradually supplied by turning on the steam till the acid is exhausted. The stills are then allowed to cool down, usually till the next morning. They are then opened, the sieve is lifted out, the manganese remaining in it is washed and replenished by more ore, the liquor is siphoned or run out of the still, fresh acid is run in, and a new start can be made at once.

The large stone stills are cleaned out frequently, and are charged with from 6 to 10 cwt. of manganese broken up into pieces, which must be smaller in the case of hard ores, but should not be too small, lest too much is washed down below the false bottom. The still is then closed and acid is run in, at first quickly, afterwards gradually, so that it takes several hours to run in the full charge. All this time chlorine is given off, much heat being generated in the process, of course much more with concentrated than with somewhat dilute acid. When the evolution of gas becomes slow, steam is injected into the still, but very cautiously, as otherwise the water might be thrown out of the lutes, and only at intervals, for instance for 10 minutes every hour. Too much steaming causes too rapid an evolution of chlorine, and the volatili-

sation of much acid and water. The temperature of the stills ought never to get above 90°. It is preferable not to steam all the stills of a set at the same time, but in regular rotation, to produce a more continuous current of chlorine.

Chlorine stills ought to be kept going at least 24 hours, but large stills are better kept going for 48 hours, which will utilise more of the acid. Even then the liquid, when let out, emits an intolerable stench of chlorine, so that this operation is one of the most irksome, both for the workmen and those people who live near the works. Moreover, the 'still liquor,' even after being freed from its muddy constituents by settling, is one of the worst nuisances for any watercourse into which it may be run. In alkali works, all this nuisance has been completely overcome by the introduction of the Weldon process, where the still liquor from the fresh manganese ore is run into the Weldon stills instead of into the drains. At other works where chlorine is made on too small a scale to permit of applying the Weldon or other modern processes, the still liquor ought to be collected in a closed tank, and neutralised by chalk before running it away, even in a very diluted form.

The chlorine evolved in the stills is always contaminated with hydrochloric acid and water. For most purposes these must be removed as far as possible, which is done by conveying the gas in a long string of earthenware or lead pipes, externally cooled by air (or, if needful, by water), so that the water along with the acid condenses into a liquid.

The first reaction taking place in the chlorine stills is: $MnO_2 + 4HCl = MnCl_2 + 2H_2O$ or (more probably) $2MnO_2 + 8HCl = Mn_2Cl_6 + 4H_2O + Cl_2$. (There is some discrepancy of opinion as to which of these two chlorides of manganese is formed. Compare W. W. Fisher, Chem. News, 37, 250; U. S. Pickering, *ibid.* 39, 225; Berthelot, Compt. rend. 91, 251.)

These chlorides, $MnCl_2$ and Mn_2Cl_6 , form a dark-brown solution which quickly decomposes even at the ordinary temperature into $MnCl_2$ and free chlorine, so that the ultimate result is: $MnO_2 + 4HCl = MnCl_2 + 2H_2O + Cl_2$; but this reaction is only completed at about 100° and with a certain excess of hydrochloric acid. Theoretically for $100MnO_2$, or an equivalent quantity of manganese ore, almost exactly 170 dry HCl = 530 acid of 32°Tw., ought to be consumed; practically, at least, 10 p.c. more is used, and with low-strength acid, hard manganese, direct steaming, &c., twice the theoretical quantity of acid may be consumed.

Still liquor and the processes carried out for utilising it.—The waste liquor run from the stills contains chiefly manganese chloride, ferric chloride, the chlorides of other metals present in the ore, free hydrochloric acid, and a little chlorine.

Black's analysis of still liquor from ordinary stone stills, in a well-conducted works, shows how incompletely the acid is utilised there:

HCl	= 6.6220 = 6.622 p.c. HCl
Al_2Cl_6	= 0.6200 = 0.500 " "
$MnCl_2$	= 10.5700 = 6.120 " "
Fe_2Cl_6	= 0.4551 = 0.310 " "
H_2O	= 81.7329

Even if all the Mn had been originally present as MnO_2 , only an equal quantity of HCl to that found as $MnCl_2$ (6.12) had escaped as chlorine, so that there was originally

$$13.552 + 6.12 = 19.672 \text{ HCl}$$

present. Accordingly, the HCl usefully employed was only 62.2 p.c.; that combined with Fe and Al, 4.1 p.c.; that found uncombined, 33.6 p.c. of the whole.

The free acid is tested for in daily practice by a very simple plan. To a measured volume of still liquor, standardised caustic soda liquor is run in from a burette till the formation of flakes of $Fe_2(OH)_6$, which do not dissolve on shaking, indicates the saturation of the free acid.

In small manufactories, where the scale of work does not permit the economic introduction of the Weldon process for the recovery of the manganese from the still liquors, the liquors have to be neutralised with limestone dust and run down the drain.

Of the many processes suggested before the Weldon process to overcome this difficulty and this loss of manganese, only the Dunlop process deserves mention. The Dunlop process was patented in 1855, and has been practised at St. Rollox for 30 years or more with great success. It consists in removing the free HCl and Fe_2Cl_6 by agitating the liquor with ground chalk (exactly as in the Weldon process), pumping the neutral solution of $MnCl_2$ and $CaCl_2$ into large horizontal cylinders fitted with agitating gear, mixing it with the quantity of ground chalk required for converting the $MnCl_2$ into $MnCO_3$, and producing this conversion by agitating under a steam pressure of 2-2½ atmospheres. The precipitate of $MnCO_3$ is settled out, washed, pressed, partially dried, and then oxidised by being exposed to a current of air in an oven heated to about 300° which is always kept moist. In 24 hours the process is complete. The paste is now found to consist of 67 p.c. MnO_2 , 16 p.c. MnO, and 16 p.c. $CaCO_3$. This process is only remunerative where fuel is cheap, and as it requires very costly plant, it has never spread beyond the place of its origin, where it has also at last had to give way to the Weldon process, and is now only employed for the production of an artificial oxide of manganese for glassmaking.

The Weldon process for recovering Manganese.—The process bearing the above name has, like most other important inventions, been perfected by many successive improvements. Many of its features had been foreshadowed by former inventors; but without the indomitable energy of the late Walter Weldon, and the efficient practical help rendered to him at Messrs. Gamble & Co.'s works at St. Helens, it would have remained futile, like all its predecessors. Weldon's first attempts were made in 1866; in 1869 chlorine was first actually manufactured by Weldon mud. By carefully studying all the conditions of the reaction on the large scale, at last all obstacles were overcome and the fullest practical success was secured. This achievement alone entitles Mr. Weldon to be called one of the greatest benefactors to chemical industry.

The leading idea of the Weldon process is the following. We start with a solution of

manganous chloride—*i.e.* ordinary still liquor. This is deprived of free acid and ferric chloride by agitation with calcium carbonate under ordinary atmospheric pressure. To the neutral settled solution of $MnCl_2$ and $CaCl_2$ is added milk of lime more than sufficient for precipitating all manganese as $Mn(OH)_2$, so as to leave 33 p.c. to 40 p.c. lime in excess, both lime and manganous hydrate being partly suspended and partly dissolved in a solution of $CaCl_2$. This mixture is treated with a strong current of air, at a slightly raised temperature, when the oxygen acts upon it, forming principally a compound of MnO_2 and CaO . By adding a further quantity of $MnCl_2$ and blowing in more air, the proportion of CaO is reduced, the ultimate limit in ordinary cases being a compound of $1CaO$ with $2MnO_2$. The oxidation is now stopped; the thin paste or mud is run into tanks, where it separates into a thicker mud and a supernatant clear solution of $CaCl_2$. The latter is run to waste; the former, now called 'recovered manganese' or 'Weldon mud,' is still liquid enough to be run into a special kind of still, where it is decomposed by hydrochloric acid, yielding chlorine gas and a mixed solution of $CaCl_2$, $MnCl_2$, and a little uncombined HCl (much less than in the old process of working with native ore). This solution serves again as the starting-point for the recovery of MnO_2 in the way just described.

Long before Weldon's patents existed, it had been, of course, known that precipitated manganese protoxide could be more highly oxidised by means of atmospheric air. But Weldon was the first to find out that oxidation of MnO to MnO_2 —a compound of distinctly acid properties—can only take place in the presence of a base which combines with it at the moment of its formation. If the only base present be $Mn(OH)_2$, then the MnO_2 will combine with it to form either MnO, MnO_2 or else $2MnO, MnO_2$, according to the temperature. Thus, when MnO is the only protoxide present, one half of it at most can be oxidised into MnO_2 , the other half being required to furnish the necessary base for combining with MnO_2 . If, however, another soluble protoxide be present, the MnO_2 combines with this instead of with MnO . The only other protoxide practically available is lime, which is sufficiently soluble in a solution of calcium chloride. If instead of MnO, MnO_2 , we produce CaO, MnO_2 , there is, of course, no advantage gained with respect to the consumption of acid, since in either case $6HCl$ are required to liberate $2Cl$. But the advantage lies in this, that the absorption of oxygen by $Mn(OH)_2$ in the presence of dissolved lime is much more rapid than in the absence of a soluble base. The product of oxidation of $Mn(OH)_2$ by itself would be much more costly than native manganese.

It is not possible to employ a full equivalent of lime to each of $Mn(OH)_2$, so as to form $CaMnO_3$, because there cannot be present sufficient $CaCl_2$ to hold it in solution. Hence only enough $Ca(OH)_2$ is used to convert 0.6 of the Mn into calcium manganite, the other 0.4 of the manganese present is converted into manganite of manganese, $MnMnO_3$.

When thus 60 equivalents, $CaMnO_3$ and 40 $MnMnO_3$ have been formed, a further quantity

of neutral solution of $CaCl_2$ and $MnCl_2$ ('final liquor') is mixed with it, and the injection of air is continued. At the temperature employed, $MnCl_2$ can act upon half of the lime of $CaMnO_3$, forming a compound of one CaO with two MnO_2 , and $Mn(OH)_2$, which is, at the same time, oxidised to Mn_2O_4 or Mn_2O_3 . The final product is a thin black mud, consisting of a solution of $CaCl_2$, holding in suspension a mixture of manganites of manganese with an acid manganite of calcium, and containing about 2.5 lbs. MnO_2 per cubic foot.

The following is the description of a Weldon plant. On the diagram, Fig. 5, D, D are the mud stills, of which there should be three or four, and which will be described in detail hereafter. There is, besides, an ordinary still, E, which serves for dissolving native manganese ore, to make up for the loss in recovery, and which is so fixed that its waste liquor can be discharged directly into one of the mud stills. G, G are the neutralising wells into which the manganese liquor from D, D is discharged, and where it is mixed with ground chalk or limestone dust by means of the agitator F, in order to remove the free HCl and the iron. H is a cast-iron pump with gun-metal piston, valves, &c., which forces the neutralised liquor into the chloride of manganese settlers A, A. The suction pipe, which dips in the acid liquor, is very quickly corroded unless it is made to turn on a swivel so as to lift it out before running acid liquor into the well. The settlers A, A (of which there must be at least two, or better, more) are made of wrought iron, which is only slightly acted upon by the neutralised liquor. In one of these tanks the muddy liquor is allowed to settle while the other one is being filled. They are provided with cocks or valves, continued inside into swivel pipes or india-rubber tubing, by which the liquor can be run off from any part of the tank without disturbing the sediment. The discharge pipes unite outside in an iron pipe, which divides again into two branches, one for each of the two oxidisers B (only one of which is shown here), into which they enter at about two-thirds or three-fourths of their height. Each settler also has a large bottom valve for removing the mud from time to time, by means of the pipes G, G.

If the settlers A, A are each $18 \times 12 \times 6$ feet, they hold, when full, about 40 tons apiece and weigh altogether upwards of 100 tons. They must, therefore, be very firmly mounted on a strong timber framework of 12- or 14-inch beams, resting on the same foundation as the manganese mud settlers.

The oxidisers B, in which the recovery proper takes place, are wrought-iron cylinders open at the top, with a flat bottom, fixed at such a height that there is sufficient fall for the manganese mud into the settlers C, C, and from these again into the stills D. They are charged with settled $MnCl_2$ liquor from A, A to rather more than half of their height, and with milk of lime directly from the tank J by the pump K. The 7-inch pipe L conveys compressed air (furnished by the blowing engines and the air-vessel M) into the oxidisers; it is carried over the top of B down to the bottom, and there branches out into a cross of pipes N, perforated with a number of holes for dividing the current of air. Each oxidiser also has a 2-inch steam

FIG. 5.

pipe (not shown here) which equally passes over the top down to the bottom and there branches out into a perforated cross. None of the pipes is directly connected with the shell of B, as the shaking during the blowing would loosen the joints; the only fixed connection which cannot be dispensed with is the $MnCl_2$ liquor pipe from A, A. It is usual to make the joints on this pipe with indiarubber rings to give a certain amount of elasticity. Lastly, there are discharge valves *a*, connected with a common pipe, *b*, which sends out a branch with 4-inch valves *c*, *c* over each mud settler *c*, *c*. These mud settlers, of which there must be at least four, better six, are fitted with 2-inch swivel pipes *p* for running off the $CaCl_2$ liquor, communicating with a pipe or shoot, *e*, leading to a catch-well, and at the bottom with a 4-inch pipe, *f*, with sluice valves *g*, *g*; from which each of the stills *D*, *D* is fed by a pipe and sluice valve *h*.

The engine is here shown as a horizontal twin-engine. For each ton of bleaching powder made, 100,000–150,000 cubic feet of air are required.

The milk of lime is made in the two iron cylinders *J* and *J'*, each about 6 feet high and 7 or 8 feet wide; *J* serves for slaking the lime and preparing the milk, *J'* for storing it and supplying it to the lime-pump *K*. A donkey-engine bolted to *J* drives the agitators of both cylinders. *J* has a perforated cage in which the quicklime is put in order to be slaked by the water contained in the cylinder, and a door is secured to the cylinder in line with cage bottom in order to clean out unburnt lime.

The neutralising wells *G*, *G* are sunk in the ground, and are surrounded by puddled clay. They are made of large stone slabs in an octagonal shape, or of freestones in a circular shape, always, of course, so as to be altogether acid-proof. It is most important that there should be no loss of liquor from this well.

The chlorine stills belonging to this plant (*Weldon's stills* or *mud stills*) are very much larger, especially much higher, than the ordinary manganese-ore stills. The shape usual at small works is of square section about 7 feet \times 7 feet, and 8 or 9 feet high. For large works, they are made octagonal (as shown in Fig. 5, and more in detail in Figs. 6 and 7), sometimes 12 feet wide and high. The bottom is made in two pieces, held together by corner brackets and bolts *a*, *a*. The sides, also in two tiers, are joined in the corners by indiarubber cords or bands; they are bound together by the brackets *b*, *b* and screw bolts, or by cable chains, drawn up tight by coupling screws, and pressing on wooden posts outside of the still sides. The cover is usually made dome-shaped. We note the funnel for manganese mud, *d*, the steam stone *c* resting in the socket *k*, the discharge cock *f*, the gas pipe *l*, the acid-supply pipe *e*, about half-way up the height of the still. There must be also a man hole, a stoneware cock with a glass tube for a liquor gauge, and a small testing cock, all of them not shown in the diagram.

We shall now describe the round of operations, beginning with the running of spent liquor from the mud stills into the neutralising well. The latter should be covered over, a pipe leading

the gases (never free from chlorine) into a high chimney—if necessary, through a milk of lime tower. The liquor is here neutralised with ground chalk or limestone dust, of which no more than is absolutely necessary should be employed. This is best effected by grinding the calcium carbonate with water (or preferably with still liquor itself) into a milk, and running this in, with constant agitation, till no more CO_2 is given off and till there is no more acid reaction upon litmus paper. This operation will remove the free HCl and the Fe_2Cl_6 , causing a precipitate of $Fe_2(OH)_6$; but $MnCl_2$ is not acted upon here. G. E. Davies proposed to utilise the base in the Weldon mud for the neutralisation of the free acid in the still liquor. This is done by adding to the still liquor, after it has dissolved as much manganese peroxide as possible, an excess of Weldon mud. The free acid left, though it will not attack the manganese peroxide, readily dissolves the CaO in the base. As the base has, in any case, to be dissolved in the acid, its use for neutralising the free acid left in the still liquor is a direct saving of acid. The saving made is equal to about 0.45 cwt. salt per ton of bleach for every gram per litre HCl so neutralised in the still liquor.

The neutralised liquor, along with all the mud, is now pumped into the liquor settlers at the top of the timber staging, where it must be completely clarified before being run into the oxidisers. Any matter remaining in suspension greatly interferes with the recovery process, and especially causes very troublesome frothing in blowing. The muddy deposit remaining in the settlers is run off from time to time through the bottom valve. This deposit formerly caused the principal loss of manganese in the Weldon process, by mechanically keeping a quantity of $MnCl_2$ in suspension and wasting it. But this can be avoided by removing the $MnCl_2$ from that deposit as much as possible, either by systematic washing or by a filter press, and reintroducing this $MnCl_2$ into the process. It is, of course, desirable to keep the bulk of the deposit as small as possible by not employing more calcium carbonate than is really necessary, and by employing hydrochloric acid containing very little sulphuric acid, which by the formation of $CaSO_4$ increases the bulk of the insoluble matters. Principally by attending to a thorough exhaustion of this settler mud—of course, together with carefully attending to all other manufacturing details—the consumption of fresh manganese ore, which at first often amounted to 10 p.c. of the weight of bleaching powder made, has in the best works been brought down to 2½ p.c.

The clarified liquor drawn off from this deposit is essentially a solution of $MnCl_2$ and $CaCl_2$. The latter is not merely an accidental admixture, but it is absolutely necessary to the success of the process that the proportion of $CaCl_2$ to $MnCl_2$ should not fall below 1 to 2. This seems to be owing to the circumstance that a solution of $CaCl_2$ keeps much more $Ca(OH)_2$ in solution than water, in the shape of an oxychloride, and that this is necessary to expedite the subsequent reactions. The manganese chloride, contained in normal still liquor, corresponds to about 3½ lbs. MnO_2 per cubic foot.

The liquor is run into one of the oxidisers

till this is rather more than half full; the other half serves for containing the milk of lime, the 'final liquor,' and, above all, the froth formed during the operation.

While one of the oxidisers is being charged and heated up, the other one is under blast, so that the operation is a continuous one. The liquor must be heated to 55° by blowing in steam, but, when continuously working, it often has that temperature to begin with, at least in summer, owing to being heated in the stills.

The next operation is adding milk of lime. The lime employed for the Weldon process should be as pure as possible, and ought especially not to contain more than 1 p.c. of magnesia. It ought to be particularly well burnt and slaked, and completely separated from unburnt or unslaked (dead) particles by being strained through a fine wire mesh. Those particles cannot aid in the recovery of MnO_2 , and they remain in this as injurious 'base.' The slaking takes place by directly introducing the quicklime into hot water, throwing it into the cage within the vessel J (Fig. 5), and agitating all the time. The coarser impurities remain behind in the cage, the finer ones in a drainer interposed between J and J'. The finished milk of lime in J' contains from 20 to $22\frac{1}{2}$ lbs. of CaO per cubic foot, and is pumped either directly into the oxidiser or into the top cistern, from which it can be let down in a preferably regular stream, provided that it is kept agitated in that cistern itself (cf. *supra*).

In order to begin an operation, one of the oxidisers is half-filled with well-settled $MnCl_2$ liquor (of which a stock must be in reserve for 'final liquor'), and is heated to 55° . The blast is put on slowly, and milk of lime, of which the initial level in the store tank has been carefully noted, is run in till all manganese has been

liquor whether the filtrate turns brown in consequence of containing some $MnCl_2$. When this reaction ceases, the flow of lime is at once stopped, and the quantity consumed so far is read off on a gauge. This is merely done to be able to fix upon the further quantity of lime, which ought to be from 33 p.c. to 40 p.c. of that first used. The exact quantity of excess lime to be used must be ascertained at each works by independent trials, as it varies according to the nature of the raw materials, &c.

The 'excess lime' is run in immediately after the first, and the blast is at once put on with full strength; otherwise a 'thick batch' would be produced, whilst a 'red batch' (containing Mn_3O_4) is formed when the blast is put on too soon. The oxygen contained in the blast

FIG. 7.

now acts upon the mixture of manganous and calcium hydroxides, and forms a manganite of calcium $CaMnO_3$, along with manganite of manganese Mn_2O_3 . This means that at this stage each molecule of MnO_2 is combined with a full molecule of 'base,' either CaO or MnO. This amount of base must be reduced, otherwise too much acid is consumed, all the more so as the base is augmented by the $CaCO_3$, and Fe_2O_3 present as impurities, since the base must first be saturated before the MnO_2 can be acted upon. Although there is no theoretical impossibility against it, there seems to be no practical way of getting the base below 0.5 equiv., or even quite down to that point; 0.6 is considered very good, and 0.7 is the more usual amount.

With 0.7 of base, the Weldon mud consumes 5.4HCl for each 6HCl that would be required for Mn_2O_3 ; pure MnO_2 would only require 4HCl, but native manganese ore practically requires more acid than Weldon mud, in spite of the base of the latter, because it is so much more difficult to dissolve.

It is, however, not possible to arrive at a proper result by the simple blowing of air into the mud of calcium and manganous hydroxides. With 0.6 equivalent of excess of lime, the degree of oxidation obtained is usually about 86 p.c., the product before the addition of 'final liquor' consisting of 0.14 equivalents of MnO_2 combined

FIG. 6.

precipitated as $Mn(OH)_2$. This point is ascertained by frequent testings, both by trying whether red litmus paper turns blue (from an excess of lime), and by filtering a small sample and ascertaining by the addition of strong bleach

with 0.14 MnO, 0.48 MnO₂ with 0.48 CaO as CaMnO₃, and 0.24 MnO₂ with 0.12 CaO as CaMn₂O₅. There is thus 0.74 total protoxides to 0.86 MnO₂, or 0.86 equivalents of base per 1 equivalent of MnO₂. In order to reduce the base, some more chloride of manganese liquor is run in ('final liquor'), up to the point that a filtered sample gives the reaction for MnCl₂. In this case 0.4 eq. of MnCl₂ will have been used, taking away half of the lime in the 0.48 eq. CaMnO₃. If the blowing in of air is now continued until the absorption of oxygen ceases, the 0.24 eq. of MnCl₂ added will have been converted into Mn₃O₄ or Mn₂O₃, according to temperature. In the former case, the base will be reduced from 0.86 to 0.7, but at the same time the average degree of oxidation from 86 to 75.8 p.c.; in the latter case, the base will be 0.632, the degree of oxidation 79 p.c.

It should be noticed that these calculations only refer to the *combined* base, but do not include MgO, CaCO₃, Fe₂O₃, &c., which must be included in the ordinary method of testing for *total* base. With good work the total base does not exceed 0.7.

In actual practice, it is not possible to add the lime exactly as indicated by theory, for when the bleaching powder reaction in the filtered sample has ceased, decidedly more than 1 eq. of CaO has been added to 1 of MnCl₂, Mn(OH)₂ being soluble to a certain extent in CaCl₂; nor do all the molecules of lime instantly act upon MnCl₂, but they will do so afterwards. Actually from 1.1 up to 1.45 eq. of CaO is used at first, and this is brought up to 1.6 by the 'excess lime.' With that quantity a well-settling mud is obtained, from which a good deal of CaCl₂ solution can be drawn off, thus obtaining stronger manganese mud for the stills. Usually 12 cwt. of lime per ton of bleaching powder are required for the recovery process (*i.e.* about as much as in the bleaching-powder chambers).

The operation of blowing is carried out in this way. Tests are taken from time to time; it is ascertained whether the alkaline reaction continues, which ought to be the case perceptibly for at least an hour after the commencement of the blowing; also, whether the oxidation proceeds any further or not. When the latter is the case, some more MnCl₂ liquor is run in, without stopping the blast, until a filtered sample yields the brown reaction with bleach liquor. After a few minutes this reaction ceases, all dissolved MnCl₂ having been precipitated. Then a little more final liquor is added, and the blowing is continued, and this is repeated till it takes a somewhat long time to 'blow out' the manganese, which must be done before running the batch into one of the settlers.

It has been found preferable to apply a very strong current of air by means of a powerful blowing engine; in this way the work is not merely done in much less time, but with a smaller absolute amount of air than with smaller engines. The time should not exceed 5 hours, nor the quantity of air 150,000 cubic feet per ton of MnO₂. With very deep oxidisers even better results can be obtained.

The manganese mud, as it runs from the oxidisers, must be concentrated before entering the chlorine stills, since it would otherwise become indefinitely diluted by the acid, the milk

of lime, &c. This is done by allowing it to remain some time in the mud settlers at the base of the oxidisers, where in a few hours it separates into a thicker mud and a clear solution of CaCl₂. The latter is run off by means of a swivel pipe, and before running into the waste drain it is made to pass through a catch well, where any MnO₂ carried away may be saved. The thicker manganese mud remaining behind, containing upwards of 6 lbs. MnO₂ per cubic foot, is still liquid enough to be run in pipes and through sluice valves into the chlorine stills.

The working up of the manganese mud takes place in this way. First, a charge of hydrochloric acid is run into the still, say 2 feet deep; in lieu of part of this, still liquor from native manganese ores may be employed. Then manganese mud is run in slowly by means of a sluice valve. Since in this fine state of division the action between MnO₂ and HCl is practically instantaneous, a perfectly uniform current of chlorine can be obtained by regulating the flow of manganese mud. When the liquid taken out at the test cocks begins to assume a dark colour, a little steam is blown in. The end is reached when the liquor, in spite of a sufficient temperature, is clear but coffee-coloured, and on pouring upon chalk produces only a slight effervescence. It ought not to contain more than about 1 p.c. of free HCl, if tested like ordinary still liquor (*cf. supra*). If the saturation of the HCl is driven too far, there is danger of some MnO₂ remaining behind, and getting lost with the mud from the MnCl₂ settlers. Each operation in the stills lasts from 4 to 6 hours; the liquor is then run into the neutralising well, and the round of operations begins anew.

The yield of chlorine by the Weldon process is mostly expressed in terms of the quantity of the salt required to be decomposed for manufacturing 1 ton of 37 p.c. bleaching powder.

In actual practice the quantity of salt used varies with the efficiency of the manufactory from 45 up to 70 cwt. salt per ton bleaching powder. As the quantity of chlorine (8 cwt.) required to make 1 ton of strong bleaching powder is actually contained in 14.2 cwt. salt (93 p.c. NaCl), the yield of chlorine in the Weldon process is under the best conditions less than 32 p.c.

CHLORINE PROCESSES EMPLOYING ATMOSPHERIC OXYGEN FOR THE LIBERATION OF CHLORINE.

The Deacon Process.—After many unsuccessful attempts made by Oxland (1840), Jullion (1846), Binks (1860 and 1862), Dufrené (1865), and others, the labours of H. Deacon and F. Hurter, in the years from 1868 on, produced an entirely successful chlorine process which is founded on the direct oxidation of the H in HCl by atmospheric oxygen, and which utilises much more of the HCl than any process employing either native or recovered MnO₂. Some processes patented after theirs (Henderson, 1871; Weldon, 1871; Wigg, 1873, &c.) proceed on the same lines, but have not been practically successful.

The Deacon process starts from the well-known fact that a mixture of hydrochloric acid and oxygen at a certain temperature, especially

in contact with porous substances, partially changes into chlorine and water :

This decomposition is very much assisted by the employment of substances which serve as oxygen-carriers, and of these the salts of copper (previously employed by Vogel, 1855; Gatty and Laurent, 1860; Mallet, 1866), have been found most useful. Probably in all cases cupric chloride is formed, which at once splits up into cuprous chloride and free chlorine. The Cu_2Cl_2 combines with oxygen to form oxychloride $\text{Cu}_2\text{O}\cdot\text{CuCl}_2$, and this acts again upon HCl, yielding water and reforming cupric chloride, so that the reactions can begin over again :

- (1) $2\text{CuCl}_2 = \text{Cu}_2\text{Cl}_2 + \text{Cl}_2.$
- (2) $\text{Cu}_2\text{Cl}_2 + \text{O} = \text{Cl} - \text{Cu} - \text{O} - \text{Cu} - \text{Cl}.$
- (3) $\text{Cu}_2\text{OCl}_2 + 2\text{HCl} = \text{H}_2\text{O} + 2\text{CuCl}_2.$

Theoretically, all the HCl would thus be converted into chlorine, but in practice, under the best conditions, about two-thirds of this decomposition is effected. The undecomposed HCl is, however, not lost, but is recovered and can be utilised for other purposes, *e.g.* for the Weldon process.

From a diagram constructed by Hurter, showing the affinity of technically available elements for oxygen, chlorine, and hydrogen, it appears that no other metal than copper forms two oxides and two chlorides, in which the combination is of so loose a character. It is therefore almost a certainty that a cheaper and equally efficient catalyst cannot be found, and that the Deacon process is the best for the direct conversion of gaseous HCl into free chlorine.

Deacon's process deals with the gaseous hydrochloric acid, as it is evolved in decomposing common salt by sulphuric acid without condensing it into liquid acid. This is evidently a great advantage in one way, but when the salt cake is made in the ordinary hand-worked pot and furnace, it has the drawback that in the beginning of each operation much more HCl, and hence more Cl, is got than afterwards. In practice, only the gases from the decomposing pots, say 68–70 p.c. of the total HCl, are used for the Deacon process, those coming from the roasters being too dilute and containing too much sulphuric acid. In order to equalise the operation to a certain extent, the gases from two salt-cake pots can be mixed and the pots worked alternately, so that the strong gas from the early part of one charge is mixed with the weak gas from the latter part of the other charge.

The quantity of air necessary to form chlorine enters through the joints of the doors and dampers. It is regulated by the speed of the aspirator (a Root's blower) or cast-iron fan, which is placed at the end of the whole apparatus and produces the movement of the gases through it. Usually there are 4 vols. of air to 1 vol. of HCl. An excess of air is less injurious than a deficiency of it, in which case there is a poor decomposition.

The gases leaving the pot are first cooled by a long string of pipes and a scrubber; thus much of the water and about $\frac{1}{3}$ or $\frac{1}{2}$ of the HCl

is removed. A patent by Deacon and Hurter (Eng. Pat. 2104, 1888) provides for cooling the gas and drying it in a sulphuric-acid tower before it enters the decomposer, such complete drying being very advantageous for the process. The gases now enter the heating apparatus. This is a furnace, 16 feet \times 16 feet, in which twenty-six vertical pipes, 12 inches wide and 9 feet high, are arranged in two sets of twelve each, connected like the 'breeches pipes' in the blast-heating stoves, formerly used in ironworks and now replaced by brick heaters.

The gases are here heated up to 500°; the waste heat of the furnace is sufficient for heating the decomposer, which does not possess any fire of its own.

The gases now pass into the decomposer (Fig. 8). This is an upright cast-iron cylinder, 12 to 15 feet wide.

It contains a cylindrical ring of broken bricks supported by cast-iron shutters. The gases enter at the circumference at A, pass radially across the decomposing mass D into the inner space,

FIG. 8.

and are led away through the pipe OB. The annular space between the shutters is 3 feet wide, and is divided into six compartments, one of which is emptied every fortnight. This is done by means of the discharging doors c, c below the cylinders. Fresh decomposing material is then thrown in from above through E, E; this material consists of burnt clay broken up into lumps, or ordinary bricks broken, freed from dust, and dipped into a solution of cupric chloride. The mass contains about 0.6–0.7 p.c. of metallic copper. After the active substance has served once, that is, for 10 to 12 weeks, it is thrown away. Each cwt. of clay produces about 10 to 12 cwt. of bleach. It has been found useless to attempt utilising the contact substance by redipping it in the copper solution or in any other way. The cost of copper for the contact substance does not exceed 1s. per ton of bleach produced.

The temperature, both in the heating apparatus and in the decomposer, must be most carefully regulated, for which purpose special pyrometers have been constructed (*cf.* Hurter on Pyrometers, J. Soc. Chem. Ind. 1886, 625). In the decomposer, it ought to range from 480° to 500°.

When the gases leave the decomposer, they consist of a mixture of HCl, free Cl, and steam. In the best case, two-thirds of the HCl is converted into chlorine, but sometimes only one half. They are now cooled by passing through a long string of earthenware or glass pipes, and are then freed from HCl by washing with water in the ordinary acid condensers, consisting of stone coke towers, combined or not combined with acid cisterns, Woulff's jars, &c. By properly managing this process, all the acid can be obtained in the strong state, as required for the Weldon process and other purposes.

The gases can now be employed directly for making bleach liquor or chlorate liquor from

milk of lime. If, however, bleaching powder is to be made, they must be freed from water by passing them through a lead tower packed with coke, in which sulphuric acid of not less than 140°Tw . is kept trickling down. The removal of water is very necessary for dealing with this gas, which, owing to the great excess of nitrogen and oxygen present, contains at most 10 p.c. of chlorine, and cannot be absorbed in ordinary bleaching-powder boxes, but must be treated in apparatus specially constructed for this purpose (*cf. infra*). As will be seen from the description, there is theoretically no loss of HCl in the Deacon process, the whole of the acid evolved from the salt being either converted into chlorine or recovered by condensation as liquid hydrochloric acid. In practice, of course, some losses occur, but they are not necessarily large, and their amount depends principally on the efficiency of the draughting arrangements and the avoidance of low-level escapes at the salt-cake pots and furnaces. The fuel used per ton of bleaching powder to heat the decomposing apparatus depends naturally on the efficiency of working of the process, and varies from 6 to 10 cwt. per ton of bleaching powder.

During the early years of its existence, the Deacon process had many difficulties to contend with, and the working results were disappointing and unsatisfactory.

The fact that the impurities accompanying the gaseous HCl were sufficient to seriously affect the process was not realised. The impurities are sulphuric and sulphurous acid, arsenious acid, water, and carbon dioxide.

The sulphuric acid and sulphurous acid carried along with the gaseous HCl, especially when attempts were made as they frequently were in the early days, to utilise the roaster or furnace gas as well as the pot gas, converted the CuCl_2 into CuSO_4 , which requires a higher temperature and gives a lower decomposition than CuCl_2 .

The arsenious acid derived from the As_2O_3 in the sulphuric acid used forms arsenate of copper, which is even less reactive than the CuSO_4 . The presence of these impurities necessitated the frequent renewal of the decomposing material. Water is one of the products of the decomposition, and hence, when present in the inlet gases, increases the partial pressure of the products of the reaction and lowers the maximum p.c. decomposition obtainable under the conditions of the process.

Carbonic acid derived from the fuel gases, either of the salt-cake furnaces or of the decomposing furnace itself, was a serious obstacle to, and frequently entirely prevented, the production of strong bleaching powder. This difficulty has been overcome by greater care in the construction of the apparatus and testing for leakage.

It will be noted from the above description that only the gaseous HCl from the salt-cake pot is dealt with by the Deacon process, and that allowing for the liquid acid collected after the decomposers, about 60 p.c. of the total acid is obtained in the liquid form, and has to be sold as such or used in some other way such as by the Weldon process.

Hasenclever, however (Eng. Pat. 3393, 1883),

describes a process for gasifying the HCl in the liquid acid by mixing with strong hot sulphuric acid in a series of earthenware vessels through which air is blown.

By this means, a steady continuous stream of gaseous HCl is evolved with an easily regulated supply of air.

After passing through the series of vessels, the vitriol diluted with the water contained in the liquid hydrochloric acid has to be reconcentrated to the original sp.gr. The concentration is generally performed in long, lead brick-lined pans, heated by top heat, the fuel gases being in direct contact with the sulphuric acid. This process is used to a considerable extent, but from the large quantity of sulphuric acid to be concentrated per ton of bleaching powder, a very material addition is made to the cost of manufacture.

Chlorine produced from hydrochloric acid and air by other contact substances. Many such substances have been the objects of proposals, some of which are inseparable from the manufacture of chlorine from metallic chlorides, that is, from HCl in the nascent state. A general investigation on the mutual action of HCl and O in the presence of certain metallic compounds (of Cu, Fe, Mn, and Cr) has been made by Lamy (Bull. Soc. chim. 1873, 20, 2). We must refer to the original, and will only mention that copper salts were found to be much more efficient than others, and that with these the decomposition is at its maximum at about 440° .

The proposals to employ ferric chloride (Thibierge, 1855, and others) or chromic oxide (Hargreaves and Robinson, 1872) have not had any practical success.

Nickel oxide has been proposed by L. Mond (Eng. Pat. 8308, 1886). He passes HCl over heated NiO, when the chlorine combines with the base. The product is then in the same apparatus exposed to dried and heated air, whereby NiO is reformed and Cl is given off. In order to increase the active surface, pumice stone is impregnated with the chloride, and after drying the mass is exposed to the action of the gases in cylinders made of earthenware or enamelled iron. The gaseous HCl and air being previously heated, the retorts do not require very much additional heat from without, and therefore can be made of a large diameter. It is claimed for this process that it converts the HCl completely into chlorine, and that impure HCl, which is unfit for the Deacon process, is here quite suitable.

De Wilde and Reyhler proposed (Eng. Pat. 17272 and 17659, 1889) to employ a mixture of magnesium and manganese chlorides with magnesium sulphate. The reaction takes place in two stages.

The process is not, as far as is known, actually worked.

Chlorine from the residual liquors of the Ammonia-Soda process. The principal, at present the only, reason why the ammonia-soda process has not superseded the Leblanc process, is the fact that the chlorine of NaCl in the former

process goes to waste in the form of CaCl_2 . Very numerous processes have been proposed and tried to avoid this loss by preparing HCl or free Cl from the liquors of the ammonia-soda process.

None of the processes proposed is, as far as is known, being worked or appears likely to be worked: we therefore confine ourselves to giving a list of the leading patents taken out.

1. *Chlorine from ammonium chloride.*—The most persistent efforts for the direct manufacture of chlorine from NH_4Cl were made by Mond, who took out the English patents: Nos. 65, 66, 1049, 3238, 8308, of 1886; 10955 and 17273 of 1887; 2160 and 2575 of 1889. Articles dealing with the Mond process are found in J. Soc. Chem. Ind. 1892, 466; 1893, 10; and 1893, 63.

There was also a proposition from the Verein Chemische Fabriken of Mainz (Eng. Pat. 3322 of 1886).

2. *Chlorine from CaCl_2 .*—Persistent efforts for the direct recovery of the chlorine in the CaCl_2 produced in the ammonia stills of the ammonia-soda process were made by Solvay: Patents 77 and 171 of 1877; 838 of 1880; 7253 and 7259 of 1884; 8724 of 1885; 13389 of 1886; 18574 of 1888. Other patents: Twynam's process (Eng. Pat. 731 of 1885); Bramley's process (Eng. Pat. 8289 of 1887); Lyte and Steinhart (Eng. Pat. 21225 of 1890).

Chlorine from magnesium chloride.—Many efforts were made by Weldon to produce chlorine direct from MgCl_2 ; his patents are: Eng. Pat. 565 of 1868; 967, 968, of 1881; Weldon and Péchiney, 9305, 11035, of 1884; 14653, 14654, of 1887.

Detailed description of the Weldon-Péchiney experimental plant at Salindre, is given by Dewar (J. Soc. Chem. Ind. 1887, 775).

Other patents are: Wilson (Eng. Pat. 3098 of 1885); Gamble (Eng. Pat. 11581 of 1888); Lyte and Tatters (Eng. Pat. 17217 of 1889); Schlösing (Eng. Pat. 11821 of 1887; 11469, 11470 of 1891). (See also Eschellmann, J. Soc. Chem. Ind. 1889, 2; comp. *ibid.* 100.)

Chlorine produced by passing HCl gas over heated peroxide of iron or manganese is the subject of a patent by H. Burns (No. 15448 of 1886).

Chlorine by permanganates has been the object of patents by Tilghman (1847), Condy (1866), Tessié du Motay (1871 and 1873).

Chlorine from chromates and HCl has been proposed by MacDougal and Rawson (1848), Peligot (Ann. Chim. Phys. [2] 411, 267), Gentele (1861), Shanks (1858), Claus (1867), Aubertin (1873).

Chlorine by heating metallic chlorides with MnO_2 and H_2SO_4 was patented by Binks in 1853.

Chlorine by the assistance of nitric acid or nitrates.—Baggs and Simpson (1864) proposed making chlorine from *aqua regia*. Dunlop (1847) patented the preparation of chlorine along with nitrous acid, by heating together common salt, sodium nitrate, and sulphuric acid; the nitrous acid is absorbed by vitriol and the chlorine is passed on to bleaching-powder chambers. This process was working for many

years at St. Rollox; it was patented again by Roberts and Dale in 1868; and a patent running on similar lines is that of J. Taylor (No. 13025 of 1884).

Other processes employing nitrate or nitric acid, which have not had any practical success, are those of Banks (1839), Tessié du Motay (Bull. Soc. chim. 22, 48), Schlösing (Compt. rend. 55, 284). The later patents are those of Donald, Eng. Pat. 62 of 1887; and Just, Eng. Pat. 14857 and 14859 of 1888; Davis, Eng. Pat. 6416, 6698, and 6831 of 1890; Wallis, Eng. Pat. 13822 of 1892; and Krause, Eng. Pat. 16227 of 1894.

None of these processes was apparently a technical success, and as far as is known, none of them is worked.

The electrolysis of metallic chlorides. Recent years have seen a large development of electrolytic processes for the decomposition of metallic chlorides, chiefly those of sodium and potassium into chlorine and alkali. It was observed as early as 1800 by Cruikshank that on electrolyzing a solution of common salt, caustic soda was formed at the negative pole. Berzelius, Hisinger, and Davy all worked on the same subject, but a long time elapsed before their observations were utilised in actual manufacture.

The difficulties experienced in the electrolytic decomposition of alkaline chlorides on a manufacturing scale have been first the cost of the electric current, and secondly the difficulty of preventing recombination of the chlorine liberated at the positive electrode or anode with the caustic alkali produced round the negative electrode or cathode.

The various electrical processes suggested or tried for the decomposition of alkaline chlorides are all attempts to overcome economically this difficulty of the recombination of the products of electrolysis.

Theoretically a current of 1 ampere liberates in 1 hour 1.3236 grams of chlorine.

The number of patents taken out since the year 1885 in connection with electrolytic cells for the production of chlorine, is enormous, embodying every variety of shape, design, and method of work. We shall only deal with a few representative samples, illustrating the broad classes of design which have, up to the present, been used industrially on a large scale.

The cells may be roughly divided into four classes.

I. The cells in which the electrolyte consists of the fused salt.

II. The cells in which the electrolyte is a salt solution, and in which the cathode and anode are separated by a porous partition or diaphragm.

III. The cells in which the electrolyte is a salt solution, but in which a moving mercury cathode is used to remove the sodium produced from the action of the chlorine.

IV. The cells in which the electrolyte is a salt solution, and which depend on sp.gr. to keep apart the alkali and chlorine produced.

Class I. The Cell with the Fused Electrolyte.—The best known examples of this cell are the Vautin and the Acker cell.

The Vautin cell (Eng. Pat. 13568 of 1893 and

9878 of 1894) electrolysed fused NaCl or KCl, with or without the addition of fluorides or other chlorides to lower the point of fusion, over a cathode of molten lead or tin with which the sodium or potassium formed an alloy. (See paper by Vautin, J. Soc. Chem. Ind. 1894, 448.)

The Acker cell is designed on the same principle as the Vautin cell and makes use of the lead cathode (see Eng. Pat. 6636 and 6637 of 1898).

Below is a sketch (Fig. 9) of the Aker cell,

FIG. 9.

taken from a paper by J. B. Kershaw in *Electrician*, Oct. 25, 1901.

The bottom of the cell P is trough-shaped and of cast iron. It serves as electrical connection between the main conductor and the mass of fused lead L resting on it. The upper part of the cell Q is constructed of any refractory basic material not attacked by chlorine gas or fused salt. The anode C is of carbon and dips into the fused salt.

The channels and subsidiary vessel R are arrangements designed to remove and decompose the lead alloy as it becomes sufficiently saturated with sodium. The decomposition of the alloy is effected by blowing steam into it, and the heat generated by the conversion of the sodium into hydroxide is returned to the cell and assists in maintaining the necessary temperature.

The voltage actually taken by the Acker cell is 6.75, and the current efficiency 54 p.c. (Report of Commission on Science and Arts, J. Franklin Inst. 1903, 156).

The Acker cell was worked at Niagara Falls on an industrial scale, from about 1900 to 1907, when the works were completely burned down and have not been rebuilt.

Class II. The Porous Diaphragm Cells.—The best known of the diaphragm cells is the Griesheim cell, which has been used on a very large scale for some years in Germany, and also in Spain, France, and Russia.

Figs. 10, 11, and 12 represent the Griesheim cell. A is the anode cell; K, the cathode cell; C, the carbon anodes; M, a steam-jacket; Z, the salt charging pipe; L, the chlorine exit pipe; B, sheet-iron plates acting as cathodes.

Six to twelve cells are usually worked in series. Each cell contains one or more anodes which are fastened to the cover. The bath which forms

FIG. 10.

the cathode compartment is provided with a gauge glass and a run-off tap for the caustic lye formed, while the hydrogen evolved passes away by a pipe to a gas holder.

The porous diaphragm invented by Breuer

FIG. 11.

(D. R. P. 30222 of 1884) is made by mixing cement, common salt, and hydrochloric acid into a paste and casting into any shaped articles required. The porous diaphragms which form the wall of the anode compartment are set in iron frames like windows, and are cemented in. The whole interior surface of the cell is also covered with cement.

A great improvement was made in this cell by the substitution, for the carbon anodes, of anodes made of iron oxide, produced by melting Fe_2O_3 in the electric arc and casting the Fe_3O_4 produced into plates. The advantages of the iron-oxide anodes are that first the formation of CO_2 from the oxidation of a carbon anode is avoided, and chlorine free from CO_2 is produced; and secondly, that the oxygen, which with the carbon anode forms CO_2 with the oxide of iron anode, forms the alkaline chlorate, which can be recovered as a valuable by-product. (For further information, see paper by Lepsius,

FIG. 12.

Ber. 1909, 2892, from which the above is abstracted.)

The Hargreaves - Bird Cell.—The following illustration shows the Hargreaves-Bird cell (Eng. Pat. 18871 of 1892; 5197 and 18173 of 1893).

The peculiarity of this cell is that the porous diaphragm and cathode are in one, and are made in the following way.

A layer of porous material, such as asbestos in the form of pulp, is plastered on to one side of a sheet of iron netting. On to the outside of the fibrous material is then deposited a layer of Portland cement. In some cases the fibrous material is omitted. The wire netting acts as cathode.

As is shown in Fig. 13, the cell consists of an

FIG. 13.

outer trough in which is placed the inner vessel, formed by the porous diaphragm. The cathode or the wire netting is, of course, on the outside.

The inner or anode compartment is filled with brine; the outer cathode compartment is empty, but the wire gauze is continually washed with either steam or a water spray to remove the alkali as it is formed. The cell is usually worked with an atmosphere of CO_2 in the cathode compartment, and thus produces chlorine and carbonate of soda. When attempts are made to produce caustic soda by this cell, the current efficiency falls most seriously through conduction of current by the NaOH on the cathode.

A paper on this cell, by Hargreaves (J. Soc. Chem. Ind. 1895), states the current density as 18.7 amperes per square foot; the E.M.F. as 3.4 volts per cell; the current efficiency as 80.3 p.c. The present working is understood to give a current efficiency of about 90 p.c., and to require 4 volts per cell.

The Townsend cell (Eng. Pat. 18403 of 1904) resembles the Hargreaves-Bird cell with this difference, that the cathode compartment is filled with kerosene oil which washes the alkali as it is formed off the cathode, and thus makes it possible to produce chlorine and caustic soda in this type of cell without great loss of current efficiency. Kershaw (Electrician, April 24, 1908) gives the current efficiency as 90 p.c., and the voltage per cell as 4.7.

The Finley cell (Eng. Pat. 1716 of 1906) is a

remarkable cell, in that it has a double diaphragm dividing the anode and cathode compartments. The diaphragm is very open in texture, and the brine feed for the cell is run into the centre compartment between the two diaphragms, from where it passes outwards on either side to the anode and cathode compartments. In this way, an additional obstacle, depending for its strength on the speed of feed of the brine, is interposed to prevent intermixture of the products of the electrolysis.

Class III. The cells which depend for the separation of the soda from the chlorine on a *moving cathode of mercury*.

The mercury cathode for the preparation of alkali metals was first used by Davy; it was described in an application for a patent (Eng. Pat. 4349 of 1882) by Nolf. It is mentioned again in Hermite's patent, 3957 of 1886. Further patents describing its use are Hermite and Dubose, Eng. Pat. 21959 of 1891; Greenwood, Eng. Pat. 5999 of 1891.

The general principle of these cells is that the electrolysis takes place between an anode above and a cathode of mercury vertically below. The chlorine liberated naturally rises upwards and out of the solution, and the sodium or potassium freed combines with the mercury to form an amalgam. The amalgam, when sufficiently highly saturated with the alkaline metal, is replaced by fresh mercury and the amalgam itself decomposed by water, with the liberation of H and the formation of a caustic alkaline solution.

The various patents taken out and cells suggested differ chiefly in the method adopted for the movement of the mercury.

To Castner, however, belongs the chief credit of making the mercury cell technically successful. Castner (Eng. Pat. No. 16046 of 1892) employs a moving mass of mercury, connecting up the anode and cathode chamber. Patent No. 10584 of 1893 makes this process continuous by moving the mercury by a rocking motion of the cell, see Fig. 14, which represents the original rocking cell.

Castner also claims sodium amalgam as

FIG. 14.

alternate anode and cathode, the utilisation of electric energy produced by decomposition of the amalgam and the passing of different quantities of current through the NaCl and NaOH .

A is the cell itself divided into three compartments, the back end being adjustable by the knife edges B. The front end of the cell rests on an eccentric, C, revolving on a shaft; this gives the rocking motion. The two outer or anode compartments have carbon anodes and are filled with saturated brine; the centre compartment contains iron cathodes and is filled with

NaOH solution. A layer of mercury, about $\frac{1}{8}$ inch thick, lies on the bottom of the cell and alternately flows from first one and then the other anode compartment into the cathode compartment. The chlorine liberated in the anode compartment is carried away by pipe *p*.

Castner, in the *Chemical Trade Journal*, 1894, 211, stated that the results of 1 week's work on a unit of 28 working cells, arranged in two parallel series of 14, gave a yield of 930 lbs. chlorine and 1120 lbs. NaOH per 24 hours; the amperes used averaging 571, and the volts 55.1 or 3.9 per cell.

More recent mercury cells are the

1. *Kellner pressure-displacement cell*, which differs from the Castner in the point that the

FIG. 15.

chlorine compartment is placed in the centre of the cell surrounded by the caustic compartment, which is provided on either side with a recess, *DD*, which forms the alternative receptacle for the mercury. The mercury is forced to move continuously from side to side by compressed air.

Above (Fig. 15) is a sketch which shows the construction and working of the cell, taken from the *Chemiker Zeitung*, Oct. 30, 1909.

The anodes are platinum gauze, and are placed in a cement box which has proved more satisfactory than the stoneware jars formerly used.

The anodes, including the platinum fastener, weigh 1 gram apiece. Each cell contains six electrode boxes, and each box holds 88 pieces of platinum gauze, 2×2 inches square, weighing in all about 525 grams. The cathodes are cast iron, cast in grill shape. The current used is 4000 amperes per cell.

The great advantage of this cell is the high-current density which has resulted in considerable reduction of plant.

2. *The Kellner-Solvay Scoop Wheel Cell*.—This cell consists of two slanting troughs communicating with one another, in which the mercury is kept in constant circulation by a rotating scooped wheel. This cell is built in very large units, taking up to 10,000 amperes, and it is

FIG. 16.

said that a 15,000-ampere cell is well within the bounds of possibility.

Fig. 16 is a sketch of the Kellner-Solvay cell, *b* being the mercury inlet and *D* the outlet for the amalgam; the scooped wheel is, however, not shown.

Another cell depending for the mercury circulation on a revolving scooped wheel is the Whiting cell, shown in Fig. 17.

3. *The new Castner-Kellner cell* differs from the Kellner-Solvay cell in the method of conveyance of the mercury, which, in this case, is effected by means of an Archimedian screw. Taussig, before the International Congress of Applied Chemistry, 1909, states that carbon anodes have been abandoned and anodes of platinum gauze substituted.

The current efficiency of the modern mercury cell is stated to be not less than 90 p.c., and the voltage required 4.3 volts.

Professor Lepsius (*Ber., loc. cit.*) enumerates the following advantages and disadvantages of the mercury cell as compared with the diaphragm cell:—

The advantages of the mercury cell are: (1) the purity of the caustic alkali produced, which is a very important advantage; (2) the comparatively high concentration of the caustic solution; (3) the high current efficiency and absence of evolution of oxygen.

The disadvantages of the mercury cell are:—

FIG. 17.

(1) the higher voltage, 4.3 volts as against 3.5 volts in the diaphragm cell; (2) the cost of the mercury, of which 72 tons are required for a plant utilising 6000 h.p.; (3) the greater cost of installation apart from the question of the mercury.

IV. *The Specific Gravity Cell*.—The best known cell of this type is the so-called 'Glocken Cell,' patented by the Oesterreichischer Verein für Chemische und Metallurgische Produkte, and working on a large scale at Aussig, Berlin, and Staffurt.

Fig. 18 shows the original type of the 'Glocken' or Bell cell, in which *A* is the anode and *K* the cathode, separated by the non-conducting bell *D*, *E*. The bath *w* is filled with salt solution, which enters at *L* and overflows at *F*. The chlorine escapes at *c*. Figs. 19, 20, 21 show the improved cell actually in use.

Owing to the fact that, when working, the

liquor round the anode is of lower sp.gr. than that round the cathode, at the bottom of the cell, little intermixture occurs, and owing to the

FIG. 18.

feed of fresh brine at L, a constant slow movement of the electrolyte downwards takes place.

The disadvantage of this cell, according to Lepsius, is its small size; for instance, at Aussig,

3000 h.p. are utilised and 25,000 cells required.

The voltage required lies between the Griesheim and the mercury cell, viz. 4 volts.

FIG. 19.

(For further detail, see Lepsius, Ber. loc. cit., from which paper the above is largely abstracted.)

Liquid Chlorine.—Chlorine gas can be con-

FIG. 20.

densed to a liquid at atmospheric pressure at -34° , or at atmospheric temperature (15°) by a pressure of six atmospheres. Vautin (Eng. Pat. 8820 of 1887), Heinzerling (D. R. P. 49280),

FIG. 21.

Hannay (D. R. P. 49742) describe suggestions for manufacture of liquid chlorine.

The pioneers in the manufacture have been, however, the Badische Anilin und Soda Fabrik, who (Eng. Pat. 13070 of 1888) describe two ap-

paratus (Figs. 22 and 23) for the compression of chlorine.

In Fig. 22, A, B is a U-tube of which the limb B and the lower part of A are filled with strong sulphuric acid. The upper part of A is filled with liquid paraffin, which floats on the acid. The limb B is first filled with chlorine by shutting valve C and opening valves D and E. When full, D and E are shut, C is opened, and the paraffin is forced into A by the pump. During

FIG. 22.

compression, limb B is heated by a water-bath to 50° – 80° , in order to prevent liquefaction of the chlorine there.

The gaseous chlorine under pressure is forced through the cooling coil G, from which it runs as a liquid into the receiver H. The operation is then repeated.

Fig. 23 represents an apparatus working on the same principle as that of Fig. 22, but differing in detail.

The plunger A works in paraffin, with which the upper part of the vessel B is filled. The lower part of B and its continuation C and D are filled with strong vitriol, through which the pressure produced by the plunger A is transmitted to the cylinder D. The chlorine enters by F, and is condensed and collected after leaving the cylinder D, as in Fig. 22.

As in Fig. 22, the compressed chlorine has to be kept warm in the compression vessel, and this is done by the water-jacket G.

Marx (Eng. Pat. 7058 of 1890) proposes to make the liquid chlorine direct by the decomposition pressure of chlorine hydrate. As far

FIG. 23.

as is known, this ingenious process has not been worked.

Chlorine, when dry, does not attack iron, and the liquid chlorine is safely carried and stored in iron and steel cylinders, tested to a pressure of 50 atmospheres.

Chloride of lime or bleaching powder. By far the greater part of the chlorine produced on a manufacturing scale is converted into *chloride of lime or bleaching powder*. Otherwise most of the hydrochloric acid produced in the process of decomposing common salt by sulphuric acid would be wasted; that portion of it which would be required by those preparing chlorine for bleaching purposes, &c., would cost any consumer not in the immediate neighbourhood of the works much more than the finished chloride of lime does now.

The first to suggest the industrial application of chlorine to bleaching was Berthollet, in 1785, and in 1789 was produced the liquor called 'Eau de Javel,' manufactured by passing chlorine into a solution of potash. This for the first time enabled the bleacher to buy his chlorine in an available form, but it was too dear for most purposes, and so was the kindred liquor made from soda. Both, especially the latter, have still some application in special cases, but their part is very small in comparison with that played by the analogous compound, manufactured with the cheapest of all bases, lime. The use of this was first suggested by Charles Tennant, in 1798, and this was all the more important as the alkalis were at that time enormously dearer than they are at present. At first Tennant used milk of lime, and thus obtained the solution known under the name of 'bleach liquor,' and extensively manufactured even now. In 1799 he took out his patent for absorbing chlorine by dry hydrate of lime, and the compound thus formed, 'bleaching powder,' was sold by the St. Rollox Works, established in the same year, at 140*l.* per ton.

Composition of Bleaching Powder.—The union of chlorine and lime seems to take place in a very direct way, and the composition and many of the properties of the new substance formed also seemed to favour the assumption that it was merely a compound of CaO and Cl₂; the name 'chloride of lime' was given to it on this assumption. Long before our present theories made it unlikely that CaO could combine as such with chlorine, Balard, in 1835, propounded the theory that bleaching powder was a compound or mixture of equivalent proportions of calcium hypochlorite and chloride

mixed with an excess of calcium hydroxide.

This theory, supported by Gay-Lussac in 1842, in point of fact explains nearly all the properties of bleaching powder. A more recent formula to represent bleaching powder, $\text{Ca} \begin{matrix} \text{Cl} \\ \text{OCl} \end{matrix}$ was suggested by Odling, and by Lunge, Schäppi and Naef, who showed that CaCl₂ as such does not form part of dry bleaching powder, but is only formed on solution in water, and also that the excess of lime always found can be reduced to so small a quantity that none of the theories formerly advanced in order to explain the

constant presence of such excess of lime can be upheld.

All these formulae, however, leave out of account the water of hydration present in the lime before chlorination, which is not expelled, and which is absolutely necessary for the formation of the bleaching powder.

Preparation of Lime for Bleaching Powder.—The lime required for the manufacture of bleaching powder must be from as pure a limestone as possible and must be well burned. Among the most suitable limes for bleaching powder is that used in Lancashire, and made by burning the Derbyshire limestone in the district round Buxton. The average composition of this limestone is:

CaCO ₃	98.9
MgCO ₃	0.29
Fe ₂ O ₃	0.17
Insol. etc.	0.35
H ₂ O	0.05
		99.76

The burnt lime is slaked by spreading it on a brick floor, sprinkling it with water and turning it over with a spade till it has completely fallen to powder, after which it is allowed to remain in a heap for 10 hours.

The slaked lime is then passed through a wire sieve of 12–18 wires to the lineal inch.

Mechanical lime-slaking apparatus is largely used, in which the burnt lime is treated with water in a closed vessel with continuous agitation. The mechanical apparatus has the advantage of producing a very uniform product in a much shorter time with less labour and a comparative absence of dust, which with the hand slaking is very trying to the workers.

The slaked lime as used for bleaching-powder manufacture contains about 25 p.c. H₂O, and should not contain more than 2.5 p.c. CaCO₃.

The Bleaching-powder Chambers.—The apparatus in which the chlorine is brought into contact with the slaked lime varies with the concentration of the chlorine gas to be treated.

With highly concentrated chlorine gas, such as that obtained from the Weldon stills, where the gases contain 85–90 p.c. Cl, simple chambers or boxes of large size are used, on the floor of which is spread a layer of lime.

The chambers or 'boxes' were formerly often made of tarred wood, masonry, or stone flags. For the ordinary strong chlorine gas, these have been in England universally replaced by large chambers of about 6½ feet in height, so that a man can work inside them, of a width of from 10 to 20 feet and more, and up to 100 feet long. Their sides and top are usually made of about 5- or 6-lb. sheet lead, fastened by straps on a timber framework, exactly like vitriol chambers.

The floor is made of large stone flags, or of coal-tar asphalt, the joint between the sides and the edge of the floor being specially protected by a skirting and asphalt poured behind it.

The chambers must be fitted with doors (generally made of iron protected by paint), with glass panes in two opposite doors for observing the colour of the gas, with 'lutes' for introducing the gas, and with some contrivance for removing the gas remaining at the end of the operation (*v. infra*).

Sometimes the chambers are not erected on the ground-level, but upon pillars, like vitriol chambers, leaving about 10 feet of clear space from the ground. In this case the packing of the finished bleach into casks can be done by means of trap-doors in the chamber floor, with wooden hoppers attached underneath, below which the casks are placed, the bleach being pushed down into them from above by means of wooden rakes.

Sometimes several chambers are combined to form sets, so that the gas always enters first into a nearly finished chamber, and the excess gas into a freshly charged chamber, where it is entirely taken up.

Jahne (Dingl. poly. J. 283, 287; J. Soc. Chem. Ind. 1887, 367) gives a number of observations made with a set of four chambers connected in this way.

Many proposals have been made for mechanical absorbing apparatus for strong chlorine, but none of them seems to have met with permanent success; sometimes the working parts are worn out after a short time, and sometimes the bleach produced in them is too weak. Of course, it cannot be said that the construction of a mechanical chlorine absorber for dry lime is an impossibility, but it must be difficult to construct unless a perfectly regular stream of chlorine gas is at command, and efficient means are employed for artificially removing the heat given off during the absorption.

The manufacture of the bleaching powder in the chambers takes place in this way. The hydrated lime is spread upon the floor in a layer of 4 to 6 inches in depth; its surface is drilled into furrows by means of a wooden tooth-rake, to assist absorption. All joints are plastered up with lime putty, and the gas is admitted, leaving at first an airhole open, which is only closed when chlorine issues from it. The gas is at first very quickly absorbed, as may be seen by its colour when looking through the glass panes, afterwards much more slowly. If there is not sufficient care taken to keep it free from acid and moisture, lumps are formed which are very injurious.

When the lime will not absorb the chlorine as fast as it enters the chamber, this is left to itself for 12 hours, or, better still, for 24 hours, after which time the chlorine will nearly always have been absorbed.

It is difficult to get full-strength bleach by one operation; there is always a superficial crust which prevents the gas from penetrating right through. It is, therefore, necessary to turn the stuff over with spades, and treat again with chlorine. Sometimes this must be done even a third time, before the appearance of the product, and the laboratory test show it to be finished. It ought then to consist of pretty heavy flakes, easily crushed, but not dusty, which can be kneaded with the fingers into a tough paste. The laboratory test of a sample carefully taken from various parts of the chamber ought to be at least 37 p.c. available chlorine. With impure, badly burnt, badly slaked, or badly sifted lime, with moist chlorine or such as contains carbon dioxide, no strong bleach can be expected, and when trying to force this by 'gassing' too much, it will be found that the strength actually goes back, calcium chlorate and chloride being formed.

As it is indispensable to employ an excess of chlorine in order to finish the bleach, there must be always a great quantity of unabsorbed gas in the chamber at the end, and if no special precautions are taken in this respect, the opening of the doors will cause an intolerable nuisance. This ought to be prevented in any case. It can be done by drawing the gas out of the chamber, either by chimney draught or by mechanical means, and making it to pass through a milk-of-lime or even through a hydrate-of-lime absorber.

Probably the best means for this end is the plan patented by Brock and Minton (Eng. Pat. 7199, 1886; comp. 23rd Report on Alkali, &c., Works, 58-60), who, before opening the door, sprinkle lime into it by means of a wooden hopper and fan fixed in the roof, in such quantity that the free chlorine is entirely absorbed without bringing down the strength of the chamber below the required point. There is thus also an additional yield of bleach. Lime in fine powder is put into the hopper fixed in the roof of the chamber, and is admitted into the latter by means of a valve. A vertical shaft, inside a box between the hopper and the valve, is made to turn by a handwheel, and, being armed with blades, forms a fan or distributor, which draws air from the chamber, mixes it with the descending lime, and causes this to pervade every part of the chamber. One such machine is sufficient for a chamber of 100 feet length, but generally three are provided. This treatment reduces the amount of chlorine in the chamber air to less than 1 grain per cubic foot (0.82 on the average), without materially reducing the strength of the bleach. For a chamber of 10 tons bleach, finished with a considerable excess of chlorine, 4-5 cwts. of lime dust are thrown in, which produce 6 cwts. of bleach. It requires an hour or two to settle, but the whole of the operation is complete in 3 hours. The doors can then be taken down without any strong smell being perceptible within a few feet of the chamber, and packing can at once be proceeded with. The extra bleach produced much more than pays for the treatment.

For testing the amount of chlorine in the air of bleaching-powder chambers previous to opening the doors, several kinds of apparatus have been proposed: e.g. that of Ballard (21st Report on Alkali, &c., Works, 37; 22nd do. 55) and of Stark (J. Soc. Chem. Ind. 1885, 311). Ballard's apparatus consists of a cylindrical glass jar, closed at the top by an indiarubber cork, through which the nozzle of a 4-oz. enema ball (finger pump) passes, as well as an elbow tube reaching down to the bottom. The lower end of this tube is closed at the lamp, so as to leave an opening fine enough for a needle only to pass through. The horizontal branch of this tube is inserted in the side of the chamber at a point about 2 feet from the bottom. When compressing the ball, the air is driven out by a small hole made in the nozzle just above the cork; this is now closed by the finger, and on relaxing the pressure the ball will expand, and will cause 4-oz. measures—that is, $\frac{1}{3}$, of a cubic foot—of chamber air to enter into the jar and bubble through the test solution contained therein. This is continued till the end of the reaction is indicated by the test liquor turning blue. The latter consists of 3.485 grains of

arsenious acid, dissolved in sodium carbonate and rendered neutral by sulphuric acid, to which is added 250 grains potassium iodide, 50 grains precipitated chalk, 10,000 grains water, 6-10 drops ammonia. For each test 400 grains are used, adding a little starch paste at the time of using. When $2\frac{1}{2}$ grains of chlorine per cubic foot are present in the chamber air, ten aspirations of the chlorometer will cause a blue colour to appear; if more aspirations are needed, there is less chlorine present, and *vice versa*. Stark's apparatus attains the same end, not by the finger pump (which is certainly a somewhat rough instrument), but by a gas burette on the Orsat principle.

The following rules are recommended by the Chief Inspector of Alkali, &c., Works (Mr. A. E. Fletcher), in his 21st Report, 12:—

I. Bleaching-powder chambers should contain not less than 200 square feet of floor space for every ton of powder made in them per week. If there is less space, the work, and especially the packing, must be hurried too much.

II. The chambers should be so arranged and

connected together that the residual chlorine from a finished chamber may be drawn into one containing fresh lime, unless some other means be employed for absorbing it (such as Brock and Minton's plan described above). The air finally discharged into the atmosphere or into a flue or chimney must not contain more chlorine than $2\frac{1}{2}$ grains per cubic foot.

III. No chamber should be opened when the air in it contains more than $2\frac{1}{2}$ grains of chlorine per cubic foot. In testing for this, the air should be drawn from a point not more than 2 feet above the chamber floor, and taken from the draught end.

IV. No chamber may be opened until the air in it has been tested, and the result of such test entered in a book.

V. No chamber may be opened except in daylight.

The control of the temperature in the bleaching-powder chambers is very important, as the absorption of chlorine by hydrated lime to form strong bleaching powder takes place within comparatively narrow limits of temperature.

FIG. 24.

FIG. 25.

In the hot weather of an English summer difficulty is often experienced through overheating, and in cold winter weather, especially in chambers in an exposed situation, and when working slowly, the absorption is so slowed down that strong bleach cannot be made.

The absorption of weak chlorine, that is, chlorine diluted with very much nitrogen and oxygen, as it is obtained in the Deacon process, and in most of the processes proposed for dealing with calcium and magnesium chlorides, cannot be carried out in the ordinary chambers. The most efficient plant for this purpose seems to be that worked out by Deacon himself. The absorbing-space is immensely increased, and at the same time the process is made a continuous operation by employing a large number of chambers, each of them provided with a number of shelves, and connecting them in such a way that the fresh chlorine gas always enters the chamber in which the bleach is nearly finished, and the last gas, then containing only traces of chlorine, is passed through a chamber just charged with fresh lime. These chambers cannot very well be made of any other material than of stone,

slate, sandstone flags, volcanic lava, &c. The distributing pipes are of cast iron. The chambers are arranged in pairs, the gas being made to pass down the one half and up the other half of the pair.

Practically a set of Deacon chambers consists of seven double chambers with sixteen shelves each, with a total area of 1250 square feet, upon which $18\frac{1}{2}$ cwts. of calcium hydroxide can be laid $\frac{1}{2}$ inch to 1 inch thick. Every 16 hours one of the pairs of chambers comes in turn to be drawn and recharged. Hurter has shown that such chambers would not be applicable to strong chlorine, as then the temperature would rise to 70° or 80° , but in the present case the inert gases, of which there are about 90 p.c. present, prevent the temperature rising to any hurtful extent.

Figs. 24 and 25 show a front elevation and a sectional elevation of these chambers.

The gas enters from pipe A into the top of the first chamber, and travels down over the shelves in it, as is shown by the arrows in Fig. 25. From the bottom of chamber 1 the gases pass into the bottom of chamber 2, thence upwards over the shelves as in chamber 1.

A block of such chambers containing 14 chambers, each with 16 shelves, will produce 25-30 tons of bleaching powder per week.

Before starting to lime the chambers, the cover B is removed, and the wooden slides C are pushed on one side, with the exception of that on the bottom shelf. Sufficient lime to cover one shelf with a layer nearly 1 inch thick is then dropped through the hole from which B has been removed, and falls down to the bottom shelf. There it is spread and then raked into furrows by rakes through the ends of the chamber from which the sheet-iron doors shown on Fig. 24 have been taken down. When this is done, the slide C on the bottom shelf but one is pushed over the hole and the lime charge for that shelf dropped and levelled as before. The rest of the shelves are then limed similarly one by one.

The finished bleaching powder is packed in a similar way by first pushing on one side the slides C, and then pushing the bleaching powder,

made on the separate shelves, to the centre of the chamber, where it falls through the holes down to the cask below.

Hasenclever (Eng. Pat. 17012 of 1888) describes a mechanical chamber for the production of bleaching powder, which has been at work successfully with weak chlorine such as the Deacon chlorine, for many years.

Figs. 26 and 27 show the Hasenclever mechanical chamber, which consists of several superposed tubes, into the top one of which the lime is fed, and through the series of which it is caused to travel by the agitators, finally dropping into a hopper which delivers into the cask.

The chlorine gas travels in the opposite direction to the lime, and enters the bottom cylinder.

The yield of bleaching powder may be taken as $1\frac{1}{2}$ times the weight of the calcium hydroxide.

Bleaching powder must be packed in very well-made casks, preferably made of hard wood.

FIG. 26.

FIG. 27.

The onds are sometimes secured by a coat of plaster of Paris. This is done in order to prevent the access of air, which quickly deteriorates the powder both by its moisture and its carbonic acid.

The packages must be kept in cool, dry places; both rain and sun would quickly spoil the bleaching powder, even if packed in good casks.

Properties of Bleaching Powder. — Good bleaching powder is a pure white powder, often mixed with lumps which, however, ought to be transformed to the corc, and which are often removed by riddling. It has a peculiar smell, quite different from that of chlorine, and not owing to hypochlorous acid, since it is just as perceptible in alkaline solutions, or on the skin after washing with soap, &c. It may possibly be due to the action of the compound upon organic matter.

In the air bleaching powder attracts moisture and carbonic acid, and gradually changes

into a pasty mass. Mixed with a little water, it forms a stiff paste, with a perceptible swelling and rise of temperature; this is probably caused by the transformation of 2CaOCl_2 into $\text{Ca}(\text{OCl})_2$ and CaCl_2 .

Bleaching powder decomposes gradually even in closely stoppered bottles or well-protected casks. The presence of light, heat, moisture, and carbonic acid greatly accelerates this change; so does shaking, *e.g.* in transit. Hence the strength of bleach is usually only guaranteed at the place of shipment, but it ought not to lose above 2 or at most 3 p.c. by a few weeks' journey.

Experiments on the rate at which bleaching powder loses its available chlorine have been made by J. Pattinson, in 1874 (*Chem. News*, 29, 143) and 1886 (*J. Soc. Chem. Ind.* 587). He experimented in the first case with samples kept in loosely corked bottles, sheltered from direct sunlight, and found that these lost on an

average 0.33 p.c. monthly from February to April, 0.86 from June to September, 0.28 from November to January. The greatest loss occurred in August, viz. 1.4 p.c. per month.

The keeping properties of bleaching powder depend on the quality of the lime used, on the temperature conditions under which it has been made, and on its strength. The more free calcium hydroxide is left in the bleaching powder, the more stable it is. This shows that, when bleaching powder is required for export, especially to tropical countries, it is a mistake to require a high initial test.

The experiments made by Lunge and Landolt (J. Soc. Dyers and Colorists, 1885, Nov. 25), with bleach liquor have also shown that the action of the air is nothing like so injurious to the stability of such solutions as that of the light, which ought to be excluded by all means. Solutions kept in the dark in closed vessels, remained practically unchanged up to the 24th day, and

up to the 33rd day, when the experiment was finished, the strength had only decreased from 29.58 to 29.12. Kept in open vessels in the dark, they remained unaltered up to the 12th day; on the 33rd day they had lost 3.30. But when kept in closed vessels in diffused daylight, the decomposition set in at once, and on the 33rd day only 8.52 remained of 33.02 originally present. Solutions of chloride of magnesia behaved similarly to those of chloride of lime; those of zinc or aluminium hypochlorite, as might be expected, were much less stable.

A few experiments made by Thümmel (Arch. Pharm. 1834, 22, 1) also prove that light has much more action on bleaching powder than exposure to air.

The following complete analyses of the samples of bleaching powder investigated by J. Pattinson (*v. supra*) may serve as an example of the best descriptions of the commercial article:—

—	A made of Irish limestone (from Larne)	B made of Irish limestone by another manufacturer	C made of French cliff
Available chlorine	37.00	38.30	36.00
Chlorine as chloride	0.35	0.59	0.32
Chlorine as chlorate	0.25	0.08	0.26
Lime	44.49	43.34	44.66
Magnesia	0.40	0.31	0.43
Ferric oxide	0.05	0.04	0.02
Alumina	0.43	0.41	0.33
Oxide of manganese	trace	trace	trace
Carbonic acid	0.18	0.30	0.48
Silicious matter	0.40	0.30	0.50
Water and loss	16.45	16.33	17.00
	<hr/>	<hr/>	<hr/>
	100.00	100.00	100.00
	<hr/>	<hr/>	<hr/>
Total chlorine	37.60	38.97	36.58

The following are analyses of bleaching powder made by Lunge and Schäppi, from perfectly pure lime and with the greatest care, so as to obtain the strongest possible product:—

Available chlorine	43.13
Chlorine as chloride	0.29
Lime	39.89
CO ₂	0.42
H ₂ O (direct estimation)	17.00

Calculated as:

CaOCl ₂ + H ₂ O	88.08
CaCO ₃	9.96
CaCl ₂	0.45
Ca(OH) ₂	6.74
H ₂ O not combined	3.77
	<hr/>
	100.00

The small quantity of unchanged calcium hydroxide is proof for the opinion that this is merely lime mechanically protected against the action of chlorine by the bleaching compound CaOCl₂ previously formed.

The germicidal power of bleaching-powder solution is very great, and it has been used successfully for years as a disinfectant. One part of bleaching powder will, in 2-4 hours, destroy the following bacteria: coli, typhosus, and cholera in 2000 parts of ordinary sewage.

(See Schumacher, in *Gesundheit-Ingenieur* of Munich and Berlin, August 10, 19, 30, 1905; Sheridan Delépine, in *Medical Chronicle*, May, 1894; and G. C. Clayton, in *J. Soc. Chem. Ind.* 1896, 320.)

Calcium hypochlorite. The *Chemische Fabrik Griesheim Elektron* (D. R. P. 188524, 1906) describes the production of calcium hypochlorite as follows:—

Chlorine is introduced continuously with agitation into milk of lime until the latter is nearly saturated. The solution is then concentrated *in vacuo* until the calcium hydrochlorite crystallises out and can be dried *in vacuo*. The calcium hypochlorite obtained is said to be more stable than ordinary bleaching powder, gives a clear solution in water, and contains 80-90 p.c. available chlorine.

Liquid chloride of lime or Bleach liquor. Formerly many bleachers used to make their chloride of lime by passing chlorine gas into or over milk of lime. This is now done at such alkali works as are conveniently near bleach works, so that the cost of carriage of bleach liquor is not considerable.

On a laboratory scale the chlorine would be passed into the milk of lime. On the large scale this cannot be conveniently done, and is replaced by bringing the chlorine into contact with a

continually renewed surface of the absorbent. This might be done in towers on the principle of acid-condensers, but there are some drawbacks to this, and the general plan is to employ cast-iron vessels provided with mechanical agitators so constructed that the liquid is not merely circulating round and round, but that its surface is continually renewed. In most cases these are cylinders standing on their bases, with a vertical agitating shaft and horizontal arms; horizontal agitating gear is much more efficient, but is more troublesome, owing to the necessity of passing the axle through stuffing boxes in the sides of the vessel. Even with the ordinary upright cylinders, the absorption of chlorine is quite complete if three or more vessels are used in succession, so long as the agitator is at work, but the absorption ceases almost the moment the agitation ceases, from one cause or another.

In making bleach liquor, the agitators are charged with a milk containing about 1 to 1½ lbs. of slaked lime per gallon of water. The chlorine must not be evolved too fast, because this causes too great a rise of temperature. The rule is not to exceed 32°, or at most 37°; over this point the hypochlorite is very quickly changed into chlorate (cf. *Potassium chlorate*). It is very desirable that the absorbers should be surrounded by a cold-water jacket, to avoid that contingency. When the sp.gr. has risen to 1.040, the operation is stopped by turning the gas on to the next agitators; the first vessel, after the charge has been run off, and it has been refilled with fresh milk of lime, will now be the last of the series.

Well-finished bleach liquor contains a very small quantity of free lime, generally with a slight excess of CaCl_2 or of $\text{Ca}(\text{ClO}_3)_2$. The bulk of the chlorine is present as $\text{Ca}(\text{OCl})_2 + \text{CaCl}_2$.

The bleach liquor used, however, by bleachers is made, of course, in most cases by the solution of bleaching powder in water. This operation is quite simple, but to avoid at the same time a loss of available chlorine and a waste of time in settling out the excess free lime, CaCO_3 , and insoluble matter, certain conditions have to be observed.

The conditions are that the temperature of solution should not be too low, and the agitation given too prolonged. A certain amount of agitation is necessary to avoid loss, but afterwards further agitation breaks up the aggregates of insoluble matter and delays the settling.

The following rules for making bleaching-powder solution have been found to work well in practice:—

1. The best practical temperature for the water is 21° to 26°.

2. The bleaching powder should be emptied into the agitating tank through a 1-inch mesh sieve, any lumps being knocked through with the flat of a spade.

3. The agitation should be performed so as to show a strong swirl on the surface, say, with a peripheral speed on the agitator of 500 feet per minute for tanks of 5 feet to 9 feet diameter, and the lower limbs of the agitator should be not more than 1 inch from the bottom of the tank.

After completing the volume of the bath, thorough agitation for 20 minutes is ample for all strengths of solution up to 16°Tw. Further time spent on agitation is wasted, and, by beat-

ing the bleaching powder, renders subsequent settling appreciably slower.

4. The run-off pipe should be at such a height as to allow 5 cubic feet of sludge per cwt. of bleaching powder used per batch, for all strengths of solution up to 16°Tw. Unless a sufficient space is allowed, enormous waste of time will arise in waiting for the last few inches to settle clear.

5. The sludge consists, not of bleaching powder, but of insoluble lime suspended in bleach solution. When the clear liquor has been run off, the agitating tank should be filled again with water, and the contents agitated for 5 minutes only prior to settling.

When the precautions given above are followed, the loss of bleaching powder in the washed sludge will not exceed 2 lbs. per cwt. of bleaching powder used, provided the last clear liquor is not more than 2°Tw.

Hypochlorite of potash (*Chloride of potash* or *Eau de Javel*). This liquor was first made in 1789 at the Javel Works near Paris, and was the first bleaching compound known. It was then made by passing chlorine into a solution of potashes (crude potassium carbonate) in eight parts of water. This liquor is rarely made at the present time, as it has been replaced by the cheaper soda compound, which has now mostly usurped its name.

Hypochlorite of soda (*Eau de Labarraque*, usually called *Eau de Javel*). This liquor can be made by passing chlorine into a solution of sodium carbonate in 10 parts of water till the liquid begins to effervesce and bleaches litmus. In that case it contains more or less free hypochlorous acid, according to the equations:

The liquors containing free HOCl keep very badly, the HOCl partly volatilising and partly losing its oxygen.

Hypochlorite of soda solution is used to-day as a bleaching agent for the bleaching of special fabrics, in steam laundries to whiten clothes, and as a disinfectant.

For this purpose it is prepared either:

1. By the precipitation of a solution of bleaching powder by sulphate or carbonate of soda, when a solution is obtained containing about 5 p.c. of available chlorine, but no free HClO, and which will, therefore, keep unchanged for some time. This operation is usually conducted at the factory or the place where the solution is used.

2. By passing chlorine into a solution of caustic soda until nearly all the soda is chlorinated.

This solution is made commercially, and sold at a strength of 10–15 p.c. available chlorine.

It has been found necessary to leave a small amount of free soda, about ¼ p.c. Na_2O , in order to make the solution stable, and also to remove traces of iron which is converted into sodium ferrate, and aids the decomposition by carrying oxygen from the hypochlorite to the atmosphere. A very full statement on the manufacture and stability of sodium hypochlorite solution made in this way is contained in a paper by Muspratt and Smith (*J. Soc. Chem. Ind.* 1898, 1096).

3. By electrolysis of brine solution. Under chlorine we have discussed the electrolytic cells devised to liberate chlorine from common salt, and pointed out that the difficulties in designing an economic cell have been increased by the necessity for keeping separate the chlorine and soda produced. In this case no such necessity exists, and the chlorine is allowed to recombine at once with the soda produced, thus avoiding porous diaphragms and mercury cathodes, and decreasing the energy required by the energy of combination of chlorine and NaOH.

The following cells have been introduced (see papers by W. H. Walker in *Electro-Chemical Industry*, 1, 439):—

The Kellner cell consists of a stoneware vessel divided into a number of small compartments by glass plates fitting into small grooves in its sides. These glass plates are wound with platinum-iridium wire, and form bipolar electrodes. The electrolyte is circulated rapidly through the cell and through a cooling coil.

The Schuckert cell is a large stoneware trough, separated into 8–10 compartments. In these compartments are bipolar electrodes in the making of which platinum-iridium wire may or may not be used. Circulation is effected by means of the hydrogen evolved, and each cell has a cooling coil.

The Haas-Oettel cell consists of a rectangular box divided into small compartments by a series of vertical bipolar carbon electrodes set in grooves.

From the figures given by Walker, the k.w.h. per ton available chlorine produced in solution can be calculated, and are given in the following table for the Kellner and Schuckert cells. The Haas and Oettel figure is taken from a paper by Reuss before the Society of Dyers and Colorists, Feb. 1911:—

Name of cell	Details of a standard-sized cell		K.W.H. per ton available Chlorine
	Amps.	Volts	
Kellner	120	110	8800
Schuckert	100	110	8500
Haas and Oettel	80	110	8400

These cells are adapted for the production of weak solutions only of hypochlorite of soda containing 1–2 p.c. available chlorine, as only a partial decomposition of the NaCl is possible without an enormous fall in efficiency. The cost of salt is, therefore, high, and actually about 7 tons of salt are required per ton of available chlorine produced.

Cells such as these are designed for the purpose of erection at the factory or works where the hypochlorite solution is used, usually with the object of displacing bleaching powder.

The figures given above for two items of cost alone (*i.e.* for power and salt) clearly indicate the reason why these ingenious pieces of apparatus have not attained a more extended use.

Hypochlorite of soda solution as a disinfectant. Hypochlorite of soda solution possesses strong germicidal powers, which Klein estimates for a solution containing 10 p.c. by weight of available chlorine at 21 times that of phenol. (See Klein,

Comparative Bacteriological Report on Chloros, Public Health Engineer, June 9, 1906. Also for further data, see Schumacher, *Gesundheit-Ingenieur* of Berlin and Munich, Aug. 10, 19, 30, 1905; Clayton, *J. Soc. Chem. Ind.* 1896, 320.)

Solid sodium hypochlorite. Until recently sodium hypochlorite in the solid form was unknown. Muspratt and Smith, in 1898, however, by the systematic production of a more and more concentrated solution, produced crystals of the following composition (*J. Soc. Chem. Ind.* 1898, 1100):—

NaOCl	37.6 p.c.
NaClO ₃	nil
NaCl	3.7 „
Water (by diff.)	58.7 „
	100.0

The crystals dissolve in their water of crystallisation at 18°–21°, and then rapidly decompose. By drying under vacuum part of the water of crystallisation is removed, and a more stable product obtained containing up to 60 p.c. of available chlorine with a melting-point of over 43° (see Muspratt, *J. Soc. Chem. Ind.* 1903, 592).

Bleach liquors containing magnesia, zinc, or alumina, all of them obtained by adding the sulphates of these bases to a solution of bleaching powder, are sometimes used for special purposes because they have a more rapid action than chloride of lime. Their properties have been fully investigated by Lunge and Landolt in the above-mentioned memoir. They are never manufactured for sale, but prepared by the users themselves.

Potassium chlorate. This salt is always manufactured by the process first indicated by Liebig; *i.e.* saturating milk of lime with chlorine under such conditions that calcium chlorate is formed, and afterwards decomposed by potassium chloride. For lime sometimes magnesia is substituted (*v. infra*). The reactions are:

Hence only one-sixth part of the chlorine employed is, even by theory, converted into chlorate.

The first reaction is the formation of calcium hypochlorite and chloride, that is, ordinary bleach liquor; thus:

Under certain conditions the calcium hypochlorite is subsequently changed into a mixture of chlorate and chloride:

There is, however, a concurrent change, which must be avoided, as it involves a great loss, namely, the splitting up of hypochlorites into chloride and oxygen:

The conditions under which these changes occur, which were, of course, known in a general way before, have been exactly investigated by Lunge and Landolt (*J. Soc. Chem. Ind.* 1885, 722). They operated with a strong bleach liquor, composed according to the above equation (3). When gradually heated by itself up to 60° for 3 hours, this showed no perceptible change. Chlorate begins to be formed by

equation (4); when heated another hour to 70°, more so when heated another 2 hours to 90°; but even after 2 hours' full boiling (altogether 7 hours' heating), not much above $\frac{1}{2}$ of the available chlorine originally present has been employed for the production of chlorate, according to equation (4). Oxygen begins to be given off from the first, and in the end the reaction (5) prevails over (4). Hence the conversion of hypochlorite into chlorate by mere heating is a very unfavourable process.

A second way of converting hypochlorite into chlorate consists in saturating the solution with chlorine. This even at 15° causes 70 p.c. of the $\text{Ca}(\text{OCl})_2$ to pass into chlorate. On gradually heating the solution, the reaction is quickened as soon as the temperature exceeds 40°, and it is complete at the boiling-point. Hence the presence of an excess of chlorine is a preventative against the reaction (5).

Most probably the excess of chlorine acts as follows:—

That is, the free chlorine acts only as a carrier of oxygen from two molecules of calcium hypochlorite upon a third; the first two are reduced to chloride, the third is oxidised to chlorate, and the free chlorine is fully regenerated in the end. The conclusions to be drawn for practice from Lunge and Landolt's experiments are as follows: The complete conversion of hypochlorite into chlorate is not effected either by mere heating or by a mere excess of chlorine, but both must act at the same time. A very large excess of chlorine is useless, perhaps even injurious. On the large scale the heat generated by the reaction suffices to complete the process.

Practically, chlorate of potash is manufactured in the following way.¹ Milk of lime is exposed to the action of chlorine in vessels provided with agitating gear, so that new surfaces are continually offered to the action of the gas, which in this case is quickly absorbed, and completely so if the gas partially taken up in the first vessels is ultimately brought into contact with fresh lime contained in the last vessel. Formerly the absorbing vessels were made of stone, in an octagonal shape, and hence were called 'octagons,' which name is sometimes even now used for the cylindrical cast-iron vessels which have universally displaced the real stone octagons. Such cylinders (shown in Fig. 28) are e.g. 10 feet wide and 5 feet 6 inches high, provided with a central vertical shaft *a* and agitating arms *b*, so contrived that they cause the liquid to well up and continually bring new portions of it to the surface. The shaft passes through an opening in the cover so constructed as to form a water-lute *c*, and a cup *d*, fastened on the shaft and dipping in the lute, prevents the escape of the gas round the shaft. Similar 6-inch lutes, *e, e*, serve for introducing and taking away the gas. There is also a manhole *f*, fitted with a cast-iron sleeve reaching 6 or 7 inches downwards, and forming a water-lute when the cylinder is filled. Apart from this the manhole is always open, so that observations can

be made at any time, samples drawn, and hydrate of lime put in. Sometimes a water-jacket is applied outside. Three or (better) more cylinders form a set working together, so that the fresh

FIG. 28.

gas can be always turned upon that cylinder which is nearly finished, whilst the cylinder charged with fresh lime receives the last gas. From the last cylinder there should be pipes leading to a small box charged with hydrate of lime, in case of any accident happening to the agitating machinery, when the absorption of chlorine in the cylinders would very soon cease. In lieu of this, a column charged with milk of lime can serve as well.

The milk of lime must be prepared in such a way that the finished liquor becomes of a certain strength, which is, however, not the same at all works. The sp.gr. of the milk of lime itself should not exceed 16° or 17°Tw.; that of the finished liquor, 28° to 32°Tw. Some manufacturers go as far as 40°Tw.

The reaction causes an elevation of temperature, which up to a certain extent is useful; but it must not be allowed to get too high, because in this case oxygen is evolved, and there is a corresponding loss of chlorate. In no case can the theoretical proportion of 1 chlorate to 5 chloride be attained, as on the large scale, it appears impossible to entirely avoid some evolution of oxygen; but with good work the proportion can be kept at 1:5.3.

As the reaction proceeds, froth appears on the surface and the liquid becomes warm. In the first agitator the temperature should be from 65° to 70°; if it gets hotter, water-cooling is resorted to, or else the gas is cut off for a while. Afterwards the liquid turns pink, and the froth mostly vanishes again. The operation may be considered as finished when a sample taken out settles quickly and completely, leaving little sediment, smells of chlorine, and bleaches litmus paper. On adding hydrochloric acid *in the cold*, it should not give off chlorine (as hypochlorite would do). The pink colour is caused by calcium permanganate. The operation lasts from less than 24 hours to as long as 3 days, depending on the speed at which the chlorine is passed into the octagons.

The contents of each agitating vessel, as they are finished, are run into settlers provided with drop-siphons, and thence into special measuring tanks, from which the liquor is run into the concentrating vessels. In the measuring tank

¹ According to Dr. E. K. Muspratt (J. Soc. Chem. Ind. 1886, 408), this manufacture was commenced at St. Helens in 1847.

the volume and test are carefully noted to enable the quantity of potassium chloride (technically called muriate of potash) to be accurately calculated. The potassium chloride should be of the strongest kind (95 p.c.), and a small excess of it should be used. Some add it to the agitating vessels, under the (probably mistaken) idea that KClO_3 decomposes less easily than $\text{Ca}(\text{ClO}_3)_2$. Usually it is only added in the concentrating pans.

The mud left in the settlers is, of course, washed or filter pressed; the washings can be used for making fresh milk of lime.

The liquor as it runs away from the settlers still smells of chlorine. This is a nuisance, and it also acts upon the vessels, but the addition of a small quantity of a reducing agent like sodium thiosulphate, or even tank waste, entirely destroys the free chlorine.

The boiling-down pans are usually made of either wrought or cast iron, and are heated by direct fire. Since wrought-iron pans are not liable to crack, and are more easily repaired when partly worn out, they would seem preferable.

The boiling down is continued up to 70°Tw. (measured hot), in which case the mother liquors after crystallisation are not worth working up.

There is always a great deal of mud found in the pans, partly from incomplete settling, &c., partly formed by the action of the liquor on the metal. This mud must be removed by settling or by a filtering drum before running the liquor into the coolers.

The coolers for the first salts are generally made of iron, since in no case can a pure product be obtained at this stage. They are best made like those used for soda crystals, with a plughole for running off the mother liquor. They ought to be numerous enough to permit of the liquor remaining in them 9 or 10 days in winter and 14 days in summer. Here the crude chlorate of potash crystallises in long acicular crystals, totally unlike the thin plates in which the same salt crystallises when pure, but in reality possessing exactly the same faces, only developed in different fashion. They are easily distinguishable from the large transparent prisms of hydrated calcium chloride which appear if the concentration has been too great. They must be broken up after draining, and the adhering mother liquor washed off with a little water, and finally drained in a hydro extractor.

The mother liquor is a nearly saturated solution of CaCl_2 , with a little KCl , and with about 30 grams of KClO_3 per litre. With bad work much more chlorate is left in the liquor. In the very best case 10–12 p.c. of all chlorate manufactured is lost through this cause, usually much more (25–30 p.c.). Usually it is not even attempted to recover the chlorine from these liquors by heating with hydrochloric acid—they are simply run to waste. But, with due care, the mother liquors can be quite well worked for chlorine by taking care to run the hydrochloric acid in *pari passu* with the liquor. Strictly speaking, it is not the chlorine of the chlorate which is recovered in this way, but chlorine produced by oxidation of the HCl added.

Wylde, Hammill, and Auer (Eng. Pat. 15097) describe a process for the recovery of

about half the chlorate left in the mother liquor by refrigeration. The process is described in detail by Hammill (J. Soc. Chem. Ind. 1889, 168), who states that the crude crystals obtained by refrigeration have a finer grain than the ordinary crude crystals, but when thrown down from mother liquors of not over 72°Tw., are no more impure, and are as readily refined by one recrystallisation. Hammill says that on cooling to -12° only 13.5 grams KClO_3 per litre remain in the liquors. This process has now been worked successfully for many years.

The great loss of chlorate in the ordinary process has given rise to the process of Muspratt and Eschellmann, where magnesia is substituted for lime (Eng. Pat. 3960, 5183, and 5186 of 1883; and 1900 of 1885). A detailed description of this process has been given by Higgins (J. Soc. Chem. Ind. 1887, 248). The magnesia is obtained by burning Greek magnesite at not too high a temperature; when overburnt it is useless for the absorption of chlorine. The MgO is very finely ground, suspended in water, and exposed to the action of chlorine in the ordinary octagons. The reaction is not so violent as with lime. The temperature of a finished octagon is usually 43°, and it never exceeds 60°. In the finished liquor the proportion of chlorate to chloride is very near to the theoretical, viz. 1:5.1 or less; this constitutes an important advantage over the lime process, 7 p.c. less chloride being formed. No pink colour appears with very pure magnesia, but it does when it contains manganese. The strength of this liquor varies from 1.17 to 1.22.

The octagon liquor is now boiled down to 75°–80°Tw., when on cooling about 50 p.c. of the chloride will crystallise out as $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$. The mother liquor contains 1 mol. chlorate to 2.8 chloride. Potassium chloride is now added to it in slight excess, and the potassium chlorate crystallised out. The mother liquors being much less in quantity than with lime, and KClO_3 being less soluble in MgCl_2 than in CaCl_2 , the magnesia mother liquors contain much less chlorate than lime liquor (on an average 19 grams down to 10 grams per litre), and the yield of KClO_3 rises to 90 p.c. of the total.

The mother liquor is treated with HCl to destroy the chlorate, with due precautions against explosions. The still liquor is now neutralised with MgO ; a solution of kieserite (MgSO_4) is then run in to decompose the calcium chloride present, and the gypsum, along with iron oxide, is settled out. The liquor is now concentrated in cast-iron pots (wrought iron is acted upon too much); the iron dissolving in the liquor is oxidised to the ferric state, and is precipitated by MgO ; the settled liquor is run into barrels, where it sets to a hard mass containing 47 p.c. of MgCl_2 . This magnesium chloride is sold to cotton sizars.

This process would, of course, only become general if the magnesium chloride obtained as a by-product could be profitably decomposed for chlorine, as it is not saleable by itself in very large quantities, and could not compete in price with the Stassfurt article.

Such utilisation for the manufacture of chlorine had been intended by Weldon, who first proposed magnesia for the above purpose, and it is again mentioned in a patent of J. Wilson

(5975 of 1884). Twynam (4397 of 1881) proposes dolomite, under the idea that double chloride of potassium and magnesium (carnallite) will crystallise out of the mother liquor after the chlorate. (This seems quite hopeless, since the principal question is not that of saving KCl, but KClO_3 .)

Another process for greatly reducing the loss of chlorate in the mother liquors is that of Péchiney (*cf.* Weldon, J. Soc. Chem. Ind. 1882, 41). He concentrates ordinary chlorate liquor made from lime of a density of 25°Baumé , up to 48°B . (hot), and cools it down to at least 12°C ., but not below 10°C . Of its 5.5 mols. of CaCl_2 , 4.3 are thus caused to crystallise out as $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ (probably it should be $6\text{H}_2\text{O}$), but if the temperature were allowed to fall below 10° , calcium chlorate would crystallise as well. The crystals are separated by a hydro extractor, and the mother liquor is treated with the calculated quantity of KCl,¹ there being only 1.2 CaCl_2 present to 1 KClO_3 , the mother liquors cause a very much smaller loss than in the ordinary process. Péchiney's process is specially suited, and was originally invented, for the manufacture of sodium chlorate (*cf. infra*). It is evidently only possible to work it in the cold season.

The crude chlorate of potash is always purified by recrystallisation ('finished'). For this purpose it is redissolved in a mixture of water and of the mother liquor obtained in the finishing process, which is done in a lead-lined vessel, with the aid of steam, preferably indirect steam. The solution is made at a full boiling heat, sometimes with the addition of very small quantity of sodium carbonate and of sodium sulphide, in order to precipitate any iron and lead present; it is made up to 25°Tw ., and, after good settling and straining through canvas, the liquor is run into the coolers. These are made of wood, or preferably iron lined with lead; they are either of a deep pattern, with wooden laths placed inside for the crystals to adhere to, or else they are made quite shallow, but covered over to prevent any too rapid cooling. The crystallisation lasts from 8 to 14 days, according to the season.

The crystals are drained, washed on the drainer, and then again drained in a hydro extractor. This is imperative, since it is required that chlorate of potash should show little or no trace of chlorides; 0.05 p.c. being a maximum sometimes stipulated. So long as there is PbCl_2 present, this cannot be very easily effected, but the lead can be removed in dissolving, as stated before. The mother liquors and washings are used over again till they become too impure, when they go back to the boiling-down pans. The crystals are dried on a hollow iron plate, covered with sheet lead, and heated by steam.

Chlorate of potash is either sold as 'crystals' or 'ground.' For the former purpose the crystals, as they come from the drying plates, are sifted through a sieve with eight holes to the linear inch, or less, as the case may be. The powder is best ground while still slightly warm. The mills may be of any description, horizontal, edge runners, rollers; but the chlorate during

grinding ought not to come into contact with iron, nor with any organic substances (straw, wood chips, &c.), or dangerous explosions may occur. It must be sifted through a revolving sieve, made of miller's gauze, with mechanical brushes. The powder ought to be snow-white, and without any grittiness, like fine flour. The crystals ought to be in thin, brilliant transparent plates; excessive drying will make them opaque. Both are usually packed in 1-cwt. kegs, laid out with blue paper.

Formerly it was generally assumed that 1 part of chlorate of potash required 7 or 8 times as much chlorine as 1 part of bleaching powder, but with the new processes the yield is, of course, better than that. There is, however, even now a manufacturing loss of about 30 p.c. or at least 25 p.c. One ton of chlorate in the ordinary process requires, if the mother liquors are utilised for producing chlorine, about 30 tons of hydrochloric acid of 30°Tw ., if the mother liquors are not so used, about 40 tons of acid will be used. This refers to Weldon chlorine; by combining the Deacon and Weldon process, and utilising the mother liquors as before, the consumption of acid ought not to exceed 22 tons. One ton of chlorate requires, moreover, 17-18 cwt. of 90 to 95 p.c. muriate of potash.

Chlorate of potash is principally employed for the manufacture of lucifer matches, for pyrotechnical purposes, for fuses, for some descriptions of gunpowder, and other cases where it is a constituent of explosive materials. It is also largely employed, on account of its oxidising properties, in dyeing and calico printing, in the manufacture of alizarin, &c.

Sodium chlorate. This compound, which formerly was only a chemical curiosity, has become of technical importance, since it was found that it is much more suitable for the preparation of aniline black than potassium chlorate, owing to its greater solubility.

At first when a demand for it sprang up, it was made from potassium chlorate by means of hydrofluosilicic acid (*cf.* Lunge's Alkali, 3, 320), and was sold at two or three times the price of the potassium salt. It was at that time thought that it could not be prepared from the calcium-chlorate liquor of the ordinary process, because NaClO_3 is very soluble, and cannot be separated from CaCl_2 by crystallisation. But this difficulty can be avoided, as we shall see.

The process of Bottomley and Molesworth (Pat. 3005 of 1881) consists in treating a hot saturated solution of potassium chlorate with one of bitartrate of soda, and separating the precipitated potassium bitartrate from the solution of sodium chlorate.

The real manufacture of chlorate of soda by a cheap process was first carried out by Péchiney, by means of his process of removing most of the calcium chloride from the crude liquor by crystallisation. The purified liquor thus accumulated during the colder part of the year is mixed with a solution of ordinary sodium sulphate, previously neutralised by lime. The operation is carried out in this way. An excess of solution of Na_2SO_4 is added to the chlorate liquor with continuous agitation; then more chlorate liquor is gradually run in, till the Na_2SO_4 has been completely converted into CaSO_4 . The CaSO_4 , which, under the

¹ The intermediate formation of a calcium oxychloride, described in Péchiney's patents and Weldon's paper, has since been given up.

proper conditions, is crystalline, is then separated from the liquor by filtration and washed in a hydro extractor. The solution of sodium chlorate is now concentrated by evaporation, during which most of the sodium chloride separates in the solid form and is fished out. The remaining solution on cooling yields crystals of sodium chlorate, which are purified by recrystallisation. After which the second crystals are washed. The mother liquor always goes back into the process. The purified salt contains no more than 0.16 p.c. NaCl. Nearly all the chlorate contained in the liquor is really obtained by this process, instead of the unavoidable loss occurring with chlorate of potash.

Chlorate of soda is also manufactured by the Muspratt Chlorate Process by means of their magnesium chlorate liquor, freed from nearly half the MgCl₂ by evaporation and crystallisation (*cf. supra*). To this liquor sodium carbonate is added, till all the magnesia is precipitated as a basic carbonate (magnesia alba), in order to be used over again in the process. The remaining solution of NaClO₃ and NaCl is concentrated by evaporation, with fishing out the NaCl, and after attaining 120° Tw., is allowed to cool down; the sodium chlorate crystallises out, and is purified in the usual manner.

Manufacture of alkaline chlorates by electrolysis. The passing of an electric current through a solution of NaCl or KCl liberates Na or K at the cathode, and Cl at the anode. The Na or K at once decomposes H₂O to form NaOH or KOH and hydrogen gas. If the electrolyte is heated from 45° to 100°, the Cl liberated is absorbed in the caustic alkali produced to form chlorate.

Theoretically, a current of 1 ampere will produce in 1 hour 0.7627 gram KClO₃, or 0.663 gram NaClO₃.

Gall and Montlaur, in their Eng. Pat. 4686 of 1887, describe the production of alkaline chlorates by the electrolysis of alkaline chlorides in a trough divided into two parts by a porous diaphragm.

The anodes are platinum-iridium sheets containing 10 p.c. of iridium; the cathodes are iron, though it is stated that nickel would be preferable.

The electrolyte consists of a 25-p.c. solution of KCl, kept at a temperature of about 80°. The liquor from the cathode compartment containing the alkaline hydrate there produced, is circulated through the anode compartment and combines with the chlorine liberated.

A current density of 50 amperes per square decimeter is used, and a pressure of 4.5 to 5.0 volts is required. In the case of potassium chlorate, the anode liquor is run into crystallising vessels, where the KClO₃ crystallises out, and the mother liquor, after saturation with KCl, is passed back to the cathode compartment. In the case of sodium chlorate the anode liquor has first to be concentrated to crystallise out the NaCl before crystallising out the NaClO₃.

The crystals obtained require, of course, to be refined by recrystallisation, as in the case of those produced by chemical processes.

Hurter (Eng. Pat. 15396 of 1893) electrolyses KCl in a metal vessel which acts as cathode, and which has on its inner side a coating consisting of a mixture of Portland cement, salt and sand, which, after washing out the salt,

yields a porous diaphragm. The anode is a sheet of platinum suspended in the centre of the vessel. Several vessels are superposed and worked in series, being kept apart by insulating rubber rings.

A solution of KCl containing a little caustic alkali is run into the top vessel, from which it overflows, through a glass or ebonite pipe, into the cell below. The hydrogen evolved escapes by pipes from the upper part of each compartment.

Blumenburg (Eng. Pat. 9129 of 1894) describes a cell with a porous diaphragm in which the anode compartment is closed and connected by a pipe with the bottom of the cathode compartment, so that the chlorine liberated at the anode passes into the liquor in the cathode compartment, and there combines with the caustic alkali produced, the temperature being maintained at a temperature of about 49°. In the Ger. Pat. 89035, and also in the U.S. Pat. 537179, Blumenburg passes the chlorine gases from the anode compartment into a gas holder, from which they pass to a separate combining vessel, where they are absorbed in the alkaline liquor from the cathode compartment. Chlorate is also formed as a by-product in the Griesheim cell described above, when using the oxide of iron anode.

In 1899 Imhoff made a great advance in the electrolytic production of chlorate by his discovery of the action of small quantities of chromate of potash or soda in the electrolyte (U.S. Pat. 627063 of 1899).

The action of the chromate is to prevent the reduction of hypochlorite and chlorate by the nascent hydrogen evolved at the cathode, and has resulted in a very marked and important improvement in the current efficiency.

The electrolytic manufacture of chlorates from chlorides was to commence with a simpler operation than the electrolytic production of caustic alkali and bleaching powder, owing to the fact that the products of the electrolysis do not require to be kept separate; and this fact, combined with the discovery of the use of alkaline chromates, caused the electrolytic chlorate industry to be successfully established some years before caustic soda and bleaching powder were economically manufactured electrically.

HYDROCHLORIC ACID.

Commercial hydrochloric acid is a more or less pure solution of hydrogen chloride HCl in water.

Hydrogen chloride is a colourless gas, of sp.-gr. 1.2596 (air=1), and molecular weight 36.457. By weight it consists of 2.74 parts of hydrogen and 97.26 parts of chlorine. It can be condensed into a liquid by cold and pressure; the tension of this liquid is 26.2 atmospheres at 0° and 40 atmospheres at 12.5°.

The heat of formation of a gram-molecule of HCl is 22001 cal.

Hydrogen chloride has a great affinity for water, and is greedily absorbed by it. The solution is the ordinary hydrochloric acid which, when somewhat concentrated, emits fumes of HCl on exposure to the air. The following table by H. Deicke shows the maximum solubility of HCl in water at varying temperatures. 1 c.c. dissolves at the temperature t° :—

t°	Vols. HCl at 0° and 760 mm. dissolved in 1 vol. H ₂ O	Specific gravity of the saturated solution	Percentage of HCl by weight in the solution
0°C.	525.2	1.2257	45.148
4	494.7	1.2265	44.361

The behaviour of aqueous solutions of HCl under varying conditions of temperature and pressure has been principally studied by Roscoe and Dittmar (Chem. Soc. Trans. 12, 128). We shall mention here only the fact that concentrated hydrochloric acid on heating loses both gas and water, and gradually becomes weaker, until a sp.gr. of 1.101 and a percentage of 20.24 HCl is attained at a boiling temperature of 110°; the acid in this state distils without change, provided the atmospheric pressure is 760 mm. At a lower pressure the acid distilling unchanged is stronger, at a higher pressure it is weaker. A similar, but not identical limit is attained when strong acid is exposed to the air at ordinary temperatures.

The following table gives the percentages of HCl in aqueous hydrochloric acid at various specific gravities and at a temperature of 15°:—

Deg. Twaddell	Spec. gravity	Percentage of HCl	Grams HCl per litre	1 cubic foot weighs lbs.	1 cubic foot contains lbs. of HCl
1	1.005	1.12	11.32	62.66	0.70
2	1.010	2.12	21.45	62.97	1.34
3	1.015	3.12	31.67	63.29	1.97
4	1.020	4.11	41.99	63.60	2.61

THE MANUFACTURE OF HYDROCHLORIC ACID.

Practically all commercial hydrochloric acid is, and has been for a long period, produced by the decomposition of common salt in the manufacture of sodium sulphate or salt cake.

Owing to difficulties of transport in former days, small quantities of acid were produced locally by decomposing common salt with sulphuric acid in cast-iron cylinders.

In order to utilise the more expensive sulphuric acid, an excess of common salt was used. The solid product left in the cylinder consisted of sodium sulphate, mixed with 20-30 p.c. NaCl, and was commercially known as cylinder cake.

The production of hydrochloric acid from cylinders has, however, practically ceased, and the hydrochloric acid of commerce is distributed from centres where salt cake is manufactured, and is delivered to the customers in carboys or tank waggons.

Hydrochloric acid obtained in manufacturing sodium sulphate (salt cake). When salt was first decomposed in order to obtain sodium sulphate for the Leblanc process, the hydrochloric acid evolved during this process possessed no value, and was simply allowed to escape into the air. This continued to be the case even after that manufacture had attained a comparatively large extension, but the damage caused to the neighbourhood by the acid gases soon brought about the intervention of local authorities and courts of law, and manufacturers were compelled to seek means for condensing the acid. This was first successfully done by Gossage's coke towers in 1836, but in the great majority of works there was still a considerable loss of acid gases, as was proved by a Belgian Parliamentary Commission in 1856. But it is decidedly owing to Lord Derby's Alkali Act of 1863 (which has been followed by several other Acts) that British alkali makers were compelled, ultimately for their own good, to adopt thoroughly efficient means for condensing their hydrochloric acid, and this has benefited all other manufacturing countries as well.

In fact, the reports made by the inspectors under the Alkali Acts form an invaluable record of all the various steps taken for improving the condensation of hydrochloric acid, and these reports have helped to spread a better knowledge of that process and to cause manufacturers to improve it up to the highest standard of efficiency.

The Alkali Acts of 1863 made it incumbent upon those decomposing salt to allow no more

than 5 p.c. of the hydrochloric acid to escape into the atmosphere. An additional Act of 1874 prescribed that no more than 0.2 grain of HCl might be present in a cubic foot of the gas escaping from

the factory into the air. This corresponds to 0.454 gram HCl per cubic metre, or about three ten-thousandths by volume. The latter clause applies to the chimney gases as well, and not merely to those escaping directly from the condensing apparatus. Although this requirement was at first declared by many to be impossible of fulfilment, the actual results proved at once that it was quite possible, and the escapes registered by the Alkali Inspectors have averaged far below the limits assigned by the Acts. Thus, in 1885, the average escape of HCl in chimney gases was 0.10 grain per cubic foot, or 2.39 p.c. Of the total amount produced in 1886, the figures were respectively 0.10 grain and 2.13 p.c. of the total hydrochloric acid.

Several further bills have become law since 1874, regulating the escape of other acid gases into the atmosphere, but no change has been made in the limit fixed in 1874 for escapes of HCl, viz. 0.2 grain HCl per cubic foot of chimney gas.

Although the various processes and apparatus used for the manufacture of sulphate of soda produce gases differing within wide limits in temperature and concentration of HCl, an efficient condensation, *i.e.* practically complete absorption of the HCl in water to form a liquid acid of 1.15-1.17 sp.gr. is usually obtained.

The efficiency of the condensation of gaseous HCl in water is dependent on three considerations:

1. Temperature.
2. Concentration of HCl in the gases to be scrubbed.
3. Time of contact.

On issuing from the sulphate of soda plant the acid gases require cooling. The apparatus used for this purpose depends on the temperature of the gases.

If the gases issue from the pot or pan of a handworked salt-cake furnace, the temperature is comparatively low. In this case the cooling is usually done in a row or rows of earthenware pipes. The pipes used are often unglazed, but are rendered impervious to moisture and gas by boiling in tar.

In some cases the earthenware pipes are substituted by glass pipes of 12 inches diameter, made slightly taper, as shown in Fig. 29. The glass pipes are, of course, more liable to breakages by accident, and also through the effect of violent changes of temperature than the earthenware pipes, but in sheltered positions they last well. For the hotter gases issuing from the furnace of an ordinary muffle hand sulphate of soda furnace, or from the cylinders of the Hargreaves process, cast-iron pipes are usually used to cool the gases down to a safe temperature before passing them as before into earthenware or glass pipes.

The action of the hydrochloric acid gases on cast iron, when at a temperature well above condensing-point of liquid acid, is very slight.

When open furnaces, whether 'hand' or

FIG. 29.

'mechanical' (such as the Mactear furnace), are used, the acid gases are mixed with the products of combustion, and are consequently both much hotter and more dilute.

Under these conditions extensive series of cast-iron pipes are used for the preliminary cooling before passing the gases into the earthenware pipes for final cooling.

The earthenware pipes used are usually 12-inch or 15-inch socket pipes, the joints being made with a cement of tar and China clay. The cast-iron pipes vary with the quantity of gas, and the arrangement of the cooling system of pipes from 12 inches to 20 inches; they are also usually socket pipes, the joints being made by ramming into the socket iron filings moistened with ammonium chloride solution.

The arrangement of the cooling pipes depends on the position of the different parts of the plant and the space available. When the salt-cake furnace is a long distance from the condensers, a single direct line of pipes may be not only the cheapest route, but a sufficient means of cooling.

Frequently where the distance is small the pipes are taken vertically up and down so as to obtain the necessary cooling surface. Usually the vertical columns of pipes start from and return to small stone cisterns.

The cisterns are usually made in this country of silicious sandstone found in Yorkshire, and known as 'Yorkshire flag.'

The cisterns are composed of flags 4-6 inches thick, bound together by strong iron ties, and the joints made tight by thick indiarubber cord laid in a groove between the faces of the two stones, or by a mixture of tar and fire clay (see Figs. 31, 32, and 33).

After cooling the gases to a temperature varying in many cases from 25° to 45°, they are brought into contact with water, and scrubbed so as to completely absorb the HCl. The apparatus almost

FIG. 30.

universally used are tall stone towers, packed with broken coke down which a stream of water is allowed to trickle, and up which the gases are caused to flow (Fig. 30).

These towers were invented and patented by Gossage, in 1836.

The coke tower has the merit of simplicity, and, when carefully packed, of efficiency.

The comparative efficiency of various modes of treating liquids with gases has been dealt with in a series of papers by Hurter, who also gives some interesting data on coke-packed towers (J. Soc. Chem. Ind. 1885, 639; 1887, 707; and 1893, 227 and 989).

Coke-towers are erections of stone, rarely of bricks or of acid-proof stoneware, in the shape of perpendicular shafts, mostly (except with pipes) of a square (for very wide towers of an octagonal) section, and of somewhat considerable height, varying from about 40 feet to 60 feet. The sectional area in the case of square stone or brick towers is rarely less than 5×5 feet, or more than 7×7 feet; but they have been made up to 14 feet diameter, of octagonal shape. They are provided with a grating a few feet over the bottom, on which rests the coke which forms the 'packing' of the tower. This coke, which must be of as hard a quality as possible (only the best oven-coke is applicable for this purpose), is disposed in such a way that the gas is as much as possible divided in a large number of channels (none of them being so wide that the bulk of the gas can pass up through it), and that the current of gas is constantly changed in direction. For this object long pieces of coke are laid parallel in a row; the next row is made to cross the lower one, and so forth. The size of the pieces is gradually diminished from bottom to top. In order to avoid an excessive quantity of the gas passing up the side of the condenser along the wall, it is usual to place a layer of finer coke round the condenser for a few inches from the wall. By this arrangement there is effected both a great division and constant mixture of the gases, and at the same time a suitable spreading of the feeding water over a very large surface. The water (or sometimes weak acid) is fed in at the top by some contrivance assuring a uniform distribution over the whole area of the tower; and in dropping down it keeps the irregular surfaces of the coke moist all over, thus presenting a very large area of contact between the gases and the liquid. In consequence of the large area of the tower, and the number of changes of direction the gases have to make while passing through it, they are ultimately deprived of all their soluble parts, consisting principally of hydrochloric acid, and leave the tower in a state fit to be discharged into the atmosphere without any damage to the neighbourhood.

It is, however, necessary that a condenser should fulfil certain conditions, if it is to do its work properly. In the first instance, its size must be proportionate to the work done; if the gases pass too rapidly through it, there will not be time enough to effect a complete washing out of the acids. Everything depends upon the way in which the condenser is packed, on the regularity of work in this pan and furnaces, on the proper regulation of the feed, on the draught, even upon the outward atmospheric conditions, and it is unnecessary to say that nothing like the same amount of condensing space in the shape of coke towers is required if the main work of condensation has been previously done by cooling pipes, cooling towers, and Woulffe's bottles.

Of recent years there has been a growing tendency in England to do away with all cooling

pipes, cisterns, wash towers, &c., and to adopt the system of very large stone towers to do the whole work of condensation for two or even more pots and furnaces.

The condensers are practically always worked two in series, the weak acid from the second condenser or final scrubber being run down the first or strong condenser. In this way complete absorption of the acid is assured, with production of a strong liquid acid, i.e. one of over 1.15 sp.gr. A common practice is to work two condensers in series of about 5×5×50 feet high to condense the acid from two-hand salt-cake furnaces.

No difficulty is now experienced in pumping the weak acid made in the second condenser on to the top of the first condenser, and the following apparatus is used for the purpose:—

Stoneware ram pumps, ebonite ram pumps, stoneware acid eggs, and occasionally even yet the Hazlehurst membrane pump, patented in 1876.

The ascension pipe is usually of stoneware or ebonite, occasionally of lead.

Brick towers are not to be recommended, as it is practically impossible to keep the numerous joints tight against acid oozing out. Columns

FIG. 31.

of stoneware pipes cannot be made of a large area, and, therefore, are not very well adapted to large works, at least if intended for coke

FIG. 32.

sandstone or, in France, volvic lava, just as for acid tanks. The system of joining the flags together is the same as shown in Figs. 31 and

FIG. 33.

together by means of grooves worked in the stone, and without the aid of any ironwork, which is always a source of anxiety in acid condensers.

The coke towers are generally placed at a

FIG. 34.

high level, and are, if necessary, put upon pillars, for the purpose of running the acid from them by gravitation either into chlorine stills, or into store cisterns for sale. They must, of course, have a very secure foundation, in the construction of which not merely the great weight of the tower must be considered, but also the probability that there will be now and then leakages of acid which may soften the ground and make the

foundation unsafe. This can be avoided by asphalted the ground in such a way that any acid running down cannot penetrate into the soil, and is conveyed to a safe distance. Any damage done to the foundation, even if it amounts to much less than would cause the erection to break down altogether, is extremely injurious, because it will almost unavoidably lead to the tower getting out of level, in which case the gases will always tend to rise on the higher side, and the water will principally descend on the lower side; thus the necessary contact is not attained, and the action of the condenser is most injuriously affected.

It has been already stated that the feeding of the condenser with water must take place in such manner as to supply the whole area of it with moisture. This can be done in various ways. The plan formerly considered as most efficient is that of a distributing wheel (shown in Figs. 35 and 36) worked by the pressure of the feed water

corresponds to a solid place in the plates just above and below.

FIG. 35.

itself. This causes the stream of water to reach successively every one of the holes on the top of the condenser, and thus secures a uniform action without depending upon the top of the tower being at a mathematical level. Recently most manufacturers have done away with these acid wheels, and have introduced troughs provided with a number of overflows all at the same level, feeding the same number of 'lutes,' c, c. This arrangement is indicated on Fig. 30, p. 39.

Since 1836 a number of suggestions have been made of apparatus to replace partially or altogether the Gossage coke tower.

These suggestions have, in most cases, been confined to different arrangements of packing the tower so as to expose a larger surface of water to the gas than is exposed by the broken coke. Of these we may mention the Lunge Rohrman plate tower (Figs. 37, 38, and 39).

The Lunge Rohrman plate tower consists of a tower packed with a series of perforated plates E, E, the perforations being made to alternate in successive plates, so that each hole

FIG. 36.

Figs. 38 and 39 show one of the plates in

FIG. 37.

detail. As is to be expected, the evidence for and against the improved packings for the condensing towers is very conflicting, and as the

FIG. 38.

FIG. 39.

cost of them is naturally higher, the coke-packed tower has fully maintained its position.

One great advantage the coke-packed tower has is that, owing to the porous nature of the coke, it always retains a large store of water and liquid acid, usually several hours' supply, which tends to keep the condenser steady under a fluctuating flow of HCl, and to tide over difficulties occasioned by a stoppage or breakdown of the water supply.

In France and Germany a somewhat different system of cooling and condensation is in general use.

The earthenware and glass pipes mentioned above as being used almost exclusively in this country for the final cooling of the gases are, at any rate, partially substituted by a series of earthenware Woulffe's bottles, known technically as *bombonnes* or *touries* (see Fig. 40). A long

row or sometimes two parallel rows are arranged so that the acid gases pass onward from the furnace through the pipes *b, b*, and the liquid acid

FIG. 40.

flows in the opposite direction, entering each receiver through the pipe *c* and overflowing at *d* into the next jar. In passing through the *bombonnes*, the weak acid absorbs a large proportion of the HCl passing over it, and, in spite of the relatively high temperature in the leading

FIG. 41.

bombonne, eventually gives a liquid acid of 1.15-1.18 sp.gr. The size of the *bombonnes* varies from about 50 to 100 gallons, rarely more and rarely less, and the number employed in a set varies from 40 to 100. The jars should be of

the best stoneware, which is able to stand somewhat violent changes of temperature. After leaving the *bombonnes*, the acid gases are finally scrubbed with water in a coke-packed tower or condenser, similar in design but usually

much smaller than those used in this country. The weak liquid acid produced in this tower supplies the stream of weak acid required by the bombonnes.

Fig. 41 shows a whole set of receivers as arranged for the gases from a salt-cake pot and furnace with a small coke tower to give the final scrubbing.

In the condensation of hydrochloric acid gas in water with the apparatus at present used and described above, there is little reason for difficulty in avoiding losses of HCl through incomplete absorption. The difficulty more commonly experienced is to combine the complete absorption enforced by law with a high-strength liquid acid.

The working of the condensing plant. Success depends first on sufficient time of contact for the gases to reach a state of equilibrium with the issuing liquid acid under their actual condition of temperature and gaseous concentration; and secondly, on having the gases sufficiently cooled before coming in contact with the liquid acid to keep down the temperature inside the condenser. The actual temperature admissible depends on the gaseous concentration of the HCl entering the condensing apparatus, but, as mentioned previously, frequently varies between 25° and 45°.

The impurities found in commercial hydrochloric acid are, chiefly, sulphuric acid, ferric chloride, arsenic, and either free chlorine or sulphurous acid. The acid condensed from the pan or pot gas is always much purer than that from the roaster gas. The quantity of sulphuric acid in the gases from the salt-cake furnace sometimes amounts to 2 p.c. and upwards; it is very troublesome in the Weldon, and fatal in the Deacon, chlorine process, and in some other applications of hydrochloric acid. The sulphuric acid in the salt-cake furnace gases can be removed to a large extent by a small condenser or dry scrubber before condensation.

A large number of suggestions have been made for the purification of the salt-cake furnace gases, so as to render them suitable for the Deacon process, but the only one of these processes to achieve practical success is the Hasenclever process (Eng. Pat. 3393 of 1883). (See Deacon Chlorine Process.)

Arsenic gets into the hydrochloric acid through the sulphuric acid employed in its manufacture; the arsenic is thereby converted into $AsCl_3$, and passes as such into the condensing apparatus. Many plans have been proposed for its removal—most frequently a treatment with sulphuretted hydrogen or with sulphides. Bettendorf (Dingl. poly. J. 194, 253) precipitates the arsenic from concentrated hydrochloric acid by stannous chloride, distilling it afterwards. Duflos dilutes the acid to sp.gr. 1.13, and digests it with strips of sheet copper at 30°C. for 24 hours, and repeats this treatment with freshly scoured copper. This removes all the arsenic and the free chlorine, and reduces the ferric chloride to ferrous chloride, which remains behind on distillation. Beckurts (Fischer's Jahresb. 1884, 348) distils hydrochloric acid with ferrous chloride and removes the first 30 p.c. containing all the arsenic.

Even selenium is sometimes found in such quantities in hydrochloric acid as to be trouble-

some in its application (Davis, J. Soc. Chem. Ind. 1883, 157).

HYDROCHLORIC ACID FROM OTHER SOURCES THAN THE LEBLANC PROCESS.

Attempts have been made to produce hydrochloric acid from many sources, notably from the residual liquors of the ammonia-soda process.

A number of suggestions have been made for the direct production of HCl: 1st, from $CaCl_2$; 2nd, from $MgCl_2$; 3rd, from NH_4Cl .

In this connection compare the references given for the production of chlorine from these bodies earlier in the article.

As far as is known, none of the processes is used.

Hydrochloric acid from the ammonium chloride of the ammonia-soda process (cf. this for many details). Mond (1883) heats the ammonium chloride with so much sulphuric acid that the acid sulphate is formed and all HCl is expelled. The acid sulphate is converted by means of ammoniacal vapours into the neutral salt of commerce. O. N. Witt (1886) expels the HCl from NH_4Cl by means of syrupy phosphoric acid, which forms ammonium phosphate. On heating this at a higher temperature, the ammonia is driven out as well, and the phosphoric acid is regenerated. Juriseh (Dingl. poly. J. 267, 431) has shown that this process is not practicable, because there is no material known which resists the fusing phosphoric acid, and only 63 to 86 p.c. of the NH_3 is recovered.

Mond passes the vapour of ammonium chloride over nickel oxide, heated to at least 350°, which absorbs the HCl and allows the NH_3 to pass on. After a certain time the process is changed by raising the temperature to 500° or 600° and decomposing the nickel chloride by steam, when HCl is driven off and NiO regenerated. (Several patents taken out in 1886.)

The conveyance of hydrochloric acid mostly takes place in glass carboys with basket or wire hampers, sometimes in earthenware carboys of the same size (about 10 or 12 gallons). At a large French works, some years ago, tank waggons were used, carrying iron cylinders lined with ebonite.

Tank waggons for hydrochloric acid, have of late years, come into general use, especially on the Continent.

The tank waggons usually consist of a waggon platform, carrying a number of stoneware jars of about 1 ton capacity each jar. Fig. 42 shows

FIG. 42.

such a waggon carrying 12 jars of 1 ton each, or 12 tons of acid altogether. Specially prepared wooden tanks are also used occasionally.

The applications of hydrochloric acid are very numerous, but most of it serves for producing chlorine. The acid is also used for

preparing the chlorides of various metals; for extracting the phosphates from bones, &c.; for purifying bone-char (it must be quite free from sulphuric acid for this purpose); in dyeing and tissue printing; for preparing carbonic acid; for neutralising the alkaline 'melts' in the manufacture of alizarin, resorcin, &c.; in manufacturing many other coal-tar colours; and for innumerable other purposes. A. C.

CHLOROBEZENE *v.* PHENYL.

p-CHLOROBEZENE DIAZOCYANIDES *v.* DIAZO-COMPOUNDS.

CHLOROFORM, *Trichloromethane* CHCl_3 .

Chloroform was discovered by Liebig in 1831 (Pogg. Ann. 23, 442), and independently, about the same time, by Soubeiran (Ann. Chim. Phys. [2] 48, 131). Besides its well-known use as an anæsthetic, for which purpose it was introduced by Simpson in 1848 (Edin. Monthly J. Med. Sc. 8, 415), it is largely employed as a solvent in chemical manufactures and as a valuable antiseptic.

Formation.—1. By the action of alkalis on chloral: $\text{C}_2\text{H}_3\text{Cl}_2\text{O} + \text{NaHO} = \text{CHCl}_3 + \text{HCOONa}$ (Liebig, Pogg. Ann. 23, 442; Annalen, 1, 199; 162, 161).—2. By acting on alcohol with bleaching powder. The bleaching powder probably, in the first instance, converts the alcohol into aldehyde, then into chloral, liberating calcium hydroxide, which latter, reacting on the chloral, converts it into chloroform and calcium formate:

(Liebig; Soubeiran, Ann. Chim. Phys. [2] 48, 131; Soubeiran and Mialhé, Annalen, 71, 225.) A very similar reaction takes place when a mixture of alcohol and an alkaline chloride is submitted to electrolysis, whereby chloroform is also produced (Patent, J. Soc. Chem. Ind. 1885, 243). Methyl cannot be substituted for ethyl alcohol in these processes, for it yields no chloroform when treated with bleaching powder (Belohoubek, Annalen, 165, 349).—3. Chloroform is produced by the action of chlorine or bleaching powder on acetone or acetic acid (Liebig) or acetophenone (Orndorff and Jessel, Amer. Chem. J. 10, 363). With acetone the reaction is

(Dumas, Ann. Chim. Phys. [2] 56, 115; Annalen, 32, 101; Beckurts and Otto, Ber. 14, 589).—5. Chloroform is also produced by acting upon turpentine and the terpenes with bleaching powder (Chautard, J. 1851, 501).—6. By the action of nascent hydrogen on carbon tetrachloride (Geuther, Annalen, 107, 212).—7. Together with methylene chloride by treatment of methyl chloride with chlorine in sunlight (Regnault, Annalen, 33, 328).—8. From iodoform by the action of phosphorus pentachloride (Gautier, Bull. Soc. chim. [2] 13, 127).

Manufacture.—Chloroform is chiefly prepared by distilling a mixture of bleaching powder, water, and alcohol, with or without the addition of slaked lime. The diluted alcohol is warmed in a still to which a condenser is attached,

and then the bleaching powder and lime are added, and the temperature raised till chloroform begins to come over, after which the heat evolved by the reaction itself suffices to complete the distillation. Sometimes an evolution of oxygen has been noticed during the progress of the reaction. This arises from decomposition of part of the bleaching powder by heat (Bechamp, Ann. Chim. Phys. [5] 22, 347). Operators differ as to the best proportions of alcohol and bleaching powder to be employed (*cf.* Kessler, J. Pharm. Chim. [3] 13, 162; Simmerling, Arch. Pharm. [2] 53, 23; Belohoubek, *l.c.*; Brit. Pharm. 1885, 108). For small quantities, the directions of the above Pharmacopœia may be followed. The apparatus used for manufacturing on a larger scale usually consists of a generator with an attached condenser and receiver, a washing apparatus and tanks, all made of iron, and a copper still for the final rectification (*cf.* Chem. Zeit. 10, 338). The generator is cylindrical, 1.4 m. high, and 2 m. in diameter, and is constructed of boiler plate 13–14 mm. in thickness. It is fitted with an agitator, a manhole through which the charge is introduced, a tube 75 cm. in diameter connecting with the condenser, and two other tubes, the one for the introduction of water and the other for steam. A tube, closed at the lower end, passes through the plate and filled with oil holds a thermometer. There is also arranged, outside the generator, a leaden tube connected with the water supply, by which a small current of water can be spread over the generator, when, as sometimes occurs, the temperature of the reaction rises too high. The tube leading to the condenser should be short, and should have as great a dip as possible. Between the condenser and the receiver is inserted a piece of glass tubing, by means of which the evolution of chloroform may be observed. The receiver is a cylindrical tank made of boiler-plate about 15 mm. in thickness and is about 75 cm. high and 40 cm. in diameter. The washing apparatus consists of a narrow high cylinder with a rounded bottom in which is fitted an agitator in the shape of a ship's screw. This, when working, keeps up a movement of the liquid from below upwards. Taps are placed in the sides to draw off the alcoholic washings. The final rectification is conducted in a copper still, the arm of which, leading to the condenser, is made as short as possible.

Three parts of 85 p.c. alcohol diluted with 60 parts of water are added to the generator, and then, while the agitator is in motion, 12 parts of bleaching powder, which should contain not less than 35 p.c. of available chlorine. Steam is applied till a temperature of 40° is obtained, when it is shut off. The temperature still rising, the agitator is stopped when about 45° are indicated, after which the heat of the reaction causes a further increase in temperature which generally does not exceed 60°. If it should rise higher than 60°, the cooling apparatus must be made use of. The beginning of the reaction is marked by a fine rain of chloroform, alcohol and water being driven rapidly through the condenser tube, and the air contained in the apparatus being energetically expelled. The chloroform soon follows, the agitator being set in motion to assist towards the close of the distillation. When the product, on being examined,

ceases to separate in layers, when, in fact, it consists of a solution of chloroform in alcohol, it should be collected separately. This is continued until, on the addition of water to the distillate, no further separation of chloroform takes place. After the chloroform has all come over, a quantity of weak spirit is recovered. The crude chloroform is then thoroughly washed in the washing apparatus, and finally rectified from the copper still. The washings, together with the various spirituous distillates, are utilised in subsequent operations (*cf.* Chem. Zeit. 10, 338).

In England, chloroform is prepared not only from 'rectified spirit,' but also from the duty-free 'methylated spirit,' a mixture of rectified spirit with 5 or 10 p.c. of wood naphtha. The latter product can be sold at a much lower price than the former. It has been doubted whether it is applicable to purposes of inhalation, but the weight of evidence is in favour of the view that 'methylated' chloroform when properly purified may be employed as an anæsthetic with precisely the same degree of safety as chloroform prepared from rectified spirit. Indeed, it seems impossible, either chemically or physiologically, to distinguish the one from the other.

Other reactions employed for the manufacture of chloroform are: the action of bleaching powder on acetone, of which method particulars are given with drawings of apparatus by Sadtler (*Pharm. J.* [3] 20, 84); the electrolysis of solutions of chlorides of the metals of the alkalis or alkaline earths in alcohol or acetone, the whole being kept heated during the operation (*Patents*, *J. Soc. Chem. Ind.* 1885, 243; 1896, 959; 1901, 148; 1904, 536); the destructive distillation of acetates, and subsequent treatment of the distillate with hypochlorite (*Patent*, *J. Soc. Chem. Ind.* 1885, 611); and from carbon disulphide by the formation and subsequent reduction of carbon tetrachloride (*J. Soc. Chem. Ind.* 1896, 555, 612; 1904, 383).

The chloroform prepared by any of the above-mentioned processes is not of so high a degree of purity as that produced by the action of alkalis on previously purified chloral, and requires purification before it is adapted for purposes of inhalation. The first step is usually to wash it with water, which removes traces of ethyl alcohol. Then it is left for a short time in contact with sulphuric acid (*Gregory*, *Proc. Roy. Soc. Edin.* 1850, 391), which must be free from nitrous compounds (*cf.* *Christison*, *Pharm. J.* 10, 253; *Redwood*, *Year Book of Pharmacy*, 1870, 119). This acid has no action on chloroform itself unless the operation be unduly prolonged, but it chars most of the impurities which are commonly present. In the next place, the product is allowed to stand in contact with recently ignited sodium carbonate (*cf.* *Thorpe*, *Chem. Soc. Trans.* 37, 196), or with oxide of manganese, or it is washed with lime water and afterwards dried over calcium chloride. In any case, it is finally distilled at a temperature not above 64° (*cf.* *Werner*, *Arch. Pharm.* [3] 12, 450; *Thorpe*, *l.c.*; *Remys*, *Arch. Pharm.* [3] 5, 31; *Michaelis* and *Mayer*, *Dingl. poly. J.* 261, 496).

Other methods of purification are by freezing (*Eng. Pat.* 15514, *J. Soc. Chem. Ind.* 1892, 59), on cooling to -80°, foreign bodies crystallising

above this temperature can be removed, the temperature is then reduced to -82°, when pure chloroform crystallises and may be separated; and by means of the compounds formed by chloroform with salicylide or *o*-homosalicylide (*Anschutz*, *Annalen*, 273, 94). These, on gentle heating, give off pure chloroform.

Chloroform is liable to decomposition in presence of air and sunlight. Among the products formed are hydrochloric acid and chlorine (*Marson*, *Pharm. J.* 8, 69; *Abraham*, *ibid.* 10, 24), and sometimes carbonyl chloride (*Regnault*, *J. Pharm. Chim.* [5] 5, 504). Such decomposed chloroform may be purified by washing with sodium thiosulphate and subsequent distillation (*Shuttleworth*, *Pharm. J.* [3] 3, 1016; *cf.* *Remys*, *Arch. Pharm.* [3] 5, 31). The addition of 1 p.c. of ethyl alcohol is largely practised to prevent the decomposition of chloroform. This somewhat retards the formation of carbonyl chloride and hydrochloric acid, but does not altogether prevent it. Carefully purified sulphur effectually prevents decomposition. No impurities could be detected in a sample treated in this way after four months' exposure to sunlight (*Allain*, *Chem. Zeit.* 19, 310). *Breteau* (*Fr. Pat.* 353858, 1905; *Breteau* and *Woog*, *Compt. rend.* 143, 1193) gives a list of substances which also prevent the decomposition of chloroform by air and light.

Properties.—Chloroform is a liquid having a sweet taste and an agreeable ethereal odour. When inhaled it produces anæsthesia. As an antiseptic it prevents the growth of micro-organisms, but does not affect the action of soluble ferments (*cf.* *Patent*, *J. Soc. Chem. Ind.* 1886, 331). (For antiseptic applications, *v. Robin* (*Compt. rend.* 30, 52), *Augendre* (*ibid.* 31, 679), *Barnes* (*Pharm. J.* [3] 5, 441), *Salkowski* (*Chem. Rep.* 1888, 166); also *Pharm. J.* [3] 18, 315, 356 and 855.) Chloroform is very sparingly soluble in water; 1 vol. dissolves in 200 (*cf.* *Chancel* and *Parmentier*, *Compt. rend.* 100, 773). It mixes in all proportions with alcohol or ether. It may be made into an emulsion with water by means of saponin (*Patent*, *J. Soc. Chem. Ind.* 1887, 382). Sulphuric acid does not dissolve it. Chloroform is an important solvent; dissolving fats, resins, indiarubber, sulphur, phosphorus, iodine, alkaloids, many alkaloidal salts, as well as numerous other organic compounds (*cf.* *Pettenkofer*, *J.* 1858, 363; *Schlimper*, *ibid.* 1859, 405; *Nowak*, *Arch. Pharm.* [3] 3, 281; *Hesse*, *Pharm. J.* [3] 4, 649).

M.p. -70° (*Berthelot*, *Bull. Soc. chim.* [2] 29, 3), -60.2° (*Haase*, *Ber.* 26, 1053). *B.p.* 61.2° (*corr.*) *Thorpe* (*Chem. Soc. Trans.* 37, 196; *cf.* *Regnault*, *J.* 1863, 70); *Pierre* (*Ann. Chim. Phys.* [3] 33, 199); *Schiff* (*Annalen* 220, 95). *Sp.gr.* 1.52637 at 0/4 (*Thorpe*, *cf.* *Pierre*; *Schiff*). *V.D.* 4.199 (*Dumas*), 4.230 (*Regnault*). *Co-efficient of expansion*, 0.0012302 (*Thorpe*).

Chloroform is not inflammable even with a wick at ordinary temperatures. It may, however, be made to burn, with a green smoky flame when boiling, or by means of a wick when diluted with alcohol. Heated to redness, its vapour is decomposed, yielding chlorine and various chlorides (*Ragsky*, *J. pr. Chem.* 1849, 46, 170; *Ramsay* and *Young*, *J. Soc. Chem. Ind.* 1886, 232). By treatment with zinc and sulphuric acid, methylene chloride CH_2Cl_2 is formed; with alcohol or

ammonia and zinc-dust, methane (*cf.* Perkin, *Chem. News*, 18, 106); with alcoholic potash, formate and chloride (Regnault), together with carbonic oxide (Geuther, *Annalen*, 123, 121), or in closed tubes, ethylene (Berthelot, *Ann. Chim. Phys.* [3] 54, 87); with alcoholic potash in presence of monamines, isonitriles (Hofmann, *Ber.* 3, 769); with sodium ethoxide, methenyl-triethyl ether $\text{CH}(\text{OEt})_3$ (Kay, *Chem. Soc. Trans.* 1855, 7, 224); with concentrated hydriodic acid when heated, methylene iodide CH_2I_2 (Lieben, *Zeitsch. Chem.* [2] 4, 713); with red-hot copper (Berthelot, *Compt. rend.* 1, 805) or potassium amalgam (Kletznisky, *Zeitsch. Chem.* [2] 2, 127), acetylene C_2H_2 .

Chromic acid converts chloroform into phosgene COCl_2 . Repeatedly distilled in a current of chlorine, hydrochloric acid and carbon tetrachloride are formed (Regnault). Ordinary nitric acid has little or no action (Soubeiran), but fuming acid in closed tubes at 100° slowly converts it into chloropicrin $\text{C}(\text{NO}_2)_3$ (*cf.* Mills, *Chem. Soc. Trans.* 24, 641). Bromine and iodine derivatives, *v.* Paternò (*Gazz. chim. ital.* 1, 593), Friedel and Silva (*Bull. Soc. Chim.* [2] 17, 537), Bolas and Groves (*Chem. Soc. Trans.* 9, 779). Sodium reacts on chloroform in contact with atmospheric air, forming formate and chloride together with free carbon and other products (Kern, *Chem. News*, 31, 121). Potassium decomposes chloroform vapour with liberation of carbon and formation of chloride (Liebig; *cf.* Heintz, *Pogg. Ann.* 98, 263). Potassium hydroxide solution has no action on chloroform even when boiled with it; but heated in closed tubes, formate and chloride are formed (Dumas). Similar products, together with carbonic oxide, are obtained by treatment of chloroform in closed tubes at 180° with ammonia and water (André, *Compt. rend.* 102, 553). At a red heat ammonia reacts on chloroform, forming hydrocyanic and hydrochloric acids (*cf.* Heintz). Chloroform combines with sulphuretted hydrogen and with water at 0° , forming the crystalline compounds $\text{CHCl}_3 \cdot (\text{H}_2\text{S})_2 \cdot (\text{H}_2\text{O})_{23}$ (Loir, *J.* 1852, 560; Forand, *Ann. chim. Phys.* [5] 28, 12); and $\text{CHCl}_3 \cdot (\text{H}_2\text{O})_{18}$ (Chancel and Parmentier, *Compt. rend.* 100, 27).

The following reactions have been made use of in the detection or estimation of chloroform:—1. The reaction between chloroform and monamines in presence of alcoholic potash. A small portion of the liquid to be tested is added to a mixture of a monamine—*aniline*, for instance—together with some alcoholic potash, and heat applied, when, if traces even of chloroform are present, the characteristic disagreeable odour of an isonitrile is distinctly perceived:

This test, which serves to distinguish one part of chloroform in 5000–6000 of alcohol, further distinguishes between chloroform and its allied derivatives such as ethylidene chloride $\text{CH}_3\text{-CHCl}_2$ (Hofmann, *Ber.* 3, 769).—2. A delicate colour reaction takes place between potassium phenate and chloroform. An alcoholic solution of phenol is mixed with potassium hydroxide and evaporated to dryness. If chloroform be now added, a splendid red-purple colour is developed (Guareschi, *Gazz. chim. ital.* 1873, 401; Raupenstrauch, *Pharm. J.* [3] 19, 668).—3. If chloroform be added to a solution of caustic soda with

an excess of resorcinol, and heat be applied to boiling, a yellow-red colour is developed which, when largely diluted, shows a yellowish-green fluorescence (Schwarz, *Zeitsch. anal. Chem.* 27, 668; Raupenstrauch).—4. α - or β -naphthol, dissolved in concentrated potassium hydroxide solution, and warmed with a little chloroform, gives a rich blue liquid which changes in the air to green and brown (Lustgarten, *Monatsh.* 3, 715).—5. Fehling's solution is reduced by chloroform, thus:

This reaction furnishes a means of indirectly estimating chloroform (Baudrimont, *J. Pharm. Chim.* [4] 9, 410).—6. (For the estimation of chloroform in alcoholic solution, *v.* Thresh (*Pharm. J.* [3] 11, 319).)—7. Chloroform is detected in blood by distillation from a water-bath, and its decomposition into chlorine and other products when the gases evolved are led through a tube heated to redness. The liberation of chlorine is observed by its action on starch and iodide of potassium paper (Ragsky, *l.c.*; Duroy, *J. Pharm. Chim.* [3] 20, 401; Ludeking, *Chem. News*, 55, 149).—8. To detect it in cases of fatal poisoning, Vitali distils the intestines and passes hydrogen through the distillate. The hydrogen, carrying with it portions of any chloroform which may be present, is burned at a jet and in the flame is fixed a copper wire. Very minute quantities of chloroform generate hydrochloric acid in the flame sufficient to act on the copper and impart a bright-green colour (*Gazz. chim. ital.* 1881, 489).—9. (For applications of the naphthol colour test to forensic analysis, *v.* Lustgarten (*l.c.*).

Detection of Impurities.—Chloroform for inhalation should leave no residue or unpleasant odour on evaporation, should be neutral to test-paper, and give no indication of hydrochloric acid when tested with silver nitrate. A much more delicate method of detecting free acid is to add to 5 cc. of chloroform 1 drop of a solution of phenolphthaleïn and 1 drop of a centinormal solution of potassium hydroxide with 1 c.c. of water. The mixture is shaken and set aside. If free from acid, the red colour should not disappear in 24 hours (Vulpis, *Arch. Pharm.* [3] 25, 998). The presence of alcohol in chloroform may be detected by the darkening in colour of sulphuric acid shaken with it (Gregory, *Proc. Roy. Soc. Edin.* 1850, 391); by the formation of iodoform (Hager, *Pharm. J.* [3] 1, 683); by the tint of the solution which it gives with iodine (Siebold, *ibid.* [3] 10, 213); by the addition of Hofmann's violet, which is quite insoluble in pure chloroform (Regnault, *J. Pharm. Chim.* [4] 29, 402); by its reducing action on an alkaline solution of potassium permanganate (Yvon, *J. Pharm. Chim.* [5] 5, 225) or manganate (Jolles, *Chem. Zeit.* 11, 786 and 1394), or on chromic acid (Cottell, *J. Pharm. Chim.* [3] 13, 359). The fact that chloroform for inhalation purposes usually contains alcohol, purposely added to increase its stability, materially lessens the value of these tests in practice (*cf.* Dott, *Pharm. J.* [3] 12, 769). Aldehyde may be detected by many of the tests for ethyl alcohol, and also by warming with potassium hydroxide, when its presence is indicated by a darkening in colour (*cf.* Regnault, *l.c.*; Scholvién, *Pharm. Zeit.* 32, 686).

CHLOROPHENINE ORANGE *v.* AZO-COLOURING MATTERS.

CHLOROPHENINE YELLOW *v.* PRIMULINE AND ITS DERIVATIVES.

CHLORORUBINE *v.* MADDER.

CHOCOLATE is a mixture of cacao paste with sugar and flavouring matter. The paste is prepared from fermented cacao beans (the unfermented kinds being unsuitable for chocolate making) in the manner described under COCOA. The sugar, which constitutes 50 p.c. or more of the mixture, consists usually of white crystals (although the lower-grade coloured sugars may be used for the cheaper chocolates), ground to the finest powder and completely dried before admixture with the cacao paste. The most common flavouring substance is vanilla, but other spices, as cardamoms, cinnamon, cloves, mace, and nutmeg, or the essential oils extracted from them, also artificial flavourings such as vanillin, are frequently employed. Peru balsam and gum benzoin are sometimes used for a similar purpose. The flavourings are introduced either in alcoholic solution or incorporated with sugar moistened with a little oil.

It is essential that during admixture the paste should be kept in a liquid condition, and to this end the mixing machines are heated to a temperature slightly above the melting-point of cacao butter, say from 35° to 40°, and the added sugar may be previously warmed with advantage to obviate a fall in temperature of the liquid cacao paste.

The various characters of French, Spanish, Swiss, and other chocolates depend upon the nature and proportions of the different ingredients used. A number of recipes for the preparation of some of the principal types of chocolate are given in Zipperer, 156.

In addition to sugar, various farinaceous substances are frequently employed in the cheaper forms of chocolate, as wheat and potato flour, rice, arrowroot and dextrin, and occasionally barley, oats, rye, and chestnut flour. In special cases where sugar is inadmissible, as in chocolate intended for use by diabetic subjects, the sugar is replaced by saccharin (*q.v.*). It is then usual, in order to give the necessary 'body' to the chocolate, to add some form of meal or flour (preferably leguminous); and pea, bean, or linseed meal are preferred for this purpose. *Nut chocolate* is made by adding nuts, either ground or whole, to the chocolate paste; and *milk chocolate* by incorporating with it 'milk powder,' *i.e.* milk deprived of its moisture and fat. The usual composition of milk chocolate, by the best makers, is approximately 10 p.c. cacao, 25 p.c. cacao butter, 40 p.c. sugar, and 25 p.c. dried milk. The above-mentioned forms of chocolate, after being ground into a more or less homogeneous mass, are placed in moulds to form bars, blocks, cakes, and numerous fancy shapes.

An immense variety of fancy preparations of chocolate consist, however, merely of a chocolate envelope containing other substances, as biscuits, creams, dried fruits, nuts, fruit jelly, liqueurs, &c., and in some cases, medicinal preparations, as chocolate-coated pills. The most important of these fancy preparations are the chocolate creams.

The so-called 'cream' is made either from

powdered loaf sugar heated until it melts, or a mixture of this with glucose, with or without various colouring and flavouring materials. While in a liquid state, it is poured into moulds of the desired shape, made in starch flour on a table, which can be kept cool and which can be agitated by mechanical means. On cooling, the creams set into a stiff granular mass, when they are either dipped into a liquid chocolate paste, or the latter is poured over them by hand and spread uniformly by means of the rocking table. The process of covering, as well as most of the other processes in the manufacture of chocolate, are now generally effected by means of ingenious and complicated machinery.

An extra amount (about 15 p.c.) of cacao butter (or substitute) is added to the chocolate intended for covering purposes, to keep the latter in a sufficiently plastic condition during the process of cooling and to give smoothness to the finished article. The latter, whether in the form of plain chocolate or chocolate confections, should be quickly cooled, and attention to temperature is important throughout all the various operations.

The adulterants commonly used in chocolate are similar to those mentioned under COCOA, the most important being the replacement of the cacao butter by other fats and oils (as coco-nut fat, illipé butter, &c.), the addition of various farinaceous substances, including dextrin, and the admixture of finely ground cocoa shells. (Zipperer, Die Shokoladen Fabrikationen; Villiers et Collin, Traité des Substances Alimentaires.)

J. C.

CHOCOLATE FATS. Under this name, the writer comprises those vegetable fats which are used in the manufacture of chocolate as cacao butter substitutes. The natural chocolate fat is cacao butter, and best chocolates contain cacao butter only. 'Cheap' chocolates are made, to a larger or smaller extent, if not entirely, with substitutes. At first, animal fats were used, but as they impart an unpleasant flavour ('animal flavour') to the chocolate, at present fats of vegetable origin only are employed, such as coco-nut stearine and palm-nut stearine. During recent years, attempts have been made to produce chocolate fats from Borneo tallow, dika fat, and similar vegetable fats.

J. L.

CHOLESTEROL. Discovered by Conradi, in 1775, in gall-stones. Found in human bile, in blood, and in the brain; in epidermis and in hair; also present in various morbid products of the animal body, *e.g.* cerebral concretions, scirrhus matter of the mesocolon, hydropic liquid of the stomach, testicles, &c. Also found in horn and hoofs; in whalebone, tortoiseshell, feathers and bristles, &c. Its most abundant source is, however, the fat of greasy wool (wool grease), in which it was first detected by Hartmann and Schulze.

It is separated from the fatty acids in wool grease by distillation with superheated steam or by direct heating. Distillation is continued until the yellow granular distillate, consisting chiefly of fatty acids, begins to go brown. The residue is a black-brownish product and is mainly cholesterol (Mayer, Eng. Pat. 20639; J. Soc. Chem. Ind. 1894, 162). It is also prepared from animal and vegetable substances

rich in lecithin (Fischer, Eng. Pat. 11597; Fr. Pat. 390683; J. Soc. Chem. Ind. 1908, 176). Lifschütz has obtained it in small quantities by oxidising oleic acid with potassium permanganate (Chem. Soc. Abstr. 1908, i. 263).

Cholesterol crystallises in thin white nacreous monoclinic laminae, m.p. 145° and of sp.gr. 1.067. Has a neutral reaction, and is without taste or smell; insoluble in water; sparingly soluble in cold but readily dissolved by boiling alcohol. Also soluble in ether, chloroform, acetone, wood spirit, benzene, oil of turpentine, and in the neutral fats and fatty acids. Sublimes unchanged at 200°, but is decomposed at a higher temperature. Cholesterol appears to be an alcohol containing two double linkages, and combines with the fatty acids, forming esters or compound ethers similar to the glycerides, but whether it should be represented by the formula $C_{26}H_{44}O$ or $C_{27}H_{46}O$ is still under discussion (Windaus, Arch. Pharm. 1908, 117; Mauthner and Suida, Monatsh. 15, 362; Diels, Ber. 1908, 544, 2596; Molinari and Fenaroli, Ber. 1908, 2785).

Detection.—By evaporating a weak ethereal solution of the substance, adding 3 drops of an alcoholic solution of benzaldehyde and 1 drop of conc. sulphuric acid, and gently warming, a reddish-violet colour is soon produced, changing after a short time to a deep violet, if cholesterol is present (Chem. Zeit. 1899, [3] 21). Another method is to dissolve the substance in anhydrous acetic acid, add excess of acetyl chloride and a few lumps of zinc chloride. In the presence of cholesterol, the solution assumes a reddish colour, and has a greenish-yellow fluorescence, the colour being deepest after five minutes' boiling. This reaction will detect 1 part of cholesterol in 80,000 (Tshugaiëff, J. Soc. Chem. Ind. 1900, 933). Lifschütz (Ber. 1908, 252) dissolves a few milligrams of the substance in glacial acetic acid, adds a few particles of benzoyl peroxide and 4 drops of conc. sulphuric acid. If cholesterol is present, a blue-green or violet colour is produced, changing on standing through green to violet.

Estimation.—Lewkowitsch (J. Soc. Chem. Ind. 1897, 134) estimates cholesterol by obtaining its saponification value and its iodine absorption value in the usual way. Ritter (Chem. Zeit. 1901, 872) heats 50 grams of the fat on the water-bath with 100 c.c. alcohol, and when boiling, adds a hot solution of 8 grams of sodium in 160 c.c. of 99 p.c. alcohol. The alcohol is evaporated off and 75 grams of salt added and sufficient water to dissolve the contents of the basin. Evaporate to dryness and complete in an oven at 80°. The mass is pulverised and extracted in a Soxhlet apparatus with ether, the ether extract being transferred to an Erlenmeyer flask. The extraction flask is washed out with ether, the combined extract and washings being evaporated to dryness and the residue dissolved in as little alcohol as possible. The flask is gradually filled with water, the precipitate being filtered off and dried at 60°. When dry, it is extracted with ether, transferred to a weighed flask, the ether evaporated off, the residue dried at 100°–120°, and weighed (v. also OILS and FATS).

Cholesterol is found in commerce under the name of lanolin, and is used mainly for medicinal

purposes, and, owing to the ease with which it is absorbed by the skin, as a substitute for vaseline, or lard, in the composition of plasters, ointments, and salves. It has also been employed in the manufacture of cosmetics and pomades, and for softening leather. Lanolin is obtained from wool oil, which contains about 70 p.c. of cholesterol and 30 p.c. fatty acids, by saponification by means of caustic soda, whereby an emulsion is obtained which on dilution with water gives so-called 'wool milk.' On treatment in a centrifugal machine, impure lanolin separates out as a cream, and may be precipitated by lime. The purified product is afterwards kneaded with about 30 p.c. of water, in which state it is found in commerce.

Anhydrous lanolin absorbs about 100 p.c. of water, does not become rancid, and is antiseptic.

CHOLESTROPHAN v. PARABANIC ACID.

CHOLINE $C_5H_{15}NO_2$, *Hydroxyethyl-trimethylammonium hydroxide* $CH_2(OH) \cdot CH_2 \cdot N(CH_3)_3OH$, occurs in many animal and vegetable tissues. It has been found in the brain, in egg-yolk, in putrefying horse-flesh, in the seeds of the vetch (*Vicia sativa*), fenugreek (*Trigonella fœnum græcum*), the pea (*Pisum sativum*), and hemp (*Cannabis sativa*); in seedlings of wheat, barley, the pea-nut, lupines, soy-beans, and cucumber; and in the cakes left in the extraction of coconut oil, palm oil, sesame oil and cotton-seed oil.

In addition to its occurrence as the free base in the products mentioned, it is present in many animal and vegetable substances in the form of lecithin (*q.v.*). Choline may be obtained from aqueous extracts of plant or animal tissues by adding lead acetate, filtering, removing the excess of lead by sulphuretted hydrogen, evaporating the filtrate to dryness, extracting with alcohol, and precipitating with alcoholic mercuric chloride solution. The mercuric double chloride is recrystallised, dissolved in warm water, and the mercury removed by sulphuretted hydrogen, the filtrate is then evaporated and the hydrochlorides left are treated with cold alcohol in which the choline salt dissolves, leaving the betaine hydrochloride (often present with the choline) undissolved (Schulze, Zeitsch. physiol. Chem. 1909, 60, 155).

Choline can be synthesised by the action of trimethylamine on a strong solution of ethylene oxide (Wurtz, Annalen, Suppl. 6, 201):

Choline is a syrupy liquid with a strongly alkaline reaction. It forms a crystalline chloride which is readily soluble in alcohol and gives crystalline compounds with platinum tetrachloride or gold trichloride. It forms a precipitate with potassium triiodide in alkaline solution.

Choline acts as a poison, and to its presence in cotton-seed cake the injurious effects which this food has upon young animals and especially upon pigs, are probably due. The typical effect of choline upon the animal body is a lowering of the arterial blood pressure (Mott and Halliburton, Proc. Physiol. Soc. 1899, 9; also Aberdalden and Müller, Med. Klinik. 1910, No 22; and Mendel and Underhill, Zentr. Physiol. 1910 24, 251) H. I.

CHONDRIN. A substance allied to and much resembling gelatin. Obtained by boiling

cartilage with water. When dried it is a hard, horny substance, which softens to a jelly in cold water, and is entirely dissolved by boiling water. It is precipitated from its aqueous solution by nearly all acids, in excess of certain of which it redissolves; and by alum, lead acetate, copper and iron sulphates, and mercuric and mercurous nitrates. These reactions are said to distinguish it from gelatin.

By Morochowitz, chondrin is regarded as a mixture of gelatin, mucin, and salts (v. GLUE).

CHROMATOMETERS v. COLORIMETERS.

CHROMAZONE BLUE, -RED v. AZO-COLOURING MATTERS.

CHROME-BLACKS, -DEEP BLACK, -BROWNS, -FAST BLACK, -FAST CYANINE, -FAST YELLOWS, -YELLOW, -ORANGE, -PATENT GREEN v. AZO-COLOURING MATTERS.

CHROME VIOLET. Syn. *Mauveine*, *Perkin's violet* (v. AZINES AND COLOURING MATTERS). The term is also applied to the sodium or ammonium salt of aurintricarboxylic acid (v. AURIN, and TRIPHENYLMETHANE COLOURING MATTERS).

CHROMITE or **Chrome-iron-ore.** A member of the spinel group of minerals, consisting essentially of ferrous oxide and chromic oxide $FeO \cdot Cr_2O_3$, or $FeCr_2O_4$, analogous to the aluminates. The ferrous oxide is, however, often partly replaced by magnesia, and the chromic oxide by alumina, so that there is a passage to chrome-spinel or picotite; on the other hand, with a replacement of chromic oxide by ferric oxide, there may be a transition to magnetite (Fe_3O_4 or $FeFe_2O_4$). All these minerals are cubic in crystallisation and belong to the same isomorphous group—the spinel group. The actual amount of chromic oxide varies considerably, as shown by the following analyses; the ordinary ore, as mined, contains on an average 45 p.c. Cr_2O_3 :—

	Cr_2O_3	Al_2O_3	Fe_2O_3	FeO	MgO
I.	67.9	—	—	32.1	—
II.	44.15	22.41	5.78	11.76	15.67
III.	59.20	7.15	n.d.	25.02	4.42
IV.	41.23	24.58	2.28	16.99	14.77
V.	56.54	12.13	—	18.01	14.08

- I. Calculated for $FeCr_2O_4$.

 - V. Dun Mountain, New Zealand.
- (For analyses of chromite isolated from meteorites, see W. Tassin, Proc. U.S. Nat. Museum, 1908, xxxiv. 685.)

In general appearance, chrome-iron-ore is very like magnetite, but it is readily distinguished from this by the dark-brown colour of its streak or powder, and by the fact that it is only slightly, if at all, magnetic. Sp.gr. about 4.5. Crystals are of rare occurrence, the mineral being usually found as grains disseminated in basic rocks of igneous origin, especially those rich in olivine (viz. the peridotites). Sometimes these grains are segregated into nodular masses of considerable size and with a granular to compact texture. Rocks of this kind, when subjected to weathering processes, become hydrated and altered into serpentine, and for this reason most of the workable deposits of chrome-iron-ore are in serpentine-rocks. With the denudation and

breaking down of these rocks, the heavy grains of the chemically resisting chromite collect in the beds of streams and rivers; and some of the deposits worked in the Ural Mountains are of this nature.

Chromite is the only commercial source of chromium and its compounds. It is used for the preparation of the oxides and chromates employed as pigments, and in dyeing, calico-printing and tanning; in the manufacture of chrome-steel, and for chrome-bricks and furnace linings. It is mined in European and Asiatic Turkey, Greece, the Ural Mountains, New Caledonia, India, Rhodesia, and Quebec; and formerly, to a considerable extent, at Bare Hills, near Baltimore in Maryland, and in Lancaster co. in Pennsylvania. Quarries were, at one time, worked on Unst, one of the Shetland Isles. The world's output amounts to about 80,000 tons per annum.

CHROMIUM. (Fr. *Chrome*; Ger. *Chrom.*) Symbol Cr. At. wt. 52.0. Chromium occurs principally as chrome-iron-ore, or *chromite* (q.v.). As sesquioxide Cr_2O_3 , it is found in small quantities in *chrome ochre*, generally mixed with clay and associated with chromite, in France and Siberia. As lead chromate it occurs in *crocoisite* and *malanchroite* $PbCrO_4$, and as a basic lead chromate in the rare mineral *phanicite* $3PbO \cdot 2CrO_3$. It is usually present in the form of *chromite* in meteorites, but rarely to the extent of more than 1 p.c. The greenish colour of the emerald, verd-antique marble, serpentine, sapphire, and many other minerals, is due to the presence of chromium sesquioxide.

Preparation.—Metallic chromium may be prepared by several methods. Deville produced it in combination with a small quantity of carbon, in ingots weighing as much as 100 grams, by the ignition of a mixture of chromium sesquioxide and sugar in a lime crucible, at the highest temperature of a blast furnace.

Wöhler (Annalen, 111, 230) prepared chromium by fusing a mixture of the violet chromium sesquichloride with twice its weight of zinc under a layer of equal parts of potassium and sodium chlorides. The mixture of zinc and chromium so produced was treated with dilute nitric acid to remove the zinc, and the chromium remained as a light-greenish powder consisting of minute octahedra belonging to the quadratic system (Bolley), of sp.gr. 6.81 according to Wöhler, 7.3 according to Bunsen.

Chromium may be prepared by the electrolysis of its salts, but the purity and condition of the deposit vary greatly with current strength and solution concentration. A bright deposit, capable of receiving a polish, can be obtained by the use of a hot 25 p.c. acid solution of chromic chloride, with a current density of about 40–50 amperes per square foot. As in the case of nickel, the deposits have a strong tendency to peel (Cowper Coles, Chem. News, 81, 16).

It is most easily obtained in small quantities by heating equivalent parts of chromic oxide (or mixture of the oxide and anhydride) with aluminium powder. When started, the heat of the reaction causes it to continue and a fused mass of chromium of a high degree of purity is obtained (Goldschmidt, Annalen, 301, 19).

In large quantities it is best prepared by heating the oxide with carbon in the electric furnace. The crude metal thus obtained always contains *carbides*, of which two definite compounds appear to exist: Cr_3C_2 and Cr_4C . It may be refined by further heating in the electric furnace on a bed of lime mixed with chromic oxide. The refined metal crystallises in cubes or octahedra and still contains about 1.5 p.c. carbon. By further refining, however, with a double oxide of chromium and calcium, the pure metal is obtained (Moissan, The Electric Furnace).

Pure chromium is a steel-grey metal, slightly harder than glass; the carbides, however, are harder than quartz, so that a metal with between 1.5 and 3 p.c. carbon can only be cut and polished by diamond dust. Its density is 6.92, and it oxidises superficially in moist air; the melting-point is probably above 2000° . The pure finely divided metal burns rapidly when heated in the blowpipe flame, and a pyrophoric powder may be prepared by distillation of chromium amalgam *in vacuo* (*v. infra*). It also unites with nitrogen when heated in nitrogen or ammonia, forming a very stable *nitride*. Crude chromium does not burn until heated to above 2000° . It combines with sulphur vapour at 700° , and when heated to redness in hydrogen chloride, forms *chromous chloride*. Electrolytic chromium occludes 250 times its volume of hydrogen. Aqueous hydrochloric acid acts slowly on the metal, but the action is accelerated if the chromium is made the anode in electrolytic hydrochloric acid. Heating with sulphuric acid causes evolution of sulphur dioxide; concentrated nitric acid and *aqua regia* have no action. As in the case of iron, *active* and *passive* varieties of chromium exist; in general, the metal is rendered passive by oxidising solutions, whilst hydrogen ions make it active. In the electromotive series, the active chromium immediately follows zinc, the inactive metal is near platinum. The cause of the passive state is usually ascribed to the existence of a superficial film of oxide, but this view has been disputed.

Alloys. Various alloys of chromium have been prepared, chiefly by means of the electric furnace, by the 'thermit' method, or by the mixture of the molten metals.

Molten zinc dissolves but little chromium; a hard and brittle alloy has been obtained in the form of hexagonal lamellæ. *Aluminium* and chromium mixtures, containing between 5 and 55 p.c. chromium, separate into two liquid layers, and probably contain a compound, Cr_2Al . The alloys with a low percentage of chromium are brittle, one containing 13 p.c. chromium can be powdered in a mortar.

Alloys with *antimony* are brittle, and compounds represented by SbCr and Sb_2Cr are known. Chromium alloys with *copper* with difficulty, but an alloy can be obtained by stirring in copper oxide into a molten alloy of aluminium and chromium (Moissan). The liquid metals are miscible only to a small extent.

Cobalt and chromium are miscible in all proportions, both in the liquid and the solid states, and yield a mixture of minimum melting-point (1320°) with 47 p.c. Cr. Homogeneous alloys, containing above 30 p.c. Cr, when cooled, separate

into two sets of crystals, distinguishable by electrolytic etching.

Nickel chromium alloys with less than 90 p.c. nickel are non-magnetic.

Silver and chromium, although partially miscible in the liquid state, form no solid solution. Molten *cadmium* does not dissolve any chromium. Molten mixtures of *lead* and chromium, containing more than 27 p.c. lead, separate into this mixture and pure lead.

Chromium also forms *silicides* and *borides* in the electric furnace; of the former, compounds represented by SiCr_3 , SiCr_2 , Si_2Cr_3 , and Si_3Cr , have been described. They are very hard— SiCr_2 is harder than corundum—and are not attacked by ordinary acids, though attacked readily by hydrofluoric acid and by *aqua regia*. The *borides* Cr_2B_3 and CrB are metallic-looking crystalline solids, not attacked even by a mixture of *aqua regia* and hydrofluoric acid. The compound CrB is stated to be weakly magnetic. The *phosphide* CrP , obtained from the metal and copper phosphide, forms dull-grey crystals, sp.gr. 5.71, which burn in oxygen, forming chromium phosphate, but are unattacked by all acids except a mixture of hydrofluoric acid and *aqua regia*.

By electrolysis of a strongly acid solution of chromic chloride, using a platinum anode and a mercury cathode, an amalgam Hg_2Cr is obtained, soft and brilliant, and altering but slightly in air. By pressure, a harder amalgam HgCr is obtained, which alters in air more rapidly. By distillation *in vacuo*, both lose mercury and yield pyrophoric chromium (*v. supra*). An amalgam may also be obtained by the action of sodium amalgam on a chromium salt.

With *iron* the alloys of chromium are of great interest. The presence of chromium in iron or steel produces a much finer texture, greater hardness, tenacity, and elasticity, and greater smoothness of fracture. Chromium cannot be used to replace carbon in steel, as has been asserted (Boussingault).

When crystalline, the tendency of these alloys is to produce needles instead of plates, as in the case of manganese. Two to 4 p.c. chromium with 1.2 to 1.4 p.c. carbon, renders it so hard that it is bored with difficulty, and when tempered has a fracture resembling porcelain. In these alloys of steel and chromium, the hardness is probably due to the formation of a definite ferro-chrom-carbide of great hardness, which is completely miscible with its components. All alloys containing between 10 and 90 p.c. chromium appear to consist of two structural elements, that separating primarily being the softer. *Chrome-steel* is now very largely used in railway work for the manufacture of tyres and springs. It also possesses great penetrating power and penetrating resistance, and is therefore largely used for the manufacture of armour plates and armour-piercing projectiles; the addition of nickel further increases its toughness and use in armour plating. Chrome steel is also used in the manufacture of special kinds of files. The alloy is usually prepared of the requisite composition by the addition of a definite amount of 'ferrochrome,' containing from 40 to 85 p.c. chromium to the molten steel. The 'ferrochrome' is prepared from rich chrome-

iron ores in blast furnaces by the use of coke and hot high-pressure blast.

The addition of chromium decreases the magnetic properties, but all alloys, to 80 p.c. chromium, are magnetic. A carbide of chromium and tungsten of great hardness and of sp.gr. 8.41, has been produced in the electric furnace, and to it the special properties of chrome tungsten steels are probably due. These latter (as well as chrome molybdenum steels), containing up to 3 p.c. chromium and 8 p.c. tungsten, are used for the manufacture of machine tools.

Detection of Chromium. When heated strongly, all compounds of chromium impart a green colour to a borax bead in both the reducing and oxidising flames. On ignition with potassium nitrate, all chromium compounds produce a yellow colour, due to the presence of potassium chromate. If this is dissolved in water, the addition of a solution of lead acetate produces a precipitate of chrome yellow. A similar oxidation occurs when chromium compounds are fused with sodium peroxide, or when solutions of chromium salts are boiled with sodium peroxide.

Solutions of chromic salts or salts of sesquioxide of chromium have an acid reaction. With caustic alkalis they produce a green precipitate of hydrated oxide partially soluble in excess of the reagent, but reprecipitated on boiling the solution. With carbonates, a green precipitate is produced, likewise soluble in excess.

Chromates (in which the chromium exists as an acid) are usually strongly coloured. Soluble chromates are reduced, when warmed with sulphuric acid and a reducing agent such as alcohol, with the production of a green colour. The chromium is then present as a base, and may be precipitated, as already mentioned. When heated with hydrochloric acid, they are partially reduced, with evolution of chlorine and formation of chromium chloride and chloride of the metal present as chromate, together with the formation of chromyl chloride CrO_2Cl_2 .

Solutions of chromates containing no free acid except acetic acid give a yellow precipitate with a salt of lead, a red precipitate with silver nitrate, and a yellow precipitate with a salt of barium.

Estimation.—When present as a base, chromium is usually estimated as sesquioxide Cr_2O_3 . For this purpose, the solution is heated nearly to boiling, ammonia solution added in slight excess, and the temperature maintained until the liquid is perfectly colourless, indicating that the hydroxide, which is slightly soluble in excess of ammonia, is completely precipitated. The precipitate is well washed by decantation and transferred to a filter, washed thoroughly with hot water, dried, and ignited. The oxide produced contains 68.63 p.c. of chromium. The precipitation is not complete in presence of organic matter, and when a glass vessel is used, the precipitate always contains a small percentage of silica. Chromium, when present as a chromate, cannot be estimated directly by that method. It requires to be first reduced to a base. For this purpose, hydrochloric acid and a small quantity of alcohol are added, and the solution heated until the odour of alcohol is dispelled. The chromium may then be precipitated as above. For the direct estima-

tion of chromium in chromates, the precipitation with lead acetate is most satisfactory. The solution is mixed with sodium acetate and acidified strongly with acetic acid. A solution of normal lead acetate is then added, and the precipitate of PbCrO_4 is collected on a weighed filter, washed, dried at 100° , and weighed. It contains 16.19 p.c. of chromium, or 31.06 p.c. of chromic anhydride CrO_3 . The following scheme may be adopted for the estimation of chromium in chrome iron ore: A few grams of the carefully sampled mineral are ground in an agate mortar and passed through a fine muslin sieve. The dust so produced is further ground in small portions until all grittiness, on passing a little between the fingers, has disappeared and the ore cakes as an impalpable powder round the pestle. About 0.5 gram of the powder is weighed into a platinum crucible of about 50 c.c. capacity, covered with twelve times its weight of recently fused hydrogen potassium sulphate (potassium bisulphate), and gently heated to just fuse the sulphate. After keeping at this temperature for 15 or 20 minutes, the heat is gradually increased until the crucible bottom becomes red hot. The fused mass should not be allowed to rise above half-way up the crucible. The mixture soon fuses quietly, and evolves dense fumes of sulphuric acid; the heat is gradually increased to bright redness. In about half an hour, 6 parts of powdered anhydrous sodium carbonate are added and the mixture again fused for an hour at a red heat, 6 parts of nitre being added in small portions. The temperature is then raised to a full red heat for about 20 minutes; the crucible cooled and transferred to a porcelain basin where the mass is boiled out with water. The solution is filtered, and the residue washed with hot water until the filtrate comes through colourless. The filter and its contents are dried, the precipitate detached and placed with that still remaining in the basin, the filter paper burned, and the ash also added. To ascertain if the fusion has been satisfactory, this residue is digested with moderately strong hydrochloric acid, when the whole should dissolve. Any insoluble black residue indicates either imperfect grinding or insufficient fusion. It must be collected on a filter, dried, and the whole ignited in a crucible and treated with potassium bisulphate, &c., as in the first instance. The aqueous extract, after fusion, is mixed with the main solution. To the liquid, a few grams of ammonium nitrate are added, and the whole evaporated to dryness, taken up with water, and filtered from the alumina, silica, &c., into a porcelain basin. An excess of sulphurous acid solution is then added, and the solution heated until that gas is nearly expelled. The chromate, having thus become reduced to chromium sulphate, a slight excess of ammonia is added, and the solution boiled until colourless. The precipitated chromium hydroxide is washed by decantation with hot water, transferred to the filter, and washed with hot water six times. The use of the suction pump is of great assistance in this operation. The precipitate and filter are then dried, transferred to a weighed platinum crucible, and heated gently until the paper is charred. The crucible lid is then placed at the edge of the crucible so that the flame may reverberate into the crucible, and the whole ignited strongly for 10 or 15

minutes. The weighed precipitate should show no yellowish colour on treatment with a few drops of water; if such a colour is produced it indicates imperfect washing of the precipitate from alkali salts. The oxide contains 68.63 p.c. of chromium.

The oxidation may also be effected by means of sodium peroxide, and the chromate produced, instead of being reduced to chromic oxide, may be estimated as chromic acid volumetrically. For this, various methods are available, e.g.: (1) boiling with standard arsenious oxide and estimating the excess by standard iodine; (2) adding potassium iodide and titrating iodine liberated by standard thiosulphate; (3) adding standard ferrous ammonium sulphate solution and titrating excess with standard potassium dichromate.

A speedy and accurate method for the estimation of chromium in ferrochrome or chromite, is the following: 1 part of the ore is finely powdered, as described above, and fused with a mixture of 5 parts of sodium peroxide and 8 parts of caustic soda in a silver crucible. The aqueous extract is filtered and again similarly treated; three or four such fusions are necessary to dissolve all the ore, when the only residue is a little silver extracted from the crucible. The filtrate is acidified with sulphuric acid, boiled for 40 minutes and diluted to a known volume. An aliquot part is then titrated with potassium iodide and standard sodium thiosulphate.

Chromates may also be readily estimated in acid solution by hydrazine sulphate, whereby nitrogen is liberated, 100 c.c. of nitrogen at N.T.P. being equivalent to 0.59576 gram Cr.

COMPOUNDS OF CHROMIUM.

Chromium forms a number of oxides; of these, *chromous oxide* CrO , and *chromic oxide* or *chromium sesquioxide* Cr_2O_3 , are definite basic oxides, yielding with acids salts in which chromium is present as a divalent or trivalent cation, forming the *chromous* and the *chromic* salts. Chromic oxide can also combine with bases to form salts, the *chromites*, of the type MCrO_2 , in which the chromium is present in the monovalent anion CrO^- . *Chromic anhydride* CrO_3 is an acid anhydride forming, with bases, salts of the type M_2CrO_4 , the *chromates*, or $\text{M}_2\text{Cr}_2\text{O}_7$, the *dichromates*, in which the chromium exists as the divalent anion CrO^- or Cr_2O^- . Other oxides have been prepared and are usually regarded as compounds of the basic and acid oxides, e.g. $\text{Cr}_2\text{O}_5 \cdot \text{Cr}_2\text{O}_3 = \text{chromic chromate}$. The chromous salts are of no industrial importance at present.

Chromic oxide, Chromium sesquioxide Cr_2O_3 . This compound is produced by the oxidation of metallic chromium and by ignition of chromic hydroxide, chromic anhydride, and certain chromates.

Wöhler prepared this oxide in fine, small rhombohedral crystals by passing the vapour of chromyl dichloride through a tube heated to redness. The crystals are isomorphous with corundum and of equal hardness; their sp.gr. is 5.21. Crystalline chromic oxide is also obtained when a mixture of potassium dichromate and sodium chloride is heated to redness (Ditte, Compt. rend. 134, 336). The finest coloured amorphous chromium oxide is produced by heating mercurous chromate Hg_2CrO_4 in a covered

crucible; mercury and oxygen escape, and the oxide remains as a green powder. For the preparation of this substance on the large scale, a great number of methods are recommended.

Boil a solution of potassium dichromate with half its weight of flowers of sulphur so long as the green hydroxide is precipitated. The addition of a little potash solution, by forming potassium sulphide, accelerates the decomposition. The precipitate is filtered from the solution containing potassium sulphate, and washed. The sulphur retained in the precipitate may be removed by heating. Instead of performing the reaction in the wet way, the mixture may be ignited in a crucible, and the resultant mass digested with water (Lassaigne, Ann. Chim. Phys. [3] 14, 299). Wöhler (Pogg. Ann. 10, 46) heats a mixture of potassium dichromate with its own weight of ammonium chloride and a small quantity of sodium carbonate, and purifies the residue by washing.

According to Barian (Rev. Scient. 20, 425), a very pure colour, suitable for colouring fine porcelain, is produced by igniting in a crucible a mixture of 4 parts of potassium chromate and 1 part of starch. The mass is washed free from potassium carbonate and reignited.

Chromic sesquioxide is a green pigment of great permanence. It is not acted upon by chlorine or sulphur gases or by an intense heat. At a white heat it melts, and crystallises on cooling.

Hydrogen and carbon monoxide are without action, but it is reduced to the metallic state on heating with carbon at a temperature of 1185° or higher.

This oxide is largely used under the names *chrome green* (mixtures of *chrome yellow* and Prussian blue are also frequently called *chrome greens* and must not be confounded with the true chrome green), and *ultramarine green* for imparting a green colour to glass, porcelain, &c., as a pigment, in oil and water colours and in printing, and as a mordant in calico-printing and dyeing. Certain hydrated oxides are also used under various names; their colours are, generally speaking, brighter than that of the anhydrous oxide, but they usually contain small quantities of other substances besides the oxide and water.

Guignet's Green; *Pennettier's Green*; *Emerald Green*; *Veridian* $\text{Cr}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$. This pigment appears to be identical with that formerly manufactured in secret by Pennettier. According to Guignet's method, 3 parts of boric acid and 1 part of potassium dichromate are heated to dull redness in a reverberatory furnace. The mass swells up, evolves oxygen, and becomes of a fine green colour; it contains the borates of potassium and chromium, or a double borate of those two metals. It is boiled with water, whereby the borate of chromium is decomposed into boric acid and hydrated chromium sesquioxide, potassium borate also remaining in solution. The precipitate is well washed, dried, and finely ground. It usually contains boric acid even after thorough washing. The washings and mother liquors are evaporated for the recovery of the boric acid.

According to the Chem. Zeit. 9, 851, the process now used on the large scale is as follows: The boric acid is first purified by solution in hot

water, treated with animal charcoal, and recrystallised. The crystals are dried in a centrifugal machine. The mother liquor may be employed three or four times for recrystallisation of fresh portions of acid, but becomes then too impure for further use. Eight parts of potassium dichromate and 3 parts of purified boric acid are ground into a stiff paste with water, and the mixture in charges of about 1 cwt. is heated to dull redness for about 4 hours in a reverberatory furnace. The fused mass is thrown into water, and washed repeatedly by decantation; the pigment is ground while wet, again washed, filtered, and dried. The first two washings contain considerable quantities of potassium borate, which is recovered by evaporating in leaden pans, adding hydrochloric acid and allowing the boric acid formed to crystallise. The mother liquor is further evaporated and crystallised. The crystals are redissolved, the lead (from the pans) precipitated by hydrogen sulphide, and the filtrate recrystallised. In this manner, from 70 to 75 p.c. of the boric acid is recovered.

Gugnet's green is the most permanent green pigment known; it is unacted upon by light or concentrated boiling alkalis; it is not affected by acids in the cold, but hot hydrochloric acid slowly dissolves it. When heated to 200° it becomes anhydrous. It is a fine green pigment largely used for the same purposes as the ordinary oxide. It may be used in place of the dangerous arsenical greens. It possesses good covering power, and can be mixed with other pigments without alteration. When mixed with lead chromate, it is employed for the production of a pale-green colour in landscape painting.

Other *chrome greens* are obtained by the use of sodium phosphate. These always contain some phosphoric acid. They are, however, not as brilliant as the oxide chrome greens. Various methods of preparation are employed. Arnaudon dissolves ammonium phosphate with slight excess of potassium dichromate in a little boiling water, evaporates until mass solidifies on cooling, heats at 80° and later at 200°, washes with hot water, dries and powders. Another method consists in boiling a solution of 10 lbs. potassium dichromate with 18 lbs. sodium phosphate, adding 10 lbs. sodium thio-sulphate and a little hydrochloric acid, and boiling until precipitation is complete. The precipitate is washed, ground, and dried.

According to Bong (Ber. 29, 201), a blue pigment, retaining its colour at high temperatures, suitable for colouring porcelain, &c., is produced by igniting strongly, in the air, an intimate mixture of 5 parts boric acid, 15 parts alumina, 20 parts magnesium carbonate, and 2 parts barium chromate.

Chromic chloride or CrCl_3 or Cr_2Cl_6 . The anhydrous chloride is obtained by heating a mixture of carbon and chromium sesquioxide in a current of chlorine. It forms pale-violet scales of sp.gr. 3.03; it is almost insoluble in water, but dissolves readily, being transformed to the green variety (*v. infra*), if only a minute trace of chromous chloride (1 in 20,000) is present. Chromic chloride may be prepared in solution by dissolving the hydroxide in hydrochloric acid. It forms two isomorphous hexahydrated salts ($\text{CrCl}_3 \cdot 6\text{H}_2\text{O}$), one blue and the other green, and also a tetrahydrate and a decahydrate. The

blue hexahydrate, when dissolved in water, appears to give the ions $\text{Cr}(\text{OH}_2)_6^{+++}$ and 3Cl^- , all the chlorine being precipitated by silver nitrate; the green salt, however, at first forms the ions $\text{Cr}(\text{OH}_2)_4\text{Cl}_2 \cdot 2\text{H}_2\text{O}$ and Cl^- , only $\frac{2}{3}$ its chlorine being immediately precipitated (Werner and Gubser, Ber. 1901, 34, 1579). In calico-printing, a neutral solution of chromic chloride, prepared from potassium dichromate, is frequently used. The following method is recommended by De Karrur: Dissolve 9 lbs. of potassium dichromate in 5 gallons of boiling water. Prepare also a solution of 9 to 11 lbs. of white arsenic in 24 gallons of boiling water, and mix, with constant stirring, with the solution of dichromate. A greenish precipitate of chromic hydroxide soon separates; it is cooled, filtered, and washed with boiling water. The precipitate is added in portions to a solution of hydrochloric acid (diluted until it no longer fumes), with constant stirring, until a portion remains undissolved. A solution of soda is then added and well mixed, until the hydroxide begins to precipitate. The dark-green solution, being thus neutralised, is evaporated to 46°B. and is ready for use. A basic chloride $\text{CrCl}(\text{OH})_2$ is also employed as a mordant for silk and cotton.

Chromic fluoride $\text{CrF}_3 \cdot 4\text{H}_2\text{O}$. This product is used in the printing and dyeing of woollen goods. It is a fine crystalline green powder, very soluble in water. It has a corroding action on glass, and is therefore best kept in lead or wooden vessels. It may be used as a mordant with both vegetable and animal fabrics, and is often employed in the place of acetate or nitrate of chromium for printing, and in general gives finer results. Alizarin dyes, coerulein, gallein, &c., and logwood extracts, are fixed as perfectly as with acetate of chromium. One advantage in using it is that it is solid. It has no injurious effect on the pile, and is often used in place of chromates where the oxidising action of these is injurious, especially with wools. *Chromium silicofluoride*, prepared by dissolving the oxide in hydrofluosilicic acid, has also been used in dyeing and printing in place of the fluoride, and is stated to give better results.

Chromium sulphates. These are prepared by the dissolution of the hydroxide in sulphuric acid. It yields a bluish-violet solution, which, on boiling, becomes green. The experiments of Recoura have shown that numbers of compounds of different constitution exist both in the violet and green varieties, but they are not of commercial interest. The double sulphates of chromium and potassium, sodium and ammonium, are, however, of importance. These are known as *chrome alums*; they crystallise in fine octahedral crystals containing 24 molecules of water isomorphous with those of ordinary alum, and of corresponding composition.

Potassium chrome alum, Chrome alum

This substance may be prepared by mixing solutions of chromic sulphate and potassium sulphate in molecular proportions, or more conveniently by the reduction of potassium dichromate in sulphuric acid solution.

The best method is to add 5 parts of strong sulphuric acid to a solution of 3 parts potassium dichromate in 30 parts of water with the addition

of a reducing agent, preferably a current of sulphur dioxide:

When the sulphur dioxide is substituted by other reducing agents, such as alcohol, a larger quantity of sulphuric acid is required.

Chrome alum is obtained in large quantities as a by-product from the oxidation of organic substances by a mixture of potassium dichromate and sulphuric acid, as in the oxidation of anthracene to alizarin, in the manufacture of aniline violet, &c.

It crystallises in fine dark-purple octahedra, especially in presence of excess of acid, is soluble in 7 parts of cold water, forming a reddish-blue solution, which, when heated to about 70°, becomes green. It returns to its original colour after standing some weeks.

When heated to 25°–30°, the crystals lose half their water and become lilac-coloured; at 100° a further quantity of water escapes and the crystals turn green; at 350° they become anhydrous, but are still soluble in water; at a temperature slightly above 350° they become greenish-yellow, insoluble in water (Löwe), and only slowly soluble in acids. The green salt only contains $\frac{1}{2}$ of the SO_4 as an acid ion, and is probably a sulphate of a sulphochromyl hydroxide. For these compounds, reference should be made to the extensive researches of Recoura (Ann. Chim. Phys. [7], 4, 494).

Chrome alum is used in dyeing, calico printing, and tanning.

Sodium chrome alum $\text{Na}_2\text{SO}_4 \cdot \text{Cr}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$ corresponds to the potassium salt, but is more soluble in water.

Ammonium chrome alum

is prepared like the preceding alums. It is less soluble in water than potassium chrome alum. It melts at 100°.

Chromium chlorate $\text{Cr}_2(\text{ClO}_3)_3$ is used to some extent in calico printing (Despicrres and others, Dingl. poly. J. 228, 260–263), and for increasing the permanence of aniline black. It may be prepared by the addition of a solution of potassium chlorate to chrome alum or by the addition of barium chlorate to a solution of chromium sulphate, the barium sulphate being precipitated. According to Lauber and Weinreb (Dingl. poly. J. 257, 290), it is best prepared by the following process: Dissolve 60 parts of chrome alum in 80 parts (by weight) of hot water; add 20 parts of soda dissolved in 60 parts of water, and wash the precipitated hydroxide. Redissolve the precipitate in 10 parts of cold sulphuric acid of 66°B., filter if necessary and add 22 parts of potassium chlorate dissolved in 50 parts of water. The solution is evaporated slightly and the potassium sulphate crystallised out; the more soluble chromium chlorate remains in solution. When heated at 100° it gives off quantities of chlorine and forms a yellow-red liquid containing chromic acid and other compounds.

Chromic anhydride, Chromic acid CrO_3 . This important oxide is best prepared by the decomposition of a chromate by sulphuric acid. A cold saturated solution of potassium chromate is added to from 1 to $1\frac{1}{2}$ parts of concentrated

sulphuric acid, with constant stirring. On cooling, if the acid used be strong enough, crimson crystals of chromic anhydride separate; if necessary, the solution is evaporated until the crystals are formed on cooling. The liquid is poured off and the crystals drained on porous tiles or pressed between porous plates. They may be recrystallised by dissolving in water and evaporating to a syrup. The excess of sulphuric acid may be removed by the cautious addition of barium chromate to the solution of the crystals, or the crystals may be gently fused, when the heavier oxide sinks to the bottom of the vessel and the sulphuric acid above slowly evaporates. The mother liquors from the chromic anhydride are used for a fresh preparation until the percentage of potassium sulphate becomes excessive; they are then precipitated by the addition of lead acetate with the production of a light-coloured 'chrome yellow' containing much lead sulphate.

According to Zettnow (Pogg. Ann. 143, 468), the largest yield is obtained as follows: 300 grams of potassium dichromate are dissolved in 500 c.c. of water, and 400 c.c. of strong sulphuric acid are added. The mixture is allowed to stand for 10 or 12 hours, the solution decanted from the deposited crystals of potassium sulphate, and heated to 80° or 90°; 150 c.c. of sulphuric acid are then added, followed by sufficient water to redissolve the chromic anhydride at first deposited, and the solution evaporated until the oxide commences to crystallise. The mixture is allowed to stand for 12 hours, decanted from the crystals, and evaporated with the production of a second and third crop of crystals. The crystals are drained, introduced into a crucible, mixed thoroughly with 50 c.c. of nitric acid of not less than 1.46 sp.gr. (weaker acid would dissolve the crystals) and drained for some hours on a tile. The operation is repeated if necessary with 25 c.c. of nitric acid. The whole of the sulphuric acid and sulphate having been thus removed, the crystals are heated on a sand-bath and the nitric acid evaporated, or they may be heated to 80° in a current of air. In this manner, Zettnow obtained from 85 to 90 p.c. of the theoretical yield of pure dry chromic anhydride.

Duvilliers (Compt. rend. 75, 711) prepares this oxide by dissolving 100 parts of barium chromate in 100 parts of water and 140 parts of nitric acid of sp.gr. 1.38 (40°B.) and heating the solution until it becomes red. 200 parts of water are then added, and the whole boiled for 10 minutes; cooled, and the barium nitrate allowed to crystallise out. The solution is decanted, evaporated to the bulk occupied by the original amount of acid used, and a further crop of crystals of barium nitrate removed. The solution, which contains only about 1 part of barium nitrate for 200 parts of the anhydride, is evaporated nearly to dryness, a little water added, and the evaporation repeated until all the nitric acid is driven off. The anhydride is then crystallised out and dried as usual.

Barium chromate is digested for some time with about half the amount of dilute sulphuric acid required for complete precipitation, with the production of chromic anhydride and barium dichromate and precipitation of barium sulphate. Sufficient sulphuric acid is then added to just precipitate the barium, and the solution, which only contains chromic anhydride, is

decanted from the precipitate and the solution evaporated (Meissner). According to C. Watts, the barium chromate is best treated with excess of strong nitric acid, the precipitated chromic oxide filtered through asbestos, and the nitric acid driven off by heat.

Chromic anhydride is a powerfully acid substance crystallising in scarlet rhombic prismatic needles of sp.gr. 2.788 (Zettnow). They melt at 193° without decomposition, and the melted mass exhibits supercooling; at higher temperatures oxygen is evolved together with red vapours, probably CrO_2 .

When heated to 250° they decompose into chromium chromate $\text{CrO}_3 \cdot \text{Cr}_2\text{O}_3$ with evolution of oxygen. Above that temperature, the whole is converted into chromium sesquioxide. The perfectly dry anhydride, when heated to 120° *in vacuo*, slowly volatilises and condenses in red needles (Arctowski). By the action of light on a solution of this oxide, oxygen is evolved and chromium chromate precipitated as a brown powder.

Chromic anhydride is very soluble in water. 100 parts of water, at 26°, dissolve 62 parts of the oxide. The aqueous solution contains $\text{Cr}_2\text{O}_7^{2-}$ ions, with a small proportion of CrO_4^{2-} ions. These ions are capable of transformation by the action of acids or alkalis, as indicated by the equations:

It dissolves in acetic acid or ether without decomposition; is almost insoluble in sulphuric acid of 1.77 sp.gr., but dissolves in stronger or weaker acid; is insoluble in nitric acid of sp.gr. 1.46.

Chromic anhydride is a powerful oxidising agent. Warm anhydrous alcohol inflames when dropped upon it, and even dry ammonia gas is oxidised with production of water and nitrogen. Addition of oxalic acid is said to increase its oxidising power. The solution in water, sulphuric acid, or acetic acid, is largely used as an oxidising agent in organic work. In most of these oxidations, precautions must be taken to moderate the velocity of the reaction. When acetic acid is used as the solvent, the substance to be oxidised is usually dissolved in the same solvent and the oxidising solution slowly added, the temperature being kept sufficiently low, *i.e.* seldom above 100°. Chromic acid, as an oxidising agent, has the advantage that the close of the reaction is frequently indicated by a pure green colour in place of the brownish colour.

It has the property of producing a permanent yellow colour with silk or wool, but not with cotton. The chromium in such material may be converted into lead chromate upon the fibre or further dyed by logwood, &c. Chromic anhydride usually contains sulphuric acid and sulphates or nitrates; Moissan found 24 p.c. of sulphuric acid in samples of the commercial article.

Chromates. *Chrome iron ore.* All chromates are prepared, directly or indirectly, by the action of oxidising agents upon *chrome iron ore* or *chromite* $\text{FeO} \cdot \text{Cr}_2\text{O}_3$. This important mineral is found in a large number of localities, principally in Turkey, Greece, Asia Minor, Siberia, and New South Wales. Large deposits of iron ore are found

in New Caledonia, containing sometimes 5 p.c. of chromium sesquioxide in a form soluble in acid, probably as chrome ochre.

Chromite belongs to the spinel group of minerals. It is isomorphous with magnetic iron ore $\text{FeO} \cdot \text{Fe}_2\text{O}_3$, and may be considered as that substance in which the sesquioxide of iron is replaced by sesquioxide of chromium. A portion of the chromium is usually replaced by aluminium, and some of the iron by magnesium, though this is sometimes absent. The composition of chromite varies extremely; an ore, containing 50 p.c. of the sesquioxide, is of very good quality. Of seven samples from varying localities analysed by Clouet, the chromium sesquioxide present averaged 44 p.c. For analyses *v. CHROMITE*.

Chromite is black or brownish-black, and infusible before the blowpipe. It will scratch glass, but is itself scratched by a good steel knife.

A scheme for the analysis of chromite has been given under the estimation of chromium.

Potassium chromates. Both the normal and acid chromates are of importance in the arts. The acid or dichromate, containing the larger proportions of the active constituent CrO_3 , is generally prepared on the large scale.

A great number of processes have been adopted for the treatment of chromite for this purpose; they all depend upon the oxidation of the chromium sesquioxide into chromic anhydride.

The ore is heated to redness and plunged into cold water to facilitate the powdering, stamped, ground in a mill, and finely sifted.

In former times, the ore was mixed with about two-fifths of its weight of potassium nitrate and ignited on the bed of a reverberatory furnace, the oxygen required for the oxidation of the sesquioxide into the anhydride and the potassium for its conversion into potassium chromate, being both provided by the nitrate. A great saving was introduced by the substitution of atmospheric oxygen as the oxidising agent in place of the nitre, the potassium being supplied by potassium carbonate or, as proposed by Watt, by potassium sulphate. The latter salt is largely used where, as in Russia, the demand for potassium sulphate is small, and hence this salt, produced during the later conversion of the chromate to dichromate, is used to replace some of the potassium carbonate. The mass, however, was very liable to fuse and the heavy particles of chromate to sink through the liquid and escape the action of the blast. This difficulty was overcome by Stromeyer, who introduced lime into the mixture, thus rendering the mass porous and non-fusible and much increasing the rapidity and completeness of the action.

Tilghmann (Patent 1847) makes use of felspar as the source of alkali. For this purpose, 1 part of chrome ore is mixed with 4 parts of felspar and 4 parts of lime or 7 parts of chalk. The mixture is heated to bright redness, but not to fusion, in a reverberatory furnace for about 20 hours, with constant stirring. The chromate thus produced is removed as described later.

The ore may also be mixed with potassium chloride, and heated to whiteness with frequent stirring while a current of superheated steam is passed over the mass; the iron is stated to pass away almost entirely as chloride (Swindells, Chem. Gazz. 1851, 419).

Jacquelin (Ann. Chim. Phys. [3] 21, 478) prefers to produce calcium chromate in the furnace and to convert it subsequently into the required chromate by double decomposition. He thus avoids the loss of alkali always experienced in the ordinary process. The ore is finely powdered, preferably levigated and dried before use, mixed ultimately with chalk in the required proportions, and heated to bright redness on the bed of a reverberatory furnace for 9 or 10 hours, with occasional stirring (at least once an hour). The product is ground in a mill, suspended in hot water, and treated with sulphuric acid until slightly acid; calcium dichromate is thus produced. A little chalk is stirred into the solution to precipitate the iron as oxide, and a solution of potassium carbonate or other salt, according to the chromate required, is added. The calcium is thus precipitated as carbonate and the dichromate required remains in solution. The solution may also be used directly for the production of chrome yellow, &c.

According to Booth's method (Pat. 1852, Dingl. poly. J. 131, 137), the ore is mixed with one-fifth of its weight of charcoal or coal and ignited in a reverberatory furnace like that used for puddling iron, out of contact with the air. The product is thrown into vats, and the reduced iron dissolved out by dilute sulphuric acid, the residue being treated in the usual manner for the production of chromates. The weight of oil of vitriol used, amounts to about two-thirds that of the ore. It is stated that the value of the ferrous sulphate obtained repays the extra labour involved.

Atherley (Hoffman's Ber. u. Entw. Chem. Ind. [1] 725) gives a description of the manufacture of potassium dichromate as usually practised on the large scale, of which the following is the abstract:—

The ore is stamped, ground in a mill, and passed through a sieve of 80 meshes to the inch.

Potash lye is prepared by soaking 7 cwts. of burned limestone (containing but little silica and magnesia) in a solution of $2\frac{1}{2}$ p.c. of potassium carbonate free from chloride (which would hinder the crystallisation of the product), dried, ignited, and powdered.

It is then mixed with $4\frac{1}{2}$ cwts. of the ore, and spread in a layer 2 inches deep upon the previously heated bed of a reverberatory furnace, at the end nearest the fire. The furnace is about 9 feet long and 6 feet broad. The heat is maintained at bright redness, and the mixture turned over every 15 minutes; in about 2 hours it is gradually pushed towards the farther end of the furnace, and its place supplied by a fresh charge. The operation is completed in about 4 hours, when the mass is greenish-yellow and contains chromates of potassium and calcium, lime, potassium silicate, and ferric oxide. It is broken into coarse powder and lixiviated in wooden pans, placed steplike one above another, with a hot solution of potassium sulphate, which converts the calcium chromate into potassium chromate with precipitation of calcium sulphate. The liquid is allowed to run from one vat to another, until at last a saturated solution of potassium chromate is produced. This is run into a depositing vat lined with lead and treated with sufficient sulphuric acid and water to con-

vert the normal salt into the dichromate, and the solution cooled.

As the solution of normal chromate was saturated and contained about 1 part of salt in 2 parts of solution, the dichromate solution formed is supersaturated, that salt requiring nearly five times as much water for solution as the normal chromate; about three-quarters of the total amount in solution is thus deposited on cooling. The crystals are redissolved in sufficient water to form a solution of 1.120 sp.gr. and crystallised in deep iron pans at a temperature of 21° .

The production of chromates is said to be rendered easier by the addition of oxygen-carriers, such as manganates or oxides of copper or iron (D. R. P. 163814). A method dependent on this, in which ferric oxide obtained by heating pyrites is used, is the following: 240 parts chrome iron ore of 50 p.c., 170 parts sodium carbonate, and 150 parts ferric oxide, with, if desired, 50 to 80 parts lime, are intimately mixed, roasted, and lixiviated. The residue contains all the original ferric oxide and may be used over again. The solution is concentrated and treated as usual. The action of the ferric oxide is regarded as due to the production of an alkaline ferrite which becomes converted to the chromate and ferric oxide (J. Soc. Chem. Ind. 1895, 865).

Chromates are also produced by mixing finely divided chrome iron ore with alkaline carbonates and roasting in an oxidising atmosphere in a revolving furnace at a temperature sufficient to keep the mass fluid (National Electrolytic Co. New York; J. Soc. Chem. Ind. 1908).

Potassium chromate K_2CrO_4 is prepared, as already described, from chrome ore. It may be produced by adding potassium hydroxide to a solution of the dichromate. It crystallises in anhydrous yellow rhombic prisms isomorphous with those of potassium sulphate, sp.gr. 2.71 (Kopp). 100 parts of water dissolve of potassium chromate

at	0°	30°	60°	105.8°
	54.57	65.13	74.6	88.8 parts,

105.8° being the boiling-point of the saturated solution. The solution has a fine yellow colour of great tinctorial power; a distinct yellow tinge is imparted by 1 part in 400,000 parts of water. It is insoluble in alcohol and ether, and is very poisonous, producing a condition resembling diabetes when administered by mouth or subcutaneously. It also produces slow-healing sores, especially among workers in chromate factories. For these, a sodium bisulphite wash is efficacious. Such workers should pay attention to constant washing of face, nose, and hands, and packers are advised to wear respirators.

When heated, it reddens and fuses without decomposition; heated with reducing agents, such as sulphur, it is reduced to chromium sesquioxide. The addition of an acid, even carbonic acid, determines the decomposition into potassium dichromate, as is indicated in the previous equations, and it is evident further that, even when excess of acid is present, the solution still contains CrO_4' ions. The equations also indicate that a solution of potassium chromate possesses an alkaline reaction

Owing to the much smaller solubility of the dichromate (4.64 parts at 0°), when the chromate is crystallised some dichromate also separates.

Potassium chromate is not largely used, the dichromate, on account of its greater richness in chromic acid, being generally preferred. The general uses and oxidising properties, however, described under potassium dichromate, also apply to the normal chromate.

Potassium dichromate, generally known as 'Bichromate,' or 'Bichrome,' $K_2Cr_2O_7$. This important salt is prepared in large quantities by the methods already described. It may be made electrolytically by the use of a solution of potassium hydroxide, a cathode of porous copper oxide, and an anode of ferrochrome (50 p.c.), which has an E.M.F. of 2 volts: ferric oxide is also formed and precipitated (Lorenz, *Zeitsch. anorg. Chem.* 1896, 12, 396). Considerably over 10,000 tons are annually produced in Great Britain.

It crystallises in anhydrous, fine, red, square tables, derived from triclinic prisms, of sp.gr. 2.692, and of intensely metallic, bitter taste. They melt at about 400° (Tilden and Shennstone), and resolidify on cooling without change. At bright redness, decomposition ensues, and the normal chromate and chromic sesquioxide result. Other chromates of composition, $K_2Cr_3O_{10}$ and $K_2Cr_4O_{13}$, appear to exist in equilibrium with the solution with certain limits of concentration.

100 parts of water dissolve at 0°, 4.64 parts; at 30°, 18.13 parts; at 60°, 45.44 parts; and at 104.8°, 108.2 parts; 104.8° being the boiling-point of the saturated solution (Koppel and Blumenthal, *l.c.*).

Potassium dichromate is used in the preparation of all chrome pigments; of 'discharge' for Turkey red, &c.; for the production of a large variety of colours in calico printing and dyeing; in the manufacture of safety matches, &c. In solution with sulphuric acid, it is used as a bleaching agent for tallow, palm oil, &c.; in the oxidation of anthracene to alizarin, and in the manufacture of aniline violet and in many other organic oxidations. It is also used for tanning leather (*v.* LEATHER).

When mixed with organic substances it is reduced on exposure to light; gelatin under such circumstances is rendered insoluble. This reaction is taken advantage of in the 'Carbon' process of photography. The gelatine is mixed with a pigment of any colour, and the paper carrying this film is sensitised by floating on a solution of potassium dichromate. On exposure under a negative, the gelatine in those portions exposed to the light becomes insoluble, and retains the pigment, while the portions protected by the darker parts of the negative are almost unacted upon, and may be dissolved in warm water. In this manner, photographs of any desired colour, and of great beauty and permanence, may be produced. Contact of the chromated gelatine with the reduced silver of an ordinary bromide print has a similar effect, and bromide photographs may hence be copied by squeezing into contact with a sensitised pigmented gelatine. After a few minutes' contact, the pigmented paper is developed like a carbon print. The bromide has become bleached and reduced to silver, but

can be redeveloped. The insoluble gelatine does not absorb water, but will take oil, which may be mixed with any desired pigment, and this forms the basis of the oil and bromoil processes. Gum, mixed with dichromate, is also made insoluble by exposure to light, and this is made use of in photography in the gum dichromate process (*v.* PHOTOGRAPHY).

Sodium chromates. The normal chromate $Na_2CrO_4 \cdot 10H_2O$ and the dichromate $Na_2Cr_2O_7 \cdot 2H_2O$ are prepared by methods corresponding to those used for the potassium salts. According to Nic. Walberg (*Dingl. poly. J.* 259, 188), they are prepared on the large scale as follows: 6 parts of powdered chrome ore (44 p.c. Cr_2O_3) are mixed with 3 parts soda ash (92 p.c. Na_2CO_3) and 3 parts of chalk, and heated in charges of 1 ton in a reverberatory furnace for 8 hours. The mass is lixiviated to produce a solution of 45°B., boiled down to 52°B., and allowed to crystallise in leaden pans. The crystals are first dried by a centrifugal machine, and finally heated to 30° in a drying chamber, where they crumble to a yellow anhydrous powder containing about 96 p.c. of the normal chromate.

For the production of dichromate, these crystals are dissolved to a solution of 40°B. and treated with sufficient chamber acid to determine the conversion into the dichromate, the right point being found by potassium iodide and starch paper. Sufficient neutral sodium chromate is then added to bring the percentage of CrO_3 to about 72.5. The liquor is cooled in lead tanks to 1°, artificially if necessary, and the sodium sulphate crystallised out. The liquor is drained off, filtered if necessary, and evaporated to dryness in an iron pot, with constant stirring. The residue is powdered while still hot. If the amount of CrO_3 be allowed to exceed 72.5 p.c., the product is damp and cannot be stored in wooden casks. An analysis of this substance showed CrO_3 , 72.3; Na_2O , 26.20; SO_3 , 1.40.

Normal sodium chromate forms fine large efflorescent crystals of the composition

isomorphous with Glauber's salt. Unlike potassium chromate, it is less soluble than the dichromate; it is, however, more soluble than potassium chromate, 100 parts of water at 30° dissolving 87.36 parts of sodium chromate.

Sodium dichromate $Na_2Cr_2O_7 \cdot 2H_2O$ crystallises in thin, six-sided prisms with bevelled edges of a fine hyacinth-red colour, and is very soluble in water, 100 parts of water at 30° dissolving 197.6 parts of the salt. It is hence more than 10 times as soluble as potassium dichromate, which frequently makes its use preferable to that of the potassium salt.

Ammonium chromate and dichromate are prepared by mixing in proper proportions solutions of ammonia and of chromic acid. The dichromate, on heating, yields nitrogen, water, and chromic oxide, and forms a convenient method for the preparation of nitrogen free from argon.

Lead chromates. The neutral lead chromate $PbCrO_4$ is best produced by the action of a solution of lead acetate on a solution of a chromate. Thus produced, it is of a fine lemon-yellow colour, insoluble in water and dilute acids. When heated at 250°, it becomes a reddish-brown, at a higher temperature it fuses, and finally evolves oxygen with the formation of

chromic sesquioxide and a basic lead chromate. On account of this evolution of oxygen on heating, this substance is frequently used in organic analysis.

Lead chromate is soluble in cold lime water or caustic alkali, but is unattacked by hot lime water. For this reason, in immersing calico coloured with chrome yellow in lime water, for the production of an orange colour, care should be taken that the solution is hot.

When heated with caustic alkali, a portion of the chromic oxide is removed, with the production of a basic lead chromate of colour varying from orange to vermilion.

The *normal chromate* is largely used as a pigment, and for calico printing, and is the essential constituent of various chrome pigments as *Chrome yellow*, *Paris yellow*, *Leipsic yellow*. The name *Cologne yellow* was originally given to chrome yellow containing a mixture of lead chromate and lead sulphate, but the latter compound is usually present in pale yellows known commercially as 'pure' chrome yellows.

Chrome yellows. The finest chrome yellow is produced by precipitation; the lead acetate used should not be basic, or the product will be of an orange colour; the solution should be dilute, and the lead salt should be in excess; the presence of excess of chromate is liable to 'turn' the yellow—i.e. to produce an orange tinge. The substances used should be comparatively pure.

For the lighter yellows, the solution of chromate is mixed with an appropriate quantity of sulphuric acid, Glauber's salts or alum (American chrome yellow), before precipitation; the latter yields good colours but considerable care is required in the precipitation. The lead chromate is thus precipitated, together with any desired amount of sulphate, and the colour correspondingly lowered. For cheaper chromes, the colour is toned down by the admixture of kaolin, barytes, gypsum or whiting, the finely powdered solid being ground with water and well mixed with water in the tank into which the precipitating liquids are run (*vide infra*). Bouthron Chatard gives the composition of ordinary Cologne yellow as CaSO_4 , 60 p.c.; PbSO_4 , 15 p.c.; PbCrO_4 , 25 p.c.

Biot and Delisse first precipitate lead sulphate from a solution of the acetate, and digest 3 parts of the washed precipitate with 1 part of normal potassium chromate dissolved in hot water. The chromate is thus wholly converted into chrome yellow, mixed or perhaps combined with the lead sulphate, and a 'Cologne yellow' of good colour is produced. The colour is said to be equal to that obtained when double the quantity of chromate has been used. Its covering power is, however, stated to be inferior to that of the precipitated yellow.

Liebig uses for this purpose the lead sulphate obtained in dye works, &c., as a by-product. The pigment, on account of the basic character of the sulphate, is of an orange colour.

Anthon substitutes lead chloride for sulphate, treating 100 parts of freshly precipitated chloride with 27 parts of dichromate.

The method usually adopted for production of chrome yellow is the following: The two precipitating solutions are placed separately in wooden tanks, and heated by steam pipes.

The solutions are either filtered or allowed to settle in the tanks and drawn off from above. They are run together into the precipitating tank, which contains about 200 gallons. The chrome yellow is allowed to settle and the clear liquid drawn off; more water is added, the whole thoroughly stirred and the process is repeated three or four times. The pigment is then put in a filter press and dried at as low a temperature as possible.

According to the Textile Colourist, the preparation of chrome yellow is as follows: For the preparation of the lead acetate, four wooden tubs, 3 feet in diameter and $1\frac{1}{2}$ feet high, are arranged one above another, so that the liquid may pass downwards from one to the other. They are filled with granulated lead, and strong wood vinegar poured on the uppermost; after remaining there for a few minutes, it is run into the second, third, and fourth for an equal time. The surface of the lead is thus thoroughly acted upon, and becomes heated and oxidised by the air. The vinegar is then passed through a second time, remaining in each tub for an hour; on leaving the fourth tub, a saturated solution of acetate is produced.

Bichrome is dissolved in 10 or 12 parts of water in steam-cased copper pans, and sufficient acetate added to just precipitate the chromate completely. The precipitate is settled, washed by decantation, filtered, and dried slowly on boards. The filtration should be performed as rapidly as possible, because the pigment swells considerably while drying, and this should take place on the boards.

By mixing some lead chromate with the lead acetate solution, a dark lemon colour is produced, and by the addition of caustic potash to the precipitate, a much redder pigment may be obtained.

The chrome yellows, by mixture with Prussian blue, form greens known as 'Brunswick greens' and also as 'chrome greens' (not the true *chrome green*, *vide supra*). These are valuable and cheap pigments, but not as stable as the corresponding *zinc greens* (*vide infra*).

By removal of some of the acid from normal lead chromate, a *basic lead chromate* of a deep red colour is obtained, $\text{PbO} \cdot \text{PbCrO}_4$, which is the base of a number of *chrome reds*. Between these and the various yellows a large number of shades of *chrome orange* may be obtained. The chrome reds are known by a variety of names, e.g. *Austrian cinnabar*, *Persian red*, *Chinese red*, *Victoria red*, *Derby red*, *American vermilion*, &c.

The pigment is usually prepared by boiling chrome yellow with caustic alkali or by boiling together the lead salt, potassium dichromate, and an alkali. One such method is—20 parts of white lead are mixed into a fine paste with water, 10 parts of potassium dichromate and 3 of caustic soda, are dissolved in a little water, added, and the whole boiled until the desired colour is obtained. It is then washed and dried.

Runge mixes 45 parts of litharge, 6 parts of salt, and 50 parts of water; the mass becomes white, and swells considerably; more water is added to prevent it from hardening. In three or four days, the whole has been converted into lead oxychloride; a solution of 15 parts of potassium dichromate is then poured on, and the

mass well stirred and washed. A corresponding process is used with carbonate of lead, the colour produced being preferable to that when chloride, sulphate, or oxide of lead are used.

For the production of a fine 'Persian red,' Prinvolts digests 25 parts of lead carbonate in a cold solution of 10 parts of potassium chromate for 2 days. A red crystalline precipitate of basic lead chromate is thus produced, while potassium bicarbonate remains in solution. The mixture is boiled for half an hour, whereby a portion of the red precipitate becomes decomposed, with the formation of normal lead chromate and of potassium chromate, turning a violet-red colour. This is filtered off, washed, and digested with one part of sulphuric acid dissolved in 100 parts of water, with the production of 'Persian red.'

For the production of a fine vermilion pigment, Liebig and Wöhler's method may be used. A mixture of equal parts of potassium and sodium nitrates is just heated to fusion, and chrome yellow, in small fragments, is dropped in; ebullition takes place, and the mass becomes black. The heating should be continued until ebullition ceases. The chrome yellow has thus become converted into basic lead chromate and potassium chromate. If the temperature used be too high, the product becomes brown and is spoiled. The supernatant yellow liquid is poured from the heavy basic lead salt, which is then well washed in water. The washings should be poured off as quickly as possible, or the action is liable to be reversed and the normal chromate reproduced in part, with a corresponding reduction of colour.

The colour of the varieties of chrome red is due principally to the size of the crystals, those pigments of which the crystals are largest being of the most intense colour.

For the production of *chrome orange*, the chrome yellow is boiled with lime or alkali (in smaller quantity than that used for production of chrome red), until the shade required results. The cheaper chrome orange pigments, as in the case of the yellows, contain admixed kaolin, gypsum, &c.

The lead chromates all possess good covering power and brightness of colour; they are durable, but blacken under the action of sulphuretted hydrogen. They mix well with other pigments, but should not be used with sulphides.

Calcium chromate $\text{CaCrO}_4 \cdot 4\text{H}_2\text{O}$ is largely produced in the manufacture of chromates from chrome iron ore. It is soluble in water and alcohol. It becomes anhydrous at 200° , and is then almost insoluble in water.

Barium chromate BaCrO_4 is a canary-yellow powder, known as *Yellow ultramarine* or *Lemon yellow*. It is produced by the addition of a chromate to a solution of a salt of barium.

Barium chromate is insoluble in water and acetic acid, soluble in hydrochloric and nitric acids. On treatment with a boiling solution of chromium anhydride, it dissolves, and crystallises on cooling as a yellowish-red powder, consisting of the dichromate $\text{BaCr}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$.

Both barium and calcium chromates have been employed as pigments, but are now little used on account of their lack of brightness and covering power.

Bismuth chromates. The addition of potassium dichromate to a neutral solution of bismuth

nitrate gives a yellow flocculent precipitate, $3\text{Bi}_2\text{O}_3 \cdot 2\text{CrO}_3$, soluble in acids (Löwe). On heating, it becomes partly decomposed and turns greenish. From an *acid* solution of bismuth nitrate, the precipitate formed consists of $\text{Bi}_2\text{O}_3 \cdot 2\text{CrO}_3$ (Löwe; Muir), and is quite insoluble in water. Bismuth chromate is used as a pigment and in calico printing.

Zinc chromate, Zinc yellow, or Buttercup yellow ZnCrO_4 , is a beautiful, stable, yellow pigment, produced by the addition of hot neutral solution of zinc sulphate to potassium chromate, or by adding a cream of zinc oxide in water to a boiling solution of potassium dichromate.

Zinc chromate can be obtained in various tints and has a good colour. Though not equal to *chrome yellow* in covering power or body, it has the advantage of not blackening by exposure to sulphides. It is largely used for mixing with *Prussian blue* to form the *zinc greens*, which are more stable and faster to light than the corresponding *chrome greens*.

CHROMOCYANINES v. OXAZINE COLOURING MATTERS.

CHROMOMETERS v. COLORIMETERS.
CHROMOPHORES and **CHROMOGENS.**

The introduction of artificial dyestuffs of known constitution in the latter part of last century, drew attention to the question whether any relationship could be found connecting the colour of organic substances with their molecular structure. At the time, little information could be derived from a study of the natural dyestuffs in general use (e.g. indigo, alizarin, cochineal, &c.), since their constitution was unknown: the study of synthetic compounds promised results, and in 1876 an attempt was made by Otto Witt (Ber. 9, 522) to correlate colour and constitution.

These early endeavours were chiefly directed to finding an immediate relationship between structure and colour rather than to the general question of absorption spectra; in recent years a different standpoint has been adopted, and in studying absorption the invisible portion of the spectrum has been taken into consideration.

A substance is coloured on account of an absorption band or bands being produced in the visible portion of the spectrum, and physically there is only a difference of degree as to whether the absorption is of radiant energy of short wave-length in the ultra-violet, of medium wave-length in the visible spectrum, or of long wave-length in the infra-red. That a substance exerts selective absorption is probably due to its molecules having oscillation frequencies which correspond to certain wave-lengths of radiant energy, the energy corresponding to such wave-lengths being absorbed by the molecules.

The parent hydrocarbons (benzene, naphthalene, &c.) from which the artificial dyestuffs are derived, are colourless in the ordinarily accepted sense, but, if examined with regard to radiant energy of short wave-length (high-oscillation frequency) are found to exhibit distinct absorption bands in the ultra-violet spectrum (Hartley and Huntington, Phil. Trans. 1879, 170, i. 257; Hartley and Dobbie, Chem. Soc. Trans. 1898, 73, 695; Baly and Collie, *ibid.* 1905, 87, 1332; Hartley, Proc. Roy. Soc. 1908, 80A, 162). The hydrocarbons giving such selective absorption are, in general, members

of the aromatic series, or at any rate possess double linkages in conjugated positions. By substitution, it is possible to so retard the oscillation frequency that an absorption band (or bands) is formed entirely or partially in the visible spectrum. Thus, colourless benzene with its absorption bands entirely in the ultra-violet, may be converted into pale yellow nitrobenzene or into red azobenzene by introduction of a nitro group, or by linking up two phenyls by the azo grouping $\cdot N : N \cdot$.

Witt's theory started with facts of this character. Benzene is a colourless substance, but gives coloured derivatives when one (or more) of its hydrogen atoms is replaced by a group known as a *chromophor*. In general, the substance, though coloured, is not a dyestuff; in Witt's terminology it is known as a *chromogen*, since, by the introduction of salt-forming auxochromic groups, a dyestuff may be obtained.

As an illustration, consider the compounds derived from benzene by the introduction of the nitro and hydroxyl groups. Colourless benzene gives pale yellow nitrobenzene, the nitro group conditions the colour of the compound, and is hence known as the chromophor. Since phenol is colourless, the hydroxyl group is not looked on as a chromophor, but it has auxochromic properties. If introduced into the nitrobenzene molecule, a nitrophenol is produced which has distinct dyeing properties, although these are wanting in the chromogen nitrobenzene. (Whilst the mononitrophenols are of no technical importance as colouring matters, trinitrophenol or picric acid can be used as a dyestuff.)

The chief auxochromes are hydroxyl, the amino and the mono and di-alkylamino groups. Although the carboxyl and sulphonic groups are salt forming, they have, as a rule, no auxochromic influence. The alkoxy groups have a certain auxochromic effect, thus nitroquinol dimethyl ether and other similar compounds possess a yellow colour (Kauffmann, Ber. 1906, 39, 2722, 4237, 4243; Die Auxochrome, Ahren's Sammlung, 1907, xii).

The auxochromic effect of alkoxy groups is generally feeble, and an ether is usually lighter in shade than the coloured parent phenolic substance.

Acylation produces a much greater lightening effect than alkylation. Although amino-groups have a pronounced auxochromic effect which is shared by the mono- and di-alkylated derivatives, acylation of an amino group, as well as its conversion into a quaternary ammonium salt group, inhibits its auxochromic action. The inhibition of the auxochromic properties of hydroxyl groups by acylation may be illustrated by a reference to fluorescein. Fluoran, the chromogen of fluorescein, is a colourless compound, the introduction of two hydroxyl groups in the positions shown gives the brown compound fluorescein, whilst acetylation of fluorescein furnishes a colourless diacetyl derivative.

Diacetyl-fluorescein
(colourless).Quinol-phthalein
(colourless).

The examples just mentioned show that the chromogen may itself be devoid of colour, whilst comparison of fluorescein with quinol-phthalein shows that of two isomeric compounds, one may be coloured and the other colourless, the position of the auxochromic groups in the molecule having a decisive influence in most cases.

Chromophoric properties have been assigned to:

- The nitro ($\cdot NO_2$) and nitroso ($\cdot NO$) groups.
- The carbonyl ($: C : O$) and allied groups, e.g. $: C : S$ and $: C : N \cdot$.
- The azo group ($\cdot N : N \cdot$) and the nearly related hydrazone configuration, $: C : N \cdot NR \cdot$.
- The heterocyclic rings contained in polynuclear dyestuffs.¹

Whilst the chromophor theory has had its uses, difficulties are encountered which necessitate the modification of the original idea that colour is developed in a hydrocarbon structure by the mere introduction of a chromophoric group, the case of the hydroxyl derivatives of fluoran quoted above affording a good example. The difficulty is further increased when one takes into account the fact that coloured hydrocarbons are known. Bisdiphenylene-ethylene (Harpe and van Dorp, Ber. 1875, 8, 1049; Graebe, *ibid.* 1892, 25, 3146) has a red colour which cannot be ascribed to linkage of the benzene nuclei, since diphenyl is colourless. There is difficulty in ascribing chromophoric properties to the grouping $: C : C :$ since stilbene and tetraphenyl-ethylene (Behr, Ber. 1870, 3, 752, and others) are colourless compounds.

A different view as to the relationship between constitution and colour is due to H. E. Armstrong (Chem. Soc. Proc. 1888, 4, 27; 1892, 8, 101, 103, 143, 189, 194; cf. Hartley, *ibid.* 1892, 8, 188; and R. Nietzki, Organische Farbstoffe). There are practically no exceptions to the rule that dyestuffs easily take up two atoms of hydrogen, forming the so-called leuco-compounds, which are reoxidised more or less readily to the original coloured substances. The relationship of colouring matter to leuco-compound bears a close resemblance to the relationship of quinone, a coloured compound, to the colourless quinol.

Quinone.

Quinol.

Fluoran (colourless).

Fluorescein (brown).

¹ Certain non-metals such as iodine may occasionally act as chromophors (H. Ley, Die Beziehungen zwischen Farbe und Konstitution bei organischen Verbindungen, p. 20, S. Hirzel, Leipzig, 1911).

In fact, the parallelism is so close that a temptation arose not merely to recognise all quinones and quinonoid substances as coloured, but to class all organic coloured substances as necessarily quinonoid in structure. In certain cases, e.g. azobenzene, this led to strange distortion of the usually accepted formulæ, whilst such compounds as hydroxyazobenzene were written with a possibly greater show of reason and probability as quinone-hydrazone. Substitution experiments indicate, however, that hydroxy- and amino-azobenzene and other allied compounds, are not of quinone-hydrazone type, although the salts they form with mineral acids have a quinonoid structure (see Farmer and Hantzsch, Ber. 1899, 32, 3089; Armstrong, Chem. Soc. Proc. 1899, 15, 243; Hewitt, Chem. Soc. Trans. 1900, 77, 99; Hewitt and Aston, *ibid.* 712, 810; Auwers, Ber. 1900, 33, 1302).

Whilst the quinonoid and chromophor theories have their limitations, no doubt can exist as to the utility of both these ideas in leading to the preparation of new dyestuffs as well as many interesting compounds, amongst which may be mentioned the coloured tetraphenylquinodimethane (1 : 4-bis(diphenylmethylene- $\Delta^{2,5}$ -cyclohexadiene)

of Thiele and Balhorn (Ber. 1904, 37, 1463; cf. Staudinger, Ber. 1908, 41, 1355). The production of coloured carbonium salts by the action of acids on carbinols, which von Baeyer at one time attributed to the presence of halogen in an ionisable condition (Ber. 1905, 38, 569), is now more frequently ascribed to the assumption of quinonoid structure.

(See Norris and Saunders, Amer. Chem. J. 1901, 25, 54; F. Kehrmann and F. Wentzel, Ber. 1901, 34, 3815; Gomberg and Cone, Ber. 1907,

40, 1847; 1909, 42, 406; Annalen, 1909, 370, 145; K. A. Hofmann, Ber. 1909, 42, 4856; 1910, 43, 183; Flürschein, Chem. Soc. Trans. 1910, 97, 91.)

In recent years, considerable attention has been paid to the question of what molecular structures would be likely to correspond to more or less definite periods of molecular vibration, thus causing selective absorption; if this absorption is within certain limits of wave-length, visible colour will be produced. In 1900 Hewitt (Zeitsch. physikal. Chem. 34, 1) put forward the view that symmetrical compounds, capable of equal tautomeric displacements in either of two directions, should be those to exhibit the phenomenon of fluorescence, for the molecule would swing between the two extreme positions like a pendulum, the energy absorbed of one wave-length being degraded and given out with slower frequency. This idea was supported by the examination of a number of cases.

In 1904 Baly and Desch (Chem. Soc. Trans. 85, 1029) stated that in the case of tautomeric compounds 'the absorption bands are due to the oscillation between the two isomerides,' and that as a tautomeric compound altered its configuration, so would energy of fairly definite wave-length be selectively absorbed. This idea was based on the observation that whilst metallic derivatives of ethyl acetoacetate show marked selective absorption, the alkyl derivatives, ethyl β -ethoxyacetate

and ethyl ethylacetoacetate

exhibit respectively merely general absorption and transparency at the concentrations and thicknesses examined.

Baly and Desch (Chem. Soc. Trans. 1905, 87, 768) state that 'no organic substance shows an absorption band unless a possibility of tautomerism exists in the molecule. Secondly, this tautomerism need not be due to a labile atom, but may be of the same order as that occurring in those aromatic substances containing the true benzenoid structure. Thirdly, in all cases of the simpler tautomeric molecules, the vibration frequencies of the absorption bands are very nearly the same. Fourthly, an increase in the mass of the molecule causes a decrease in the oscillation frequency of the absorption band.'

At a later date, the idea of tautomeric change had to be somewhat extended since camphorquinone and ethyl pyruvate, compounds in which no tautomerism, in the ordinary sense, can be detected, also show selective absorption. The idea was suggested that in the case of such compounds, rearrangement of linkages occurred which, in the case of ethyl pyruvate, may be represented by the formulæ

To linkage change of this type, the term *Isorropesis* was applied (Stewart and Baly, Chem. Soc. Trans. 1906, 89, 498).

In later papers, application of these views was made to the case of the nitrophenols, the nitroanilines, and their salts. Armstrong pointed out that whilst practically colourless nitrophenol is probably a benzenoid compound,

its sodium salt may have a quinonoid structure; this relationship is exhibited by the formulæ

Study of the absorption spectra of the nitrophenols and their alkaline derivatives led Baly, Edwards, and Stewart (Chem. Soc. Trans. 1906, 89, 514) to agree with this view, but recently, Baly, Tuck, and Marsden have abandoned the hypothesis of quinonoid transformation on salt formation or ionisation taking place (Chem. Soc. Trans. 1910, 97, 571, 1494). Evidently the structure of these substances must eventually be settled by chemical methods, whilst the isolation of highly coloured labile *aci*-ethers of the nitrophenols by Hantzsch and Gorke (Ber. 1906, 39, 1073), may be adduced as evidence in favour of the quinonoid structure of the metallic salts.

Hypotheses, involving oscillation of linkages, have been put forward by other authors to explain the colour of certain classes of compounds. Morgan observed colour in the case of certain diazonium salts (Chem. Soc. Trans. 1908, 93, 614; 1909, 95, 1319), which he supposes is conditioned by a rhythmical change of linkage in the molecule which can be represented by the following scheme:—

Von Baeyer (Annalen, 1907, 354, 164) has suggested that the intense colour of the triphenylmethane dyestuffs is conditioned by an oscillation of the quinonoid linking between two benzene nuclei, the parent quinonoid substance, fuchsonium chloride $\text{C}(\text{C}_6\text{H}_5)_2(\text{C}_6\text{H}_4:\text{NH}_2\text{Cl})$ not being a dyestuff, although it possesses an orange shade. A further development of these ideas is due to A. G. Green (J. Soc. Chem. Ind. 1909, 28, 638), who points out that the similar crimson-red colour given by aqueous solutions of the sodium salt of aurin and the hydrochloride of rosaniline, are hardly explicable, using the ordinary formulæ for these compounds.

In one case, the salt formation occurs with regard to the non-quinonoid nucleus; in the other case it is the quinonoid nucleus that has salt-forming properties. If, however, the sodium and chlorine ion in the two cases be supposed to be oscillating constantly between the two groups, the distinction disappears, for both groups may be considered as engaged in the salt formation.

Meanwhile, it must be remembered that the

exhibition of colour is not confined to aromatic compounds; fulvene and its alkyl derivatives are coloured, as are also the fulgides described by Stobbe. In the latter case, it may be mentioned that aromatic derivatives have a deeper shade than fulgides in which only alkyl groups have been introduced.

In every case of coloured compounds, the molecules contain not merely double linkages, but these linkages are in a conjugate position. Generally speaking, the longer the chain of conjugate linkages, the slower the oscillation frequency of the molecule: this was pointed out by Hewitt and Mitchell, in the case of the *p*-nitroarylazophenols (Chem. Soc. Trans. 1907, 91, 1251).

An excellent example of the necessity of conjugate linkages is afforded by ω -azotoluene, described by Thiele (Annalen, 1910, 376, 265). This is a colourless substance. The comparison between this compound and azobenzene and the intermediate compound containing the phenyl and benzyl radicals on either side of the azo-group, is instructive, for the deepest colour is shown by the substance possessing the lightest molecule.

$\text{C}_6\text{H}_5 \cdot \text{N} : \text{N} \cdot \text{C}_6\text{H}_5$	M.W.182	Red crystals
$\text{C}_6\text{H}_5 \cdot \text{CH}_2 \cdot \text{N} : \text{N} \cdot \text{C}_6\text{H}_5$	M.W.196	Yellow oil
$\text{C}_6\text{H}_5 \cdot \text{CH}_2 \cdot \text{N} : \text{N} \cdot \text{CH}_2 \cdot \text{C}_6\text{H}_5$	M.W.210	Colourless crystals

In this case one is considering three compounds, each of which contains the chromophore $\text{N} : \text{N}$ and possesses the same number of double linkages. Here decreasing molecular weight is associated with increase in length of chain of conjugated double linkages, and increasing depth of colour is the result.

An attempt to explain the dependence of oscillation frequency on length of conjugate chain, from a mechanical point of view, has been made by Hewitt (1909, VII. Internat. Cong. of Appl. Chem.). The mass of carbon atoms in such a chain is proportional to the number of double linkages, but should a displacement of linkages occur, the restoring force will not be proportional to the number of double linkages, for whilst the doubly bound carbon atoms move further from one another, those connected by single linkages approach. Hence the ratio of restoring force to mass displaced will decrease with increasing length of chain and the oscillation frequency be diminished in consequence.

Selective absorption must be studied in conjunction with other optical properties, and reference should be made to Lowry's Studies of Dynamic Isomerism, especially to four papers in conjunction with Desch (Chem. Soc. Trans. 1909, 95, 807, 1340; 1910, 97, 899, 905). These deal with an extensive investigation of camphor derivatives, and afford useful evidence of the connection existing between conjugation of double linkages and selective absorption of radiant energy.

The question whether chemical combination is effected by electronic displacement does not come within the scope of this article; that such a conception may form the basis of a theory of selective absorption has been discussed by J. Stark (Phys. Zeitsch. 9, 85), H. Kaufmann (*ibid.* 9, 311) and H. Ley (*op cit.* pp. 68 *et seq.*). J. T. H.

CHROMOTROPES v. AZO-COLOURING MATTERS.

CHRYSANILINE*Diamidophenylacridine*

$C_{16}H_{12}N_2$, is obtained as a by-product in the manufacture of rosaniline by the arsenic acid method, and was isolated by Nicholson (Dingl. poly. J. 168, 133) by treating the residue with steam, whereby chrysaniline passes into solution and can be precipitated therefrom by addition of nitric acid. It was further examined by Hofmann (Ber. 1869, 378), who prepared its methyl-, ethyl-, and phenyl-derivatives. Its composition and constitution were first established by Fischer and Körner (Ber. 1884, 203; Annalen, 226, 175; compare also Anschütz, Ber. 1884, 433), who refer its formation in the rosaniline melt to a condensation and subsequent oxidation of orthotoluidine and aniline, since they have effected its synthesis by heating with arsenic acid at 180° - 200° the orthodiparatriaminotriphenylmethane obtained by Renouf (Ber. 1883, 1304) by the action of dehydrating agents on a mixture of orthonitrobenzaldehyde and aniline (v. also Ostrogovich and Silbermann, Chem. Zentr. 1907, i. 1195).

Properties.—Chrysaniline crystallises with 2 mols. of H_2O from 50 p.c. alcohol in golden-yellow needles, and from benzene with 1 mol. of benzene of crystallisation in golden-yellow scales; the latter melt, when placed in a bath heated at 150° - 160° , but when slowly heated lose the associated benzene, and melt, like the former, at 267° - 270° . It is insoluble in water, and sparingly soluble in alcohol. On oxidation with chromic acid, it yields acridine and when diazotised is converted into phenylacridine (m.p. 164°). Tetrazo-compounds have been prepared, but their couple products with amines, phenols, &c., are not as good dyes as those obtained from chrysaniline and its salts (Trillat and de Raczkowski, Compt. rend. 114, 1024). Formaldehyde reacts with chrysaniline, yielding an orange dyestuff similar to chrysaniline in its tinctorial properties (T. and de R. Compt. rend. 116, 1382). *Chrysofenol* $C_{15}H_{11}N_2O$, a yellow dye, is obtained when it is heated at 160° - 180° with concentrated hydrochloric acid, and crystallises from dilute alcohol with 2 mols. of H_2O in ruby-red needles. Chrysaniline forms two series of salts; of these, the sparingly soluble nitrate is the most characteristic: it crystallises in ruby-red needles, and is employed under various names as a valuable golden-yellow dye for silk, wool, and leather (v. ACRIDINE DYESTUFFS).

CHRYSAROBIN $C_{15}H_{12}O_5$ [*Chrysophananthranol* (Hesse, J. pr. Chem. 1908, 77, 383)]. This substance is a constituent, to the extent of 84 p.c. (Attfeld), of araroba or Goa powder, the pith of a tree belonging to a species of *Cæsalpina* (Holmes, Pharm. J. [3] 5, 801), and was first extracted therefrom by Attfeld (*ibid.* [3] 5, 721), who believed it to be chrysophanic acid, into which, indeed, it is readily converted on oxidation (Liebermann and Seidler, Annalen, 212, 36). Chrysarobin is extracted from Goa powder by hot benzene, and when crystallised from glacial acetic acid forms small yellow laminae. The constituents of commercial chrysarobin are *chrysophanic acid* (5 p.c.); *emodin monomethyl ether* (2 p.c.); the *anthranol of chrysophanic acid*, 'chrysarobin' (46 p.c.), m.p. 202° (corr.); the *anthranol of emodin monomethyl ether* (trace); *monomethyl ether of dehydroemodinanthranol*

$C_{16}H_{12}O_4$ (18 p.c.); *ararobinol* $C_{23}H_{16}O_5$ (4 p.c.); and an inseparable mixture of substances, together with amorphous material (about 25 p.c.) (Tutin and Iewer, Chem. Soc. Trans. 1912, 290; cf. Jowett and Potter, *ibid.*, 1902, 1575). The melting-points of specimens of commercial chrysarobin vary from 170° to 204° , according to the percentage of the constituents present (Hesse, Annalen, 309, 32; and Jowett and Potter, *l.c.*). It can be repeatedly crystallised without alteration, but is oxidised to chrysophanic acid when air is passed through its solution in aqueous caustic potash. On acetylation with acetyl chloride or acetic anhydride, a mixture of the di- and tetra-acetates of chrysarobin is obtained (Knoll and Co., D. R. P. 105871; Chem. Zentr. 1900, i. 524). *Eurobin* is a pharmaceutical preparation, consisting chiefly of the diacetyl-derivative (Hesse, Annalen, 309, 32). It is distinguished from chrysophanic acid by dissolving in concentrated sulphuric acid with a yellow, and in concentrated aqueous caustic potash with a dark-green colour, whilst dilute aqueous potash does not dissolve it; chrysophanic acid, on the contrary, yields a red solution with concentrated sulphuric acid and dilute aqueous potash (Liebermann and Seidler, Ber. 11, 1603). Another method to distinguish chrysarobin from chrysophanic acid is the following: 0.05 gram of the substance is mixed with 0.2-0.3 gram of sodium peroxide in a porcelain capsule, and 5 c.c. of alcohol are added; after 5 minutes 15 c.c. of water are added. Under these conditions, chrysarobin yields a wine-lees colour, not destroyed by dilution with water, changing to yellow on the addition of acetic acid. Chrysophanic acid yields a cherry-red colour, becoming brighter on dilution (Alvarez, Ann. Chim. anal. 1907, 9) (v. ARAROA POWDER).

CHRYSATROPIC ACID v. LACTONES.**CHRYSAZIN** v. ALIZARIN AND ALLIED COLOURING MATTERS.**CHRYSENE** $C_{15}H_{12}$ or $\begin{matrix} < C_6H_4 \cdot CH \\ < C_{10}H_7 \cdot CH > \end{matrix}$

This hydrocarbon occurs in the highest boiling portions of coal tar, and in the tarry products obtained in the dry distillation of wood, fats, and oils (Laurent, Ann. Chim. Phys. [2] 66, 136). Synthetically, it can be prepared by passing through a red-hot tube the vapour of benzyl-naphthylmethane (Graebe and Bungener, Ber. 12, 1078), or those of cumarone and naphthalene, which condense with the loss of a molecule of water (Kraemer and Spilker, *ibid.* 23, 84).

Purification.—Chrysene is extracted from the mixture of solid hydrocarbons consisting chiefly of pyrene and chrysene, which boil at a higher temperature than anthracene, and constitute the last portions of the distillate from coal tar, by repeated digestion with carbon disulphide in the cold. This treatment removes all the hydrocarbons in the mixture except chrysene (present to the extent of 18-19 p.c.), and this is further purified by crystallisation from coal oil (b.p. 150°), from which it separates in golden-yellow scales. The yellow colour, due to an impurity, cannot be removed by repeated crystallisation, but is destroyed by boiling with alcohol and a small quantity of nitric acid (Liebermann, Annalen, 158, 299).

A second method for obtaining chrysene

from crude greenish-yellow anthracene (m.p. 207°-208°) has been described by Schmidt (J. pr. Chem. [2] 9, 250, 270). For this purpose, 40-50 grams of the anthracene are dissolved in 5 litres of strong (95 p.c.) alcohol, and the solution, after filtration, is boiled with 30 grams of nitric acid (sp.gr. 1.4) in a reflux apparatus for some time. On cooling, red needles of a sparingly soluble compound of chrysene and dinitroanthraquinone $C_{18}H_{12}, C_{14}H_6(NO_2)_2O_2$ separate, which, when treated with tin and hydrochloric acid, decompose into chrysene and reduction compounds of dinitroanthraquinone. The hydrocarbon is then obtained pure and colourless by crystallisation from benzene.

Properties.—Chrysene crystallises in scales, or in well-defined, colourless rhombic plates, melts at 250° and boils at 448° (Schweitzer, Annalen, 1891, 193). It is a sparingly soluble substance; for example, 100 parts of absolute alcohol dissolve 0.097 part at 16°, and 0.17 part at 18°, and 100 parts of toluene dissolve 0.24 part at 18°, and 5.39 parts at 100° (v. Beech, Ber. 12, 1978), whilst ether, carbon disulphide, benzene, and acetic acid dissolve it only to a slight extent at the ordinary temperature, but more readily on boiling. The solutions, like the pure hydrocarbon, show a deep reddish-violet fluorescence. On adding chrysene to a solution of formaldehyde and sulphuric acid, a reddish-violet colour is produced; this is destroyed by the addition of water (Ditz, Chem. Zeit. 31, 445). The absorption spectrum of chrysene has been studied by Baly and Tuck (Chem. Soc. Trans. 1902, 14). Chrysene combines with dinitroanthraquinone and with picric acid (trinitrophenol) to form characteristic compounds; the *picrate* $C_{18}H_{12}, C_6H_3(NO_2)_3OH$, obtained by adding chrysene to picric acid in benzene solution, crystallises in long red needles, and is decomposed by alcohol (Liebermann, Schmidt). When heated with concentrated sulphuric acid, chrysene yields a sulphonic acid, and when treated with nitric acid, under varying conditions, yields mono, di, and tetra nitro derivatives (*ibid.*), whilst chlorine and bromine convert it into substitution-derivatives (Schmidt). Aminochrysene is obtained by the reduction of nitrochrysene with phosphorus and hydriodic acid (Abege, Ber. 1893, 792), or with tin and hydrochloric acid (Bamberger and Burgdorf, *ibid.* 1893, 1006). On oxidation with chromic acid in acetic acid solution, chrysene is converted into *chrysoquinone* $C_{18}H_{10}O_2$, which crystallises in yellowish-red needles, melts at 235°, yields azines on treatment with ortho-diamines (Liebermann and Witt, *ibid.* 20, 2242), and is characterised by dissolving in concentrated sulphuric acid with a blue colour.

CHRYSEOLIN v. AZO-COLOURING MATTERS.

CHRYSYN, 1:3-dioxyflavone $C_{15}H_{10}O_4$, is obtained from poplar buds (Piccard, Ber. 1874, 88; and Darier, *ibid.* 1894, 21). It has been synthesised by treating phloracetophenone with ethyl benzoate in the presence of sodium, when 2:4:6-trimethoxybenzoylacetophenone is formed; on boiling with hydriodic acid, the methyl-groups are eliminated, condensation takes place with the production of 1:3-dioxyflavones (Emilewicz, Kostanecki and Tambor, *ibid.* 1899, 2448; 1904, 3167). It is a yellow crystalline solid, melting at 275°. By heating

it on the water-bath with methyl iodide and potassium methoxide, tecto-chrysin, which also occurs in poplar buds, is formed (Emilewicz, Kostanecki and Tambor, *l.c.*). Chrysin is a member of the quercetin series (Perkin, Chem. Soc. Trans. 1896, 1443), and dyes cloth mordanted with aluminium a pure yellow; with chromium, an orange-yellow; and with iron, a pale chocolate (Perkin, *ibid.* 1897, 818).

CHRYSOBERYL, *Glucinum aluminat* (v. ALUMINIUM).

CHRYSOCOLLA. The Greek name for borax. Now applied to copper silicate (v. COPPER).

CHRYSOGEN. An orange-coloured substance, containing more than 94 p.c. of carbon, and said to be a hydrocarbon, discovered by Fritzsche (Zeitsch. Chem. 1866, 139) in crude anthracene. It is sparingly soluble in the ordinary organic solvents. In sunlight, its solutions become rapidly bleached, and yield a colourless crystalline compound which, on fusion, becomes orange-yellow.

CHRYSOIDINES v. AZO-COLOURING MATTERS.

CHRYSOÏN v. AZO-COLOURING MATTERS.

CHRYSONAPHTHAZINE v. AZINES.

CHRYSPHANIC ACID $C_{15}H_{10}O_4$ (De la Rue and Müller, Chem. Soc. Trans. 1858, 10, 298; Thann, Annalen, 107, 324). This acid occurs in the roots of various species of *Rheum* and *Rumex* (H. Grothe, Pogg. Ann. 113, 190). It can be obtained from rhubarb root, in which it occurs together with emodin, by extraction with benzene. After removal of the benzene by distillation, the residue is treated with aqueous caustic soda whereby emodin and other impurities are removed while the acid remains undissolved (Liebermann and Fischer, Annalen, 183, 158). According to Hesse (*ibid.* 1895, 284, 191), it is better to use ether and sodium carbonate instead of benzene and caustic soda in this extraction. The acid obtained from rhubarb always contains the methyl ether of dichrysarobin (Jowett and Potter, Chem. Soc. Trans. 1902, 1575). Chrysophanic acid may also be obtained from chrysarobin by oxidation with air in alkaline solution; the acid is then precipitated by the addition of a mineral acid, and crystallised from petroleum spirit (Liebermann and Seidler, Ber. 11, 1603).

Chrysophanic acid crystallises from alcohol in golden-yellow needles, and melts at 186°-188° (Hesse, Annalen, 1899, 32) at 190°-191° (Grandis, Chem. Zentr. 1892, i. 592; Jowett and Potter, *l.c.*). It dissolves in 1125 parts of alcohol (86 p.c.) at 30°, and in 224 parts at the boiling-point, and is soluble in hot benzene, acetic acid, and amyl alcohol. When heated with zinc-dust, it yields a methylanthracene. Reduction with hydriodic acid yields chrysophanohydroanthranole (Hesse, Annalen, 1896, 305), which has been proved to be identical with chrysarobin (Jowett and Potter, *l.c.*). Concentrated sulphuric acid and aqueous alkalis dissolve it, forming red solutions. Chrysophanic acid can be methylated by means of methyl sulphate and alkali hydroxide (Oesterle, Arch. Pharm. 1905, 243, 434) or by sodium and methyl iodide (Tutin and Clewer, Chem. Soc. Trans. 1910, 6 (v. also CASCARA SACRADA)).

CHRYSPHENIN v. AZO-COLOURING MATTERS.

CHRYSOTOLUAZINE *v.* AZINES.

CHRYSOTOLUIDINE $C_{21}H_{21}N_3$. A yellow crystalline base of unknown constitution (*cf.* Hofmann, Ber. 2, 380), occurring in the residue obtained in fuchsin manufacture by the arsenic acid method (Girard, De Laire, and Chapoteaud, Compt. rend. 63, 964; 64, 416). The hydrochloride is a yellow dyestuff.

CHRYSYL. Trade name for zinc boropierate obtained by boiling together solutions of boric and pieric acids with zinc oxide; used as an antiseptic.

CHYMASE *v.* FERMENTATION.

CIDER or **CYDER** is a vinous beverage produced by the fermentation of the juice of apples. Perry is a similar article made from pears. The two are very much alike in character, and, the principles of manufacture being generally the same for each, reference will be made to cider only in this article, except when occasion requires the special mention of perry.

The largest cider-producing country of the world is France, followed by England, Germany, the United States and Canada, and it is now also produced in increasing quantities in other countries, notably Ireland and Australia. In England the principal cider-growing districts are the counties of Somerset, Devon, and Hereford, smaller quantities being made in Gloucester, Worcester, Monmouth, Kent, and Norfolk. The mean annual production of the United Kingdom is estimated at 100,000,000 gallons, of a value of about 3,000,000*l.*

The ordinary cider of commerce in England is a beverage of widely varying character. It may contain as little as 2 p.c. or as much as 8 p.c. of alcohol by weight, depending on the apples from which it is made, and the process of its manufacture, particularly the stage at which the fermentation has been stopped. Apart from its characteristics of flavour, body, and colour, cider may be roughly divided into three classes or grades, viz.: sweet, which has been only slightly fermented; dry, well fermented; and medium, between the two. Apple juice of fair average quality has a sp.gr. of about 1050 to 1055, corresponding to 10–12 p.c. of sugar. As the fermentation produces, roughly, 1 p.c. of alcohol from every 2 p.c. of sugar, the following table shows the approximate comparative composition of apple juice, and the three grades mentioned:—

	Sp.gr.	Sugar	Alcohol
Apple juice . . .	1050–1055	10–12 p.c.	—
Sweet cider . . .	1030–1035	6–7	2–2½ p.c.
Medium cider . . .	1015–1025	4–5	3–4
Dry cider . . .	1000–1010	0–2	5–6

The rough cider of the farmhouse, found in the south-western counties, is of a very dry grade, being fully fermented, no attempt being made to check the 'working,' while the ordinary cider (bottled and draught), found in the average hotel in cities, is a beverage which has been but slightly fermented, and is of the sweet to medium grade, the greatest public demand being for cider as a summer beverage, light, sweet, and refreshing. It must not be assumed, however, that all bottled cider is sweet, for it is obtainable from several firms of repute in four well-defined grades—sweet, medium, dry, and extra dry.

The raw material from which cider is made varies in composition and character as much

as the cider itself. The majority of English orchards were originally stocked with almost innumerable varieties of apples and pears, most of them of inferior quality, for either table use or for the manufacture of cider or perry; but great improvements have of late years been made in the planting and cultivation of the orchards, with a corresponding improvement in the quality of the beverages produced. Speaking generally, it may be said that good cider cannot be made from any but essentially vintage varieties of apples, most of which are quite unsuited for table use because of their astringency, due to the large proportion of tannin they contain. The majority of table varieties yield a juice deficient in sugar and tannin, with a large excess of acidity, as compared with the vintage sorts, which are cultivated specially for the manufacture of cider. This is particularly applicable to perry pears, which are almost invariably very astringent in taste, although it is curious to note that the percentage of tannin they contain is not exceptionally high. To make good cider, the sp.gr. of the juice should not be under 1050; it should contain at least 0.15 p.c. of tannin, which gives keeping and clearing properties, with an acidity not exceeding 0.5 or 0.6 p.c. of malic acid, while those substances which constitute 'body,' consisting of mucilage, albumen, salts, colouring matter, &c., are also of importance; but, having been very little investigated, it is impossible to state definitely what proportions of each are necessary. A high sp.gr. with a correspondingly high sugar content, is generally considered the most important quality, but some apples are known to yield a juice high in sp.gr. but deficient in colour and body (the two are usually associated), while others of a low sp.gr. but rich in colour and body, may produce cider of better quality than the first-mentioned. Too much reliance, however, must not be placed on the mere chemical composition of the juice as indicative of the value of an apple for cider making, the characteristic flavour of the variety and the rate of fermentation, which varies greatly with different juices, being at least equally important.

Vintage apples are roughly divided into three classes—sharp, sweet, and bitter-sweet. The following table shows typical analyses of the juice of several of the best of each class, together with that of a hitherto unknown and unnamed variety recently found in Somerset ('Butleigh No. 14'), which is of outstanding merit:—

No.	Variety	Sp.gr.	Malic acid	Tannin	Total sugar
1.	Kingston Black	1060	0.54	0.126	12.66
2.	Foxwhelp . . .	1059	1.04	0.270	13.25
3.	Cowarne Red . . .	1054	0.65	0.230	12.05
4.	Sweet Alford . . .	1057	0.14	0.120	12.19
5.	White Jersey . . .	1060	0.25	0.190	13.33
6.	Cherry Norman . . .	1055	0.21	0.354	12.25
7.	Horner . . .	1053	0.15	0.240	11.89
8.	Royal Jersey . . .	1065	0.16	0.380	15.00
9.	Barland . . .	1054	0.62	0.119	11.32
10.	Butt . . .	1053	0.66	0.270	11.75
11.	Oldfield . . .	1068	0.80	0.128	14.92
12.	'Butleigh No. 14'	1104	0.24	0.258	22.22

Nos. 1, 2, and 3 are sharp varieties; 4 and 5, sweet; 6, 7, and 8, bitter-sweet; 9, 10, and 11, perry pears; 12, a bitter-sweet of unusually high quality.

The process of cider making is of very ancient origin, but modern scientific cider making may be said to date from the year 1893, when the Bath and West of England Agricultural Society instituted some chemical and bacteriological research into the subject, a work which was carried on by Mr. F. J. Lloyd for some seven years in Somerset, and has subsequently been continued on a more ambitious scale at the National Fruit and Cider Institute, near Bristol, under the direction of Mr. B. T. P. Barker. The results of these investigations form the foundation of modern cider making, and the reports thereon constitute the most trustworthy literature on the subject.

Whereas the quality of the cider depends primarily on that of the juice used, the nature of the product is largely influenced by the methods of manufacture and fermentation, and general management. The making of cider begins in the orchard, for no good beverage can be made from fruit which has been carelessly gathered or stored. It should be shaken from the trees when just ripe, bruising being avoided as far as possible, and stored in heaps (preferably under cover if the weather be wet), until it becomes soft and mellow, but not over-ripe, care being taken to avoid either washing by rain, which results in the loss of sugar and yeast, or heating, which produces a fustiness in the cider, as well as a great tendency to acetic fermentation. When thoroughly mellow, the fruit is selected and blended in the proportions necessary to give the degree of sweetness, acidity, and astringency required for the variety of cider it is intended to make. Sweet cider is best made from a blend of sweet, sharp, and bitter-sweet apples; while dry cider should be made from a blend giving a minimum of acidity, with only a moderate proportion of tannin. Very few varieties of apples are individually capable of producing the finest cider, an appropriate blending of varieties being necessary. This does not apply to pears and perry making, single varieties, unblended, usually giving best results. In the actual processes of grinding the fruit and expressing the juice, steam-power is generally used in modern factory practice, but, apart from economic reasons, this has no advantage over the old-fashioned hand-power machinery of former days. The fruit is ground to a fine pulp, called 'pomace,' which falls upon the press, is held together in thin squares by manilla or hempen cloths, and is usually pressed at once. In some places, however, the pomace is allowed to remain in tubs for 12 or 24 hours before pressing, which is said to improve the quality of the resulting liquor, but there seems to be no scientific reason for this custom, and investigations have failed to show that sufficient advantages are gained to compensate for the work it entails. With efficient presses, about 70 p.c. of the weight of apples is obtained as juice, and 80 p.c. in the case of pears. The most profitable means of utilising the dry-pressed pomace is as cattle food. In France the juice is sometimes extracted by the 'diffusion' process in use in the beet-sugar industry, but

this does not meet with general approval. The fresh juice is run into casks or open vats called 'keeves,' to undergo the important process of fermentation, which commences spontaneously in a few days, the time depending on the character of the juice and the temperature. An important question here arises: Shall the cider be allowed to undergo a natural fermentation, or shall a pure culture of yeast be added to dominate it? At the present time this is a debatable point. While in France and Germany it is generally acknowledged that the use of pure cultures improves the quality of the liquor, and they are largely used, in this country it seems doubtful whether the advantages of their use are sufficient to compensate for the extra expense and trouble involved. Pure yeasts, isolated from the best growths of cider and wine, have been cultivated and added in sufficient quantity to dominate the fermentation and prevent the various wild races from exercising much influence. (Owing to the impossibility of avoiding a cooked taste, sterilisation, even at comparatively low temperatures, is not advisable.) The general results tend to show that fermentation by suitable yeasts gives a somewhat superior product to that obtained by natural fermentation; but the full advantages are not apparent until the cider is about a year old, whereas, in general practice, it is usual for it to be consumed before it attains that age. The use of pure cultures in the cider industry in this country is, for that reason, far from general, and it does not seem likely to make much headway in the present state of our knowledge of the subject. Little is known of the various species of yeasts naturally occurring on the skin of the apple, which subsequently develop in the cider, forming the 'lees' at the bottom, and conducting the fermentation, but the largest number consist of forms allied to the *Saccharomyces Ellipsoideus*, *S. Pastorianus*, and *S. apiculatus* types. A fairly slow fermentation is generally desirable, but, on the other hand, it is one of the most important points in the whole process that the primary alcoholic fermentation be vigorous enough, and is not checked too soon, otherwise the cider is laid open to the attacks of numerous undesirable organisms, which will show their effects in various 'diseases' during the following summer. The 'keeving' system of fermentation, in open vats with loose covers, is preferable to that in closed casks, as the 'head,' which is soon thrown up, consisting of yeasts and light portions of tissue, can be skimmed off from time to time. It is not advisable, however, to keep the cider in the keeves more than about a week, lest incipient acetic fermentation set in, and, as soon as no further head is thrown up, it is racked into closed casks to complete the primary fermentation. The subsequent conduct of this important process is governed by the grade of cider it is desired to make, the hydrometer being in regular use for watching the fall of the sp.gr. The rate of fermentation depends partly on the character and composition of the juice, and partly on the temperature; but these conditions are practically beyond control. Blending the apples to ensure the requisite degrees of sweetness and acidity in the juice will comply with one condition of a moderate rate,

but as the proportion of nitrogenous matter is of still greater importance, and is a subject on which, strangely enough, little is known, and no reliable figures obtainable, blending to ensure the proper percentage cannot be scientifically done. Regulating the temperature is also impracticable, for a large quantity of cider would have to be handled in a very short space of time, and this would be too expensive a process. A large plant would have to be fixed up, which could only be in use a few weeks each year, and possibly it would not be required at all. Whenever the sp.gr. approaches the point at which it is desired to stop the fermentation, the cider is racked off into clean casks, with or without sulphuring or the use of other preservative. This alone, however, is not usually sufficient to stop fermentation, unless an excessive quantity of preservative is used, or racking into sulphured casks be repeated several times. The best known means, which has the advantage of adding no materials of a questionable nature to the liquor, is to filter it through one of the many useful cotton-pulp filters now on the market. Even the use of a filter is open to some objections, for it removes some of the body (probably of a colloid nature) and flavour from the cider. The clarification also presents great difficulty with many ciders, neither isinglass finings nor boiled apple pulp, which are commonly used for the purpose, having any effect, so that the filter, which clarifies the cider, and at the same time stops the fermentation, is preferred in the absence of anything better for this purpose. Depending on various circumstances, the cider is filtered and stored away to mature in casks, at any time from two to four or even six months from the time of making. If filtered perfectly bright, and stored in clean casks, kept well filled, it will 'keep its sweets' for a whole season or longer, with the loss of only a few degrees of sp.gr., even though it may contain as much as 6 or 7 p.c. of fermentable sugar. During this period of storage, it mellows and develops its fragrant aroma and delicate flavour, and also loses a certain proportion of its acidity and astringency. The strongest and best cider will keep in cask for some years, but that of average quality is at its best within the first year. It keeps best and improves most in bottle, but only cider of good and sound quality should be bottled; it should have an original gravity of at least 1055, should undergo a vigorous primary fermentation, and be perfectly brilliant when bottled. The best age for bottling is from four to six months, and if not more than a year old at the time, it will develop sparkling condition like champagne after a few weeks' storage. The carbonating process of bottling is becoming more general, and there seems to be no objection whatever to its use, some of the best brands on the market having been treated in this way.

Matured cider is liable to several disorders or 'diseases,' the principal being acetification, 'sickness,' ropiness, and blackening. It is particularly apt to acetify on very slight provocation, and for this reason, exposure to air at all stages of manufacture is to be avoided. 'Sickness' is a recommencement of alcoholic fermentation, which is set up during the summer following its manufacture, and may occur in

cask or bottle. The cider becomes very turbid, and the production of alcohol is accompanied by the development of a most disagreeable smell and flavour, due, it is thought, to formation of acetaldehyde, together with an increase in acidity, partly lactic and partly acetic, which renders the liquor quite undrinkable. It is a source of great loss, for it usually attacks the richest and most fruity ciders, and is due to the action of several special organisms, contributing causes being a deficiency of malic acid in the juice, and a weak primary fermentation. Ropiness is not so frequently met with, and little is known of its causes in cider. Some ciders turn very quickly dark on exposure to air, some almost black in less than half an hour. This may be due either to an excess of iron acquired from the soil or from the utensils used in the making, or to enzymic action; the use of a little preservative often prevents its development.

A standard of chemical composition for what is sold as cider has been formulated in some countries, but not in Great Britain. Owing to the extreme variations in the character and composition of genuine cider, it is almost, if not quite, impossible to fix a definite chemical composition and say that it represents what should be considered a standard cider. For this reason, the standard fixed in foreign countries is necessarily very low, but while it probably admits of a certain amount of adulteration, it no doubt acts as a check. It can hardly be contended that nothing should be sold as cider which is not the pure juice of apples. Brewers, wine makers, and distillers are not restricted by law to the use of malt and hops, grape juice and malt respectively, in the making of their respective products, so that a law to limit cider makers to the use of apples only would operate unfairly against them as compared with the other trades mentioned. It has been stated that many varieties of cider apples grown in this country are not capable of making first-class cider, and the better sorts are in too small a minority to meet the demand. In poor vintage seasons, also, the general quality is low, sugar being deficient and acidity excessive. It is also undoubtedly true that cider made from the poorer varieties of apples, and in poor vintage years, is capable of great improvement by the addition of a certain proportion of cane-sugar syrup, as is done in the process of 'gallissising' wines, to obtain the correct proportion of acidity to sugar. It is difficult to say what maximum proportion of this syrup should be allowed, but there is very seldom any occasion for the use of more than 10-15 p.c. to make the cider suitable for the English market. The fact that there are so-called 'ciders' on the market, which are innocent of a drop of apple juice, shows the necessity for some sort of standard. Generally speaking, it may be concluded that no cider can be considered genuine which does not contain at least 2 p.c. of alcohol by weight, or which does not show an original gravity of 1045 or upwards. Another vexed question is that of the use of preservatives, some people contending that it is impossible to do without them, and others that they are not necessary if the cider be well and carefully made. There is much to be said on both sides. Some makers

sulphur their casks, thus adding a certain quantity of sulphurous acid to the cider; but it is generally considered, though very strangely, that this does not constitute the addition of any 'chemicals.' Others use sulphites or salicylic acid, and justify their use by the argument that all cider, no matter how carefully made, is peculiarly susceptible to various 'diseases' (such as 'sickness' and acetification, previously mentioned), and has often to be kept under conditions which render them unpreventable by any other known means, for example, on draught in a warm bar, perhaps for some weeks. There is certainly a great deal of reason in this, and it would probably be a hardship to absolutely prohibit the use of any preservative; but, on the other hand, they are sometimes used in needlessly excessive quantities, which, in the interests of the public health, should be avoided. The consumption of cider is greatly on the increase, due partly to its being recommended by medical men, and if it is to hold its own as a popular, and above all as a healthful, drink, it must be kept free from any ingredients of doubtful physiological effects.

Appended are analyses of a few typical ciders of well-known makes:—

Description	Sp-gr.	Alcohol by weight	Total acid	Total solids	Ash
Sweet sparkling	1025	4.65	0.24	5.98	0.245
Standard dry	1006	3.90	0.31	3.25	0.314
Standard sparkling	1015	3.90	0.53	6.00	0.360
Champagne perry.	1013	4.75	0.35	4.80	0.390

CINNABAR. Native mercury sulphide (HgS), and the only ore of this metal. Its crystals are rhombohedral, with perfect cleavages parallel to the faces of the hexagonal prism; they are of interest crystallographically in presenting the same type of trapezohedral symmetry as quartz, and, like this, they rotate the plane of plane-polarised light. They are bright-red in colour, often transparent, and have a brilliant adamantine to sub-metallic lustre; the scarlet streak is characteristic. Sp-gr. 8.1; hardness, 2-2½. The massive ore, which may be compact or earthy in texture, is of the same colour; but sometimes it is liver-brown or black, owing to the admixture of clay or organic matter, as in the varieties called respectively *hepatic cinnabar* and *coral-ore* (German, *Korallenerz*). Cinnabar is very sporadic in its distribution, and no mineral containing mercury has yet been found in the British Isles. It is mined at Almaden in Spain; Idria in Carniola; New Almaden, in California; and in the provinces of Kwei-chou and Hunan, in central China.

L. J. S.

CINNABAR, AUSTRIAN, *v.* CHROMIUM.

CINNAMALDEHYDE, *Cinnamic aldehyde*
 $C_6H_5 \cdot CH:CH \cdot CHO$, is contained, together with

a hydrocarbon, in oil of cinnamon and oil of cassia. It may be extracted from oil of cinnamon by shaking the oil with a concentrated solution of sodium bisulphite, filtering off the crystalline bisulphite compound, washing the latter with alcohol and distilling it with dilute sulphuric acid, when the cinnamaldehyde passes over with the steam. The cinnamaldehyde is extracted from the aqueous distillate with ether, and, after expelling the ether, is purified by distillation under a pressure of from 40 to 50 mm. (Peine, Ber. 1884, 2109). It may be extracted from cassia oil by adding to it the barium salt of sulphanic acid, filtering off the crystalline compound thus formed and steam distilling, whereby the compound is resolved into its components and cinnamaldehyde distils over (Ch. Fab. von Heyden Akt.-Gesell. D. R. P. 124229; Chem. Zentr. 1901, ii. 903). It is obtained by allowing a mixture of 10 parts of benzaldehyde, 15 of ordinary aldehyde, 900 of water, and 10 of a 10 p.c. solution of caustic soda to stand at a temperature of about 30° for from 8 to 10 days, shaking from time to time:

The solution is extracted with ether and the ethereal extract treated as in the foregoing method (Krzyszycia, Ber. 1884, 2117). It is best prepared by the condensation of benzaldehyde and ordinary aldehyde at a low temperature by means of a concentrated alkali solution. The alcoholic solution of the aldehydes, cooled to -10°, is agitated with a 25-30 p.c. solution of caustic soda, previously cooled to the same temperature. Under these conditions the formation of resins is avoided (Boehringer and Söhne, Eng. Pat. 10003; J. Soc. Chem. Ind. 1897, 463). Also formed when a mixture of calcium cinnamate and calcium formate is distilled (Piria, Annalen, 100, 105).

It is a colourless oil with a pleasant aromatic smell of cinnamon. It decomposes when distilled under ordinary pressures, especially with access of air, but may be distilled without decomposition in a current of steam or under reduced pressure. It boils at 120°-130° under a pressure of 20 mm. (Peine, Ber. 1884, 2110); at 209.5° under 250 mm. (Perkin, Chem. Soc. Trans. 1896, 1247) and solidifies at -7.5° (Pietet, Compt. rend. 119, 955); sp-gr. 1.0497 20°/4° (Brühl, Annalen, 235, 18).

By oxidation it yields first cinnamic acid and afterwards benzaldehyde and benzoic acid. Direct reduction does not lead to cinnamyl alcohol as the aldehyde polymerises. Reduction with the zinc-copper couple gives rise to hydrocinnamoin $C_6H_5(OH)_2(CH:CHPh)_2$ (Thiele, Ber. 1899, 1296). It gives the usual reactions of the aldehydes. The diacetyl derivative of the aldehyde, obtained by the action of acetic anhydride, can, however, be easily reduced by iron in acetic acid solution, and by subsequent saponification the alcohol is obtained (Barbier and Leser, Bull. Soc. chim. 1905, 858).

Estimation.—To estimate cinnamic aldehyde in oil of cinnamon or oil of cassia, 10 c.c. of the oil are heated on the water-bath, and a solution of sodium bisulphite added in small quantities, time being allowed for the solid to liquefy between each addition. The precipitate is filtered off and weighed (Schimmel, Chem. Zentr. 1892, i. 92).

Hanus (J. Soc. Chem. Ind. 1903, 1154) estimates cinnamaldehyde by means of its semioxamazine.

CINNAMEIN *v. Balsam of Peru*, art. BALSAM.

CINNAMIC ACID $C_6H_5 \cdot CH:CH \cdot COOH$. (*Acide cinnamique*, Fr.; *Zimmtsäure*, Ger.) β -Phenyl-acrylic acid. The separation of a solid acid from oil of cinnamon on keeping was first observed towards the end of last century, but the acid was confounded with benzoic acid, until Bizio, in 1826, showed that it was a distinct acid. It was first investigated by Dumas and Peligot (Annalen, 14, 56).

Occurrence.—In liquid storax, partly free, partly as cinnamyl cinnamate (styracin); in tolu and Peru balsams together with benzoic acid and benzyl cinnamate; in some sorts of gum benzoïn; in Barbados aloes; and in the leaves and stalks of *Globularia alypum* and *G. vulgaris*, in the leaves of *Enkianthus japonicus*, and as esters in many varieties of guttapercha.

Formation and Preparation.—It is formed by heating benzaldehyde with acetyl chloride at 120° – 130° (Bertagnini, Annalen, 100, 126):

$C_6H_5 \cdot CHO + CH_3 \cdot COCl = C_6H_5 \cdot CH:CH \cdot CO_2H + HCl$.
Perkin showed that it might be more readily obtained by heating a mixture of benzaldehyde, acetic anhydride, and anhydrous sodium acetate

$C_6H_5 \cdot CHO + (CH_3 \cdot CO)_2O = C_6H_5 \cdot CH:CH \cdot CO_2H + C_2H_4O_2$
(Chem. News, 32, 258; Chem. Soc. Trans. 1877, 388). Edeleano and Budishteano (Bull. Soc. chim. 3, [3] 191) state that by heating 1 part of benzaldehyde, 1 part of acetyl chloride, and 3 parts of sodium acetate for 24 hours at 160° , and subsequently extracting with alkali and precipitating the cinnamic acid with hydrochloric acid, the cinnamic acid is obtained in quantitative yield. The cinnamic acid employed in the preparation of artificial indigo was at first manufactured by this method; but the process was afterwards improved by Caro (D. R. P. 17467 and 18232; Frdl. i. 26), who showed that cinnamic acid could be prepared by heating benzaldehyde with dry sodium acetate, thus avoiding the use of the expensive acetic anhydride

$C_6H_5 \cdot CHCl_2 + 2CH_3 \cdot CO_2Na$
 $= C_6H_5 \cdot CH:CH \cdot CO_2H + 2NaCl + C_2H_4O_2$

1 part benzal chloride, and from 2 to 3 parts of finely powdered, fused sodium acetate (for which potassium acetate or a mixture of the potassium and sodium salts may be substituted) are heated at 180° – 200° for from 10 to 20 hours in an autoclave furnished with a mechanical stirrer. The melt is mixed with water, rendered alkaline with caustic soda, and steam-distilled to remove volatile oils, after which the solution in the retort is filtered hot, and the cinnamic acid is precipitated with hydrochloric acid, filtered off after allowing the solution to cool, pressed, and finally purified by recrystallisation from boiling water or alcohol. A method patented by the Farbwerke vorm. Meister, Lucius and Brüning (D. R. P. 18064), in which lead acetate is substituted for sodium acetate, offers no advantages over the foregoing.

Cinnamic acid may be prepared from benzylideneacetone $C_6H_5 \cdot CH:CH \cdot CO \cdot CH_3$, which is readily obtained by the condensation of benzaldehyde with acetone under the influence

of dilute caustic soda (Claisen, Ber. 14, 2471). When this compound is oxidised by warming it with sodium hypobromite, it is converted into cinnamic acid (Farbwerke vorm. Meister, Lucius and Brüning, D. R. P. 21162; Frdl. i. 28).

By employing substituted benzaldehydes, benzal chlorides, or benzylidene-acetones in the foregoing reactions, substituted cinnamic acids may be obtained.

It may also be prepared from benzaldehyde and malonic acid in the presence of ammonia or amines; in the place of benzaldehyde the benzylidene compounds of certain amines, such as hydrobenzamide, may be used (Knœvenagel, Ber. 1898, 2602; Chem. Zentr. 1898, ii. 695; D. R. P. 97735).

Cinnamic acid may be extracted from storax by boiling in a retort 1.5 kilos. of storax with 2 litres of caustic soda of $24^\circ B$, until no more oily drops distil over with the steam. In this process the styracin is hydrolysed, forming sodium cinnamate and cinnamyl alcohol, the latter being volatile with the steam. The aqueous liquid in the retort is separated and the residue repeatedly extracted with boiling water, after which the cinnamic acid is precipitated from the united aqueous solutions by hydrochloric acid and purified by recrystallisation (Beilstein and Kuhlberg, Annalen, 163, 123); Claassen (J. Soc. Chem. Ind. 1897, 932) uses sodium carbonate instead of caustic soda. Precipitated cinnamic acid may be readily freed from adhering resin by recrystallising it from hot light petroleum.

Properties and Reactions.—Forms slender needles or large transparent prisms melting at 133° . Boils at 300° (corr.). If rapidly distilled, it scarcely suffers any decomposition, but by slow heating it is broken up into styrolene $C_6H_5 \cdot CH:CH_2$ and carbon dioxide. Sparingly soluble in cold, more readily in boiling water; easily soluble in alcohol. Forms crystalline salts closely resembling those of benzoic acid. Oxidising agents convert it first into benzaldehyde (distinction from benzoic acid) and afterwards into benzoic acid, the final products when potassium permanganate is used being phenylglyceric acid, benzaldehyde, and benzoic and oxalic acids (Fittig and Ruer, Annalen, 268, 27). When taken internally it is oxidised to benzoic acid, and appears in the urine as hippuric acid. By fusion with caustic potash it yields a mixture of benzoate and acetate. It unites with nascent hydrogen to form hydrocinnamic (β -phenylpropionic) acid; with bromine to form a dibromide; and with the hydroacids to form β -halogenhydrocinnamic acids—thus β -chlor-hydrocinnamic acid $C_6H_5 \cdot CHCl \cdot CH_2 \cdot CO_2H$.

Cinnamic acid condenses with hydrocarbons; thus with benzene and sulphuric acid, it forms phenylhydrindone (Liebermann and Hartmann, Ber. 1892, 2124); with phenols, phenol itself yielding hydroxyphenylcoumarin (L. and H. *ibid.* 1892, 957), and with sulphur to form diphenylthiophene.

Esters. *Methyl cinnamate*. White crystalline solid; m.p. 36° ; b.p. 263° .

Ethyl cinnamate may be obtained direct from benzaldehyde by means of ethyl acetate and sodium (Farb. vorm. Meister, Lucius and Brüning, D. R. P. 53671; Eng. Pat. 4946; J. Soc. Chem. Ind. 1891, 358; Claisen, Ber. 1890,

976). It is a colourless liquid, boiling at 226° (corr.) under 250 mm. (Perkin, Chem. Soc. Trans. 1896, 1228). By heating 2 parts of ethyl cinnamate with 1 part of sulphur at 150°–160° for 8 hours, a yellow odourless compound $C_9H_8S_2O$ is formed, and is suitable for therapeutic purposes (Farb. vorm. F. Bayer and Co. Eng. Pat. 8425; D. R. P. 87931; J. Soc. Chem. Ind. 1896, 293; Küster, Ber. 1897, 115).

Benzyl cinnamate v. Benzyl benzoate.

Isomeric acids. *Allo*cinnamic acid, m.p. 68°, two *isocinnamic* acids, m.p. 38° and 57°, and other isomerides have been described, but a discussion as to their constitution cannot be entered into here. Bülmann (Ber. 1909, 182 and 1443) and Liebermann (*ibid.*, 1027) consider that the three acids mentioned above constitute a case of trimorphism.

Substituted cinnamic acids. Of the substitution derivatives of cinnamic acid, the only one of industrial importance is orthonitrocinnamic acid, which is prepared in the manufacture of orthonitrophenylpropionic acid (*v. INDIGO, ARTIFICIAL*). On a large scale cinnamic acid is first converted by heating with alcohol and concentrated sulphuric acid into ethyl cinnamate. The latter substance, which, being a liquid, is more easily manipulated in the nitration process than the solid cinnamic acid, is run in a thin stream into the calculated quantity of cold nitrosulphuric acid. The mixture of ortho- and para-nitrocinnamic esters thus formed is dissolved in warm alcohol. On cooling, the para-compound crystallises out, whilst the ortho-compound remains in solution. The two ethyl salts are hydrolysed by heating with sulphuric acid. The ortho- acid has also been prepared from *o*-nitro-benzylidene acetone by warming it with a 3 p.c. solution of sodium hypochlorite (Höchstler Farb. D. R. P. 21162; Frdl. i. 29). In this process the two isomerides are formed in approximately equal quantity.

Orthonitrocinnamic acid

is insoluble in water, sparingly soluble in cold, more readily soluble in boiling alcohol, from which it is deposited in crystals melting at 240°.

The *para*- compound melts at 285°–286°, and is very sparingly soluble even in boiling alcohol. It cannot be used in the preparation of artificial indigo, and the attempt made to utilise it in the rosaniline manufacture has not proved industrially successful.

CINNAMON. The inner bark of shoots of the *Cinnamomum zeylanicum* (Nees), nat. ord. *Lauraceæ*, or true laurels. According to Percival, it is imported principally from Ceylon; but in part also from Madras, Tellicherry, and, rarely, from Java. The bark-peelers select such branches as are 3 years old, and not more than 2 or 3 inches in diameter nor less than half an inch. The bark in drying rolls up into quills, many layers being enclosed in one quill. It is used as a condiment, and yields a highly perfumed essential oil (*q.v.*), employed in the preparation of chocolate and for purposes of perfumery. Both the bark itself in its powdered state and the oil derived from it are frequently adulterated by cassia (*v. CASSIA*).

CINNAMON BROWN v. AZO- COLOURING MATTERS.

CINNAMON OIL v. OILS, ESSENTIAL.

CINNAMON-STONE or Hessonite. A gem-variety of garnet of a warm reddish-brown colour (hence the name) and transparent. It is essentially an orthosilicate of calcium and aluminium $Ca_3Al_2Si_3O_{12}$, containing, however, isomorphous replacements of iron, manganese, and magnesium. Brilliant crystals are found in veins in serpentine at Ala in Piedmont, but material of the best gem-quality is found as pebbles in the gem-gravels of Ceylon.

L. J. S.

CITRAL v. TERPENES.

CITRAMALIC ACID v. MALIC ACID.

CITRIC ACID $C_6H_8O_7$. *Occurrence.*—This acid commonly occurs in the juice of many fruits, and in the sap of many plants.

Synthesis.—The acid has been prepared artificially by Grimaux and Adam (Compt. rend. 90, 1252). A saturated solution of dichloroacetic acid was neutralised with sodium carbonate, and heated with two molecules of potassium cyanide. The resulting solution of dicyanoacetates was saturated with hydrochloric acid gas, and heated on a water-bath for 15 hours, the citric acid was then separated as calcium citrate by neutralisation with milk of lime. Another synthesis has been effected by Lawrence (Chem. Soc. Proc. 1897, 65), who obtained ethyl citrate by heating together ethyl bromacetate and ethyl oxalylacetate in the presence of zinc.

Properties.—The crystallised acid of commerce has the formula $C_6H_8O_7 \cdot H_2O$. The crystals are large prisms belonging to the trimetric system. Their sp.gr., according to Buignet, is 1.553. They deliquesce in damp air, and in perfectly dry air slowly lose the whole of their water. Different crystals (probably differently prepared) may lose water at very different rates (Warington, Chem. Soc. Trans. 28, 928; Grosjean, *ibid.*, 43, 331). According to Marchand (J. pr. Chem. 1841, 23, 60), crystals obtained from a saturated boiling solution have the formula $2(C_6H_8O_7) \cdot H_2O$. According to a later investigation by Sarandinaki (Ber. 5, 1100), the crystals from a solution long boiled are anhydrous. Citric acid is optically inactive. The ordinary crystallised acid dissolves in about half its weight of boiling water. Aqueous solutions of various strengths have, according to Gerlach (Zeitsch. anal. Chem. 1869, 295), the following sp.gr. at 15°:—

Acid p.c.	Sp.gr.	Acid p.c.	Sp.gr.
1	1.0037	16	1.0632
2	1.0074	17	1.0675
3	1.0111	18	1.0718
4	1.0149	19	1.0762
5	1.0186	20	1.0805
6	1.0227	21	1.0848
7	1.0268	22	1.0889
8	1.0309	23	1.0930
9	1.0350	24	1.0972
10	1.0392	25	1.0114
11	1.0431	26	1.1060
12	1.0470	27	1.1106
13	1.0509	28	1.1152
14	1.0549	29	1.1198
15	1.0588	30	1.1244

Acid p.c.	Sp.gr.	Acid p.c.	Sp.gr.
31	1.1288	49	1.2153
32	1.1333	50	1.2204
33	1.1378	51	1.2257
34	1.1422	52	1.2307
35	1.1467	53	1.2359
36	1.1515	54	1.2410
37	1.1564	55	1.2462
38	1.1612	56	1.2514
39	1.1661	57	1.2572
40	1.1709	58	1.2627
41	1.1756	59	1.2683
42	1.1814	60	1.2738
43	1.1851	61	1.2794
44	1.1899	62	1.2849
45	1.1947	63	1.2904
46	1.1998	64	1.2960
47	1.2050	65	1.3015
48	1.2103	66	1.3071

A 25 p.c. solution boils at 101.8°, a 50 p.c. solution at 105.8° (Gerlach, J. 1859, 48).

At 15° the solubility of the crystallised acid in alcohol is as follows:—

100 of 80 p.c. alcohol dissolve 87
” 90 ” ” ” 52.85
” 100 ” ” ” 75.90

100 parts of anhydrous ether dissolve 9.1 of the crystallised acid.

According to Buehner (Ber. 1892, 1159), the ordinary hydrated acid melts between 135° and 152°, and the anhydrous acid at 153°. Saltzer (Arch. Pharm. 231, 514) finds that the finely powdered hydrated acid, if slowly heated, becomes anhydrous at 55°, and melts at 160° in this condition.

Decompositions.—When heated to 175°, acetone and carbonic oxide are evolved, the residue is acetic acid $C_2H_4O_2$; the same acid is formed in small quantity when a solution of citric acid is long boiled (Dessaignes). When heat is continued beyond 175°, an oily distillate appears, which yields crystals of itaconic acid $C_5H_6O_4$. By further heating, itaconic acid is transformed into an uncrystallisable oil, citraconic anhydride $C_5H_4O_3$. Heated with sulphuric acid, carbonic oxide and acetone are given off, and an acid is formed not precipitated by baryta.

Solutions of citric acid are rapidly destroyed by fungi. According to F. Watts (J. Soc. Chem. Ind. 1886, 215), the action of *Saccharomyces mycoderma* on lime juice is to convert the citric acid into carbonic acid and water. According to I. Macagno (Gazz. chim. ital. 11, 443), an alcoholic fermentation in lemon juice does not affect the citric acid, but under the influence of bacteria the citric acid disappears, and acetic and propionic acids are formed.

Salts.—Citric acid is tribasic, and forms in consequence three classes of salts. The salts with the alkali metals are readily soluble in water; the neutral salts of the alkaline earths are only sparingly soluble.

Calcium citrate $Ca_3(C_6H_5O_7)_2 \cdot 4H_2O$ does not lose water at 100°. When precipitated in a crystalline state its solubility in water is 1 in 1180 at 14°, and 1 in 1730 at 90°–100°. When thrown down in an amorphous condition, the

solubility is greater, 1 in 707 at 18°, and 1 in 1123 at 100° (Chem. Soc. Trans. 28, 939).

When a solution of citric acid contains a ferrous, ferric, or aluminium salt, in not too great proportion, it may be made strongly alkaline with potash or soda without producing a precipitate. Such a solution may also be boiled with chalk without precipitating iron or aluminium, although a large part of the citric acid falls as calcium citrate. (With tartaric acid in the place of citric, iron is to a small extent precipitated by chalk in the cold, and entirely on boiling.) If, however, the ferric salt bears a large proportion to the citric acid, the whole is precipitated by chalk, even in the cold (Chem. Soc. Trans. 28, 990).

Derivatives.—Methylenecitric acid is obtained by heating citric acid with four times its weight of polymeric formaldehyde at 140°–160°, and allowing the melt to crystallise. It is used as a disinfectant for the urinary passages (Ch. Fab. auf. Act. vorm. E. Schering, U.S. Pat. 699422; J. Soc. Chem. Ind. 1902, 791).

Monophenetideneitric acid is obtained by heating 42 parts of citric acid with 27.5 parts of *p*-aminophenol for some hours at 100°. The product is dissolved in caustic soda, and the acid precipitated with hydrochloric acid. Diphenetideneitric acid is obtained similarly. They are medicinal substances, acting energetically as precipitants without producing secondary symptoms (Farb. von Heyden-Nachfolger, Eng. Pat. 1254; J. Soc. Chem. Ind. 1895, 385).

Detection.—Citric acid is best recognised when in a pure state by its yielding on heating an oily sublimate, which afterwards crystallises (itaconic acid). A solution of citric acid, neutralised with ammonia, gives no precipitate in the cold with calcium chloride, except after long standing; but on boiling, calcium citrate is precipitated. Calcium citrate, precipitated in the cold, is freely soluble in solution of ammonium chloride, and is precipitated therefrom on boiling. Alkali citrates do not reduce silver salts on boiling, as tartrates do, or only to a trifling extent.

Kämmerer (Zeitsch. anal. Chem. 8, 298) recommends the detection of citric acid by the formation of a crystalline barium salt. To the free acid, or to the alkali salt, excess of barium acetate is added, and the whole heated on a water-bath for several hours; the barium citrate

will then be found in microscopic monoclinic prisms.

Déniges (Compt. rend. 130, 32) adds to the solution $\frac{1}{50}$ of its volume of a reagent obtained by dissolving 5 grams of mercuric oxide in 20 c.c. of conc. sulphuric acid, and 100 c.c. of water. The solution is heated to boiling, and, if citric acid is present, a white precipitate is obtained on the addition of a few drops of a 2 p.c. solution of potassium permanganate.

Another method is to add potassium permanganate to the solution until it is pink. If a precipitate is formed, or a brown colour produced, ammonium oxalate is added until it is destroyed. On adding bromine water a white precipitate is obtained, which, on the addition of alkali, gives the characteristic smell of bromoform (Stahre, J. Soc. Chem. Ind. 1896, 53; Wöhllk, Zeitsch. anal. Chem. 1902, 77).

The tests for adulteration will be given at the close of this article.

Estimation.—When the quantity of citric acid in a solution is determined by alkalimetry, phenolphthalein should be used as the indicator; in coloured solutions red-brown turmeric paper (Thomson, J. Soc. Chem. Ind. 1887, 195) has been recommended. If neutral litmus paper is used, the alkali must be standardised with citric acid. The quantitative determination of citric acid by precipitation as calcium citrate will be described under the analysis of lemon juice.

Citric acid in milk and wine. Citric acid is present in milk and in wine, and as it occurs in small quantities in most wines, adulteration with a small quantity of citric acid cannot be detected (Hubert, Ann. Chim. anal. 1908, 139). It may be detected in milk by taking 10 c.c. of milk, 2 c.c. of sodium metaphosphate, 3 c.c. of mercuric sulphate solution, and filtering. Half of the filtrate is mixed with 0.5 c.c. of 10 p.c. solution of manganese sulphate, and boiled. To this 4 drops of a 2 p.c. solution of potassium permanganate is added, and the solution again boiled. This is repeated, and the liquid decolourised by a drop of hydrogen peroxide. A precipitate or an opalescence indicates the presence of citric acid. This method may be used quantitatively (Denigès, Chem. Soc. Abstr. 1902, ii. 365; v. also Scheibe, *ibid.* 1891, 1276). It may be detected in wine by the method of Spica (Gazz. chim. ital. 31, [2] 61). A portion of the wine is evaporated to a syrup and extracted with alcohol. This is nearly neutralised with alcoholic potash, and the potassium bitartrate filtered off. The filtrate is then neutralised with more potash, and the precipitate is filtered off, dried, and heated in a small tube with sulphuric acid, until it goes brown. It is then diluted, made alkaline with caustic potash, and sodium nitroprusside added. A red colour indicates the presence of citric acid. Favrel (J. Soc. Chem. Ind. 1908, 637) evaporates 100 c.c. of wine to dryness, dissolves the residue in 7 c.c. of boiling water, and adds 35 c.c. of 90 p.c. alcohol. A solution of calcium acetate (0.4 gram in 5 c.c. of water) is added, and the precipitate filtered. When dry it is transferred to a test-tube, 3 c.c. of sulphuric acid added, and the whole heated to 80°–90° for 2 minutes. The solution is cooled and extracted with ether. White crystals are obtained, giving a violet-red colour with ferric chloride, the colour being discharged by mineral acids. (For other methods and quantitative estimation, v. Williams, Analyst, 14, 25; Devarda, J. Soc. Chem. Ind. 1904, 273; Klinger and Bujard, Chem. Soc. Abstr. 1893, ii. 54; Schindler, Chem. Zentr. 1902, ii. 1016; and Robin, Ann. Chim. anal. 1904, 453.)

RAW MATERIAL.

Citric acid is prepared from the fruit juice of three species of *Citrus*—the lemon, bergamot, and lime; the first of these is the principal source of citric acid. Concentrated lemon juice is chiefly imported from Sicily; a very little comes from Naples or Sorrento. Concentrated bergamot juice is prepared in Calabria, and exported from Messina. Concentrated lime juice is imported in small quantity from Montserrat and Dominica. The lemon juice from Sicily is

prepared by pressing the inferior fruit, from which the rind has previously been removed for the manufacture of essence. The so-called 'single' juice is then boiled down till its sp.gr. equals 60° on the citrometer (sp.gr. 1.24); it then forms a dark-brown, rather syrupy liquid.

Lemon juice has its greatest acidity early in the season (November). The juice of the fine fruit, exported as lemons, has a sp.gr. 1.03–1.04; it contains free acid equal to 11–13 oz. of citric acid per gallon. The inferior fruit pressed in Sicily yields a juice containing at the beginning of the season about 9 oz. of free acid per gallon, and at the end of the season a good deal less.

There are other differences between the juice of fine lemons pressed in England, and the Sicilian juice employed for the manufacture of citric acid. The former contains very little combined organic acid, only about 2.5 p.c. of the total organic acid (free plus combined) present. In unconcentrated Sicilian juice the combined acid is about 7–9 p.c. of the total. Again, the English pressed juice contains hardly any organic acid save citric, only about 1 p.c. of the total organic acid being unprecipitable as calcium citrate. In Sicilian juice about 8 p.c. of the total organic acid is unprecipitable as calcium salt.

The concentrated lemon juice from Sicily is reckoned of standard quality when its sp.gr. is 1.24, and its acidity is equal to 64 oz. per gallon of nominal citric acid. In dealing with trade analyses it must, however, be borne in mind that the 'crystallised citric acid' of a trade certificate is not the crystallised acid of commerce, but an acid containing only half the actual amount of water, an acid, in fact, having the atomic weight 201 instead of 210:

No reason can be given for this practice, which should certainly be abolished. In the present article all quantities of citric acid will be expressed in terms of the common crystallised acid.

The concentrated lemon juice from Sicily contains pretty uniformly 7–8 oz. per gallon of combined organic acid, equal to about 10 p.c. of the total organic acid (reckoned as citric) present. Of the total organic acid about 10 p.c. is not precipitable as calcium salt, and is therefore not citric acid; this proportion is, however, by no means constant. Purchases of lemon juice are unfortunately still made on the basis of acidity, and not on the amount of precipitable acid present. Analyses of 895 pipes of concentrated lemon juice by Grosjean have been published (Chem. Soc. Trans. 43, 333). The average proportion of precipitable acid was 99.2 p.c. of the free acid, but the range of variation was considerable, individual parcels of juice giving 81.1, 85.8, and 103.6 p.c.

Concentrated Bergamot juice has a similar sp.gr. to lemon juice, but a lower acidity; it generally contains free acid equal to about 51 oz. of citric acid per gallon. The quantity of combined organic acid is apparently similar to that in lemon juice, namely, 7–8 oz. per gallon; but the proportion of combined to total is higher, 12–13 p.c. The proportion of unprecipitable acid is about 13 p.c. of the total.

Grosjean's analyses of 90 pipes of bergamot juice show a mean of 98.4 of precipitable acid for 100 of acidity, the extremes being 95.4 and 101.4.

The unconcentrated Lime juice of Montserrat has a mean sp.gr. of 1.036; it contains, according to Conroy (Pharm. J. 1883, 606), an average of 7.84 p.c., or 12.54 oz. per gallon of free acid. The extremes observed were 6.70–10.05 p.c., equal to 10.7–16.1 oz. per gallon. The juice yields 0.43 p.c. of ash. It contains only a trace of sugar. Warrington found the combined acid in two samples 5 p.c. of the total; 10 p.c. of the total acid was not precipitable.

Concentrated lime juice is a viscid liquid, sp.gr. 1.32, and with an acidity averaging about 94 oz. of citric acid per gallon. The combined acid is about 8–9 oz. per gallon. The unprecipitable acid is about 10–14 p.c. of the total. The precipitable acid bears a lower proportion to the free than is the case with either lemon or bergamot juice, the published analyses showing a mean of 93.8 of precipitable acid for 100 of free.

The nature of the organic acids, other than citric, present in lemon, bergamot, and lime juice has not been determined. A little formic acid and acetic acid have been detected in concentrated juice, but the principal acids other than citric are clearly non-volatile and have soluble calcium salts. The acids most probably present are malic and aconitic.

Besides lemon juice, some crude Calcium citrate, prepared in Sicily by precipitating lemon juice with chalk, is exported into England. It contains about 64 p.c. of citric acid.

METHODS OF ANALYSING JUICE AND CITRATE.

1. *Acidity.*—The commercial analysis of juice is confined to the determination of acidity. It is most important that the alkali (sodium hydroxide) used should be actually standardised with citric acid, and the same indicator employed in standardising as in subsequent analyses. Powdered crystals of citric acid are taken, water carefully determined in one portion, while another is used for standardising the alkali. In determining water, the powdered acid should be heated for some hours at about 60° before exposing it to 100°; if this is not done, the acid will melt, and lose the rest of its water with great difficulty. Warrington recommended delicate litmus paper for determining the neutral point. F. Watts has since employed films of turmeric tincture on a white tile (J. Soc. Chem. Ind. 1886, 214). Thomson recommends red-brown turmeric paper.

2. *Combined organic acids.*—The juice is neutralised with a known quantity of standard alkali, evaporated to dryness in a platinum basin, the residue gently ignited, the black ash treated with a known quantity (excess) of standard sulphuric acid, the whole boiled and filtered. The amount of unneutralised acid is then determined with alkali. We have now the neutralising power of the ash in terms of alkali; by subtracting the alkali added when neutralising the juice, we obtain the amount of alkali corresponding to the bases of the organic salts, which became carbonates on ignition. From the amount of these bases their equivalent in combined citric acid can be calculated.

3. *Precipitable citric acid.*—This is for the manufacturer the only trustworthy method of analysis, but is, in fact, seldom adopted. Warrington proceeds as follows: 15–20 c.c. of unconcentrated juice, or about 3 c.c. of concentrated juice, are exactly neutralised with sodium hydroxide, the solution (about 50 c.c.) is brought to boiling in a salt-bath, and a measured quantity of calcium chloride solution, known to be rather more than sufficient for all the organic acids present added. After boiling for half an hour, the precipitate is collected on a small filter, and washed with hot water. The filtrate and washings are then concentrated to 10 c.c. and the solution finally neutralised with a drop of ammonia. The second precipitate is collected on a very small filter, the filtrate being used for getting the precipitate on to the paper, which is finally washed about five times with a little hot water. The precipitates in their papers are then burnt at a low heat in a platinum basin, and the neutralising power of the ash determined with standard hydrochloric acid and alkali. The amount of citric acid which the base is equivalent to can then be calculated, three molecules of base being reckoned as equivalent to one molecule of citric acid.

4. *Analysis of calcium citrate.*—The excess of chalk present is first determined by boiling about 4 grams with dilute standard hydrochloric acid in a covered beaker, and then adding standard alkali till feebly alkaline. Two grams of the citrate are then gently ignited in a covered platinum crucible, and the neutralising power of the ash determined by solution in standard hydrochloric acid and titration with alkali. By deducting from the neutralising power of the ash that due to the chalk previously determined, we find the amount of base which has to be calculated as citrate. This method presupposes that citrates are the only organic salts present. If it is preferred, the citrate may be dissolved in hydrochloric acid, the solution boiled, neutralised with soda, the calcium citrate precipitated by boiling in the salt-bath, and its quantity determined as in the case of juice.

The information here given respecting juice, calcium citrate, and the methods of their analysis, will be found in greater detail in Chem. Soc. Trans. 28, 925; 43, 331; v. also Ulpiani and Parrozzani (Chem. Soc. Abstr. 1907, ii. 57).

PROCESS OF MANUFACTURE.

The manufacture of citric acid from concentrated lemon juice is extremely simple. A proper quantity of whiting (levigated chalk) is mixed with water, and heated by steam in a wooden vat provided with a revolving agitator; the concentrated juice is then slowly pumped in, care being, of course, taken that the whiting is finally in small excess. The liquor never becomes neutral, however long boiling may be continued, or however great is the excess of whiting present; the adjustment of juice and whiting is therefore effected by ascertaining if the liquor effervesces with more whiting, or the precipitate effervesces with more juice. The amount of unneutralised acid is about 1–2½ p.c. of the original acidity of the juice. Pure citric acid is readily neutralised by whiting, malic and aconitic acid are not; the final acidity is thus possibly due to the presence of these acids. Citric acid, however, is not

neutralised by chalk if phosphates, and especially ferric phosphates, be present; this fact will also explain the result. It is not advisable to neutralise completely by the use of lime, as vegetable impurities are then thrown down which are afterwards difficult to separate.

The precipitated calcium citrate is washed with hot water on a filter. It is next brought by the addition of water to the state of thin cream, and decomposed, with constant agitation, by the addition of a small excess of sulphuric acid (sp.gr. 1.7). The occurrence of an excess of sulphuric acid is known by the liquor affording a precipitate with a strong solution of calcium chloride after some minutes' standing.

The citric acid liquor is then separated from the gypsum, which is washed on a filter. The liquor is evaporated in shallow leaden baths by steam heat. Much gypsum is at first deposited; from this the clear liquor is run off and further concentrated. When strong enough to crystallise, the hot liquor is run into a wooden tub provided with an agitator, and the liquor is kept in constant motion while cooling; by this process, known as 'granulation,' the citric acid is obtained as a crystalline powder. The mother liquor is again concentrated, and 'salt' again obtained by granulation. The process may be repeated a third time. The liquor is then too dark and impure for further crystallisation, and is known as 'old liquor.' The granulated citric acid when drained, and, if necessary, slightly washed, is redissolved, decolourised by heating with animal charcoal (previously freed from phosphates by hydrochloric acid), again concentrated to the crystallising point, and poured into leaden trays about 3 inches deep; the crystals here formed are the citric acid of commerce. Citric acid thus prepared always contains a trace of lead, and often particles of metallic lead, probably due to the plumbers repairing the vessels. To free the acid from lead, the process usually adopted is to pass sulphuretted hydrogen through the solution after the first crystallisation, filter, and then recrystallise the citric acid in lead-free vessels.

The 'old liquor' is diluted with water, and the citric acid it contains precipitated with an excess of whiting, exactly as in the case of the original juice. The liquor is never neutralised by the whiting; this may be either due to acetic acid formed during the heating of the citric acid liquors, or to the presence of ferric or aluminic phosphate derived from the whiting.

Any considerable excess of sulphuric acid in the liquors, or any overheating, must be avoided, as occasioning decomposition of citric acid. The presence of iron or aluminium in the whiting also occasions loss, as citric acid holding iron or aluminium in solution is not precipitated by calcium carbonate. In consequence of the non-precipitation of iron or aluminium from citric solutions by whiting, the citric liquors of the factory remain nearly pure, however long the work may have been continued, a result very different from what happens in the case of tartaric acid; the purity of citric-acid liquors is however obtained at the expense of some loss of citric acid. In a well-conducted factory the total loss during manufacture will amount to 12-15 p.c. of the citric acid in the juice.

A method has been patented (Fancheux and

Boissière, Eng. Pat. 11991; Fr. Pat. 338735; J. Soc. Chem. Ind. 1904, 680) by which the crude calcium citrate is purified by passing hot gases over it, so as to roast it superficially.

Citric acid is also produced by the fermentation of carbohydrates, glycerol, and analogous substances under the influence of certain fungi, named *citromycetes* (Wehmer, Eng. Pat. 5620; D. R. P. 72957; J. Soc. Chem. Ind. 1894, 275). To prepare the organisms, a sugar solution containing 2-5 p.c. of citric acid is allowed to stand for a few days. The growth formed on this solution is introduced into sterilised sugar, where it develops. The pure culture prepared in this way is then introduced into large vessels containing sugar solution, in which are dissolved small quantities of ammonium nitrate, dipotassium phosphate, and magnesium sulphate; the liquid is then allowed to remain at the ordinary temperature for 8-14 days. At the expiration of that time, the liquid contains a certain amount of citric acid, so that it can be directly employed for lemon juice. The acid can be isolated, preferably as calcium citrate by adding calcium carbonate to the liquid. Other moulds, such as *Mucor piriformis*, which grows on putrefying fruit, specially on pears and apples, may be employed (D. R. P. 91891; v. also Maze and Perrier, Compt. rend. 139, 311).

Estimation of lead in citric acid. Forty grams of the sample are dissolved in water, pure strong ammonia added in slight excess, the liquid cooled and diluted to 120 c.c. For a preliminary experiment 10 c.c. are taken, diluted to 50 c.c. in a Nessler tube, and one drop of ammonium sulphide added; the colour determines what volume should be taken; it varies from 5 to 50 c.c. Having repeated this with the volume of liquid thus indicated, the tint has to be matched with that from the pure solution. A volume of pure ammonium citrate solution identical with that taken of the acid under examination is mixed with a measured quantity of slightly acid lead nitrate solution, containing 0.1 gram metallic lead per litre. A drop of ammonium sulphide is added, and various solutions are made up until the colour obtained matches that from the acid under examination. If iron or copper is present in any quantity, a drop of solution of potassium cyanide is added before the ammonium sulphide, which prevents them interfering with the reaction. The standard of purity suggested is that lead is not to be present to a greater extent than 5 parts per million (Warrington, J. Soc. Chem. Ind. 1893, 97; v. also Tatlock and Thomson, Analyst, 1908, 173).

Another method is that of Buchet (J. Soc. Chem. Ind. 1892, 848). To estimate the metallic lead, 200 grams of acid are dissolved in three times its weight of water, and a slight excess of ammonia added. After 24 hours the liquid is decanted, and the residue collected on a filter, carefully washed and dissolved in nitric acid. The lead is then precipitated as sulphate, and estimated as such. To determine the combined lead, the ammoniacal solution is first acidified with hydrochloric acid, the lead precipitated as sulphide, converted into sulphate, and weighed as such.

Adulteration.—Citric acid is at times adulterated with tartaric acid. To detect adulteration,

Cailletet (Chem. Soc. Trans. 36, 674) adds 1 gram of the powdered acid to 10 c.c. of a cold saturated solution of potassium dichromate. If the solution remains unchanged in colour for 10 minutes, tartaric acid is absent. If tartaric acid is present, the solution becomes brown. Pusch (J. Soc. Chem. Ind. 1885, 552) places 1 gram of the acid in a test-tube with 10 grams of pure oil of vitriol. The test-tube is placed in a water-bath, and kept at 100° for 1 hour. If citric acid only is present, the colour is lemon-yellow. If tartaric acid is present, the colour becomes brown. Both these tests are very delicate, and readily show 1 or $\frac{1}{2}$ p.c. of adulteration. Piñera (Compt. rend. 124, 291) puts 0.05 gram of the substance in a porcelain basin, and adds 10–15 drops of a reagent made by dissolving 0.02 gram of β -naphthol in 1 c.c. of concentrated sulphuric acid. If citric acid alone is present, a blue colour is formed, unchanged on heating, which on dilution gives a nearly colourless or a slightly yellow liquid. If tartaric acid is present, the colour on heating changes to green, and on dilution to a reddish-yellow. Denigès adds a small quantity of the acid to a solution of resorcinol in dilute sulphuric acid, and heats to 115°–140°. If tartaric acid is present, a violet-red colour is formed. If sugar is present, or other bodies blackened by sulphuric acid, the acid is precipitated as its lead salt, and then tested (J. Pharm. Chim. 1895, i. 586). Crismer (Chem. Soc. Abstr. 1892, 546) adds 1 gram of the acid to 1 c.c. of ammonium molybdate solution (10 p.c.) and 2 to 3 drops of hydrogen peroxide solution ($\frac{1}{4}$ to $\frac{1}{2}$ p.c.), and heats at 100° for 3 minutes. If citric acid alone is present, the yellow colour given by the molybdate is unaltered; whilst if tartaric acid is present, a beautiful blue colour results. This test detects 1 mgm. of tartaric acid in 1 gram of citric acid. Spindler has modified Denigès' mercuric sulphate method (*q.v.*), and uses potassium dichromate instead of permanganate. If citric acid alone is present, a yellow precipitate is obtained; the presence of tartaric acid is indicated by a change of colour to green, due to reduction. Tartaric acid may also be detected by adding a little solution of potassium acetate to a strong solution of the citric acid, and stirring.

The quantity of tartaric acid in an adulterated sample may be determined by adding 10 p.c. of potassium chloride to a strong solution of the acid, and precipitating the tartaric acid with citrate or acetate of potassium, with the precautions described under estimation of tartaric acid.

CITRIC ACID FERMENTATION *v.* FERMENTATION.

CITRON, OIL OF, *v.* OILS, ESSENTIAL.

CITRONELLA OIL *v.* OILS, ESSENTIAL.

CITRONINES *v.* AZO-COLOURING MATTERS.

CIVET. An odoriferous substance resembling musk or ambergris, obtained from the pouches situated between the anus and genital organs of *Viverra civetta* of N. Africa, *V. Zibetha* of Asia, and *V. Malaccensis* of Java. Is of the consistence of honey, and of a yellowish or brown colour. Contains stearin, olein, mucus, resin, volatile oil, and yellow colouring matter (J. Pharm. 1824, 537). (For analyses of civet, see

Charabol and Hébert, Bull. Soc. chim. 1910, 7, 687.) Civet melts at about 36°, and contains from 50 to 70 p.c. of fatty acids, and should have a saponification value of about 180°, and should have not more than 1 p.c. of ash.

CLAUSTHALITE *v.* SELENIUM.

CLAY. (*Argile*, Fr.; *Thon*, Ger.) The term 'clay' is ordinarily used to denote certain earths, the chief characteristic of which is that of plasticity when wet, and which have the property of baking to a hard, stone-like mass when heated to full redness. Clay is a heterogeneous mixture of certain hydrated aluminium silicates, with particles of quartz, felspar, mica, &c., resulting from the decomposition of various silicious minerals, the chief source being the felspars of granite rocks. These hydrated aluminium silicates form the essential basis of all clays, and are known as *clay substance* or *clay base*. They are all decomposed by hot concentrated sulphuric acid (*infra*), whilst the other ingredients mentioned above are affected only slightly or not at all. The method of so-called 'rational analysis' is based on this action, and it has been found that when so treated, the great majority of clays give a clay substance approximately of the composition represented by the formula $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$. This corresponds with the composition of the rare crystalline mineral *kaolinite*, and, consequently, it has often been assumed that all clays contain kaolinite as their clay base. Within the last few years, however, it has been shown that the clay substance, in some cases, does not correspond in composition with the above formula, and it is now generally accepted that other hydrated aluminium silicates may be present in clays, forming part, and in some cases the whole, of the clay base. Various investigators have attempted to define these substances, and to show that they correspond in composition with certain silicates, such as allophane ($Al_2O_3 \cdot SiO_2 \cdot 5H_2O$), pyrophyllite ($Al_2O_3 \cdot 4SiO_2 \cdot H_2O$), halloysite ($Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O + Aq$), pholerite ($2Al_2O_3 \cdot 3SiO_2 \cdot 4H_2O$), &c.

It has been suggested by J. W. Mellor (Trans. Eng. Ceramic Soc. pt. 1, 8) that the term *kaolinite* should be restricted to the comparatively rare crystalline mineral, and that the amorphous clay substance of similar composition ($Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$) should be called 'clayite.'

The same investigator points out that this latter substance occurs in clays in non-crystalline or amorphous granules, which, however, sometimes show faint polarisation phenomena. Practically all clays contain more or less free silica, undecomposed or partially decomposed felspar, and mica, and they vary in composition through a wide range, differences in composition being brought about partly as a result of different origins, and partly by differences of deposition, &c. The commoner varieties of clay generally contain a considerable percentage of oxide or carbonate of iron, and small percentages of calcium, magnesium, and titanium salts.

Clays may be divided broadly into two classes: residual clays and sedimentary clays. Residual clays are the insoluble residue left from the breaking down and decomposition of rock masses containing certain aluminium silicates (chiefly felspathic minerals), and they

are found overlying or adjacent to the rock mass from which they were formed. These residual clays usually present a gradual change in mineral character from the finer or purer portion nearer the surface to the mixture of clay and undecomposed rock which lies in contact with the rock mass. The decomposition of the mineral silicates may be brought about by the carbonic acid in the surface waters; but many of them are acted on by water alone, and although this action proceeds very slowly, it may account for the gradual decomposition of the felspathic rocks and the formation of clay. The alkalis of the felspars combine with the free silica formed in the decomposition, and with the carbon dioxide contained in the percolating water, forming soluble salts which are more or less completely washed away. In some cases the decomposition of the mineral silicates may have been brought about by the action of gases, and it has been shown by J. H. Collins (Min. Mag. 1887, 7) that when felspar is exposed to the action of hydrofluoric acid, hydrated aluminium silicate is formed, mixed with soluble potassium fluoride, whilst silica is deposited on the sides of the tube in which the reaction takes place. Residual clays, as a rule, contain a smaller percentage of oxide of iron and organic matter than sedimentary clays, and are consequently lighter in colour both before and after baking.

Sedimentary clays are formed by the transportation and redeposition in water of residual clays, and clays so formed may be again transported and redeposited in the same way, so that they may have no direct relationship to the rock formation on which they lie. Sedimentary clays belong to all geological ages, from the present to the Cambrian, and are of varying degrees of hardness, from the soft drift which may be dug with a spade to the hard clay shales of the older formations, which require to be blasted. These clays are always roughly stratified in structure, and show considerable variations in general character and composition throughout their mass, owing to the varying conditions under which they were deposited. The harder varieties of clay are readily converted into the plastic form by grinding with water, or by *weathering*, and they are now largely used for the making of bricks, &c., where formerly only the softer surface clays were used. When breathed upon or moistened, clays usually emit a peculiar odour known as argillaceous. This characteristic is more marked in the sedimentary than in the residual clays, and may possibly be connected with the contained organic matter.

Plasticity is an essential property of all clays in the moist condition, but this quality varies greatly in different clays. The presence of organic matter, finer grinding of the particles of the clay, 'ageing' in the moist condition and 'weathering,' all tend to increase the plasticity, but no entirely satisfactory explanation of the cause of plasticity has yet been put forward. Clay loses practically the whole of its hygroscopic water when dried at 100°, and it contracts and loses its plasticity at the same time, becoming hard and brittle. On being soaked or ground in water, however, it becomes soft and plastic again. The chemically combined water

is not driven off until the clay is heated to redness, the temperature of the dehydration, in the case of ordinary clay, being probably between 480° and 600°. Clay that has been heated to this temperature will not again become plastic on being ground with water, so that it is evident that the plasticity of a clay is dependent upon some physical or chemical condition, which is destroyed on heating to about 500°. When clays are heated to a higher temperature (generally about 900°), they contract more or less and become hard, compact, and stone-like, and at higher temperatures still they become vitreous and ultimately fuse. The purest varieties of china clay (which approximate to the composition of kaolinite) fuse at a temperature of about 1830°, and other clays fuse at lower temperatures, according to the nature and percentage of the various impurities contained. The chemical impurities which chiefly affect the fusibility of a clay are the salts of magnesium, calcium, iron, sodium, and potassium. Richter first pointed out that chemically equivalent amounts of the oxides of these substances exert equal influences on the fusibility of a clay. The presence of free silica (quartz sand) tends to raise the fusion point of clays containing a considerable percentage of these bases, but it has an opposite effect on the purer china clays. In the manufacture of pottery ware of all kinds, the firing temperature depends upon the chemical composition of the clay (which determines the fusibility) and upon the result required. For example, in the manufacture of porcelain, where the resultant ware must be non-absorbent or vitreous, the firing temperature ranges from about 1250° to 1550°, according to the chemical composition of the clay mixture or *body* used, whereas in the manufacture of ordinary white earthenware, where a porous or non-vitreous ware is desirable, the firing temperature ranges from about 1150° to 1250°.

The colour of fired clay, *i.e.* clay that has been heated to a temperature of over 900°, depends upon the impurities present, and upon the character of the firing gases. The purer kinds of residual clays fire to a whitish mass, but all other clays become more or less strongly coloured, the tint being determined generally by the percentage of iron oxide present. Iron may be present in clays in various combinations, such as ferric oxide (Fe_2O_3), hydrated ferric oxide ($2\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$), ferrous carbonate (Fe_2CO_3), and more rarely magnetic oxide (Fe_3O_4), but in firing in the ordinary way all these salts are converted into ferric oxide. Some clays contain a considerable amount of iron pyrites disseminated through the mass in small grains, and these clays are often troublesome in use, as the sulphide is not so readily converted into oxide in the ordinary firing process. Moreover, the sulphide on weathering with the clay gives rise to soluble sulphates which are detrimental. In the yellow and brown surface clays and red-firing shales, the iron is present in the form of ferrous carbonate, which, together with the organic matter present, produces the natural grey colour of these shales. In ordinary clays, and with an oxidising atmosphere, 1-2 p.c. of iron oxide produces a buff colour, 2-4 p.c. a salmon colour, and above 4 p.c. a red colour, which becomes darker as the percentage of iron increases. The

presence of other impurities, however, modifies the colour produced by iron oxide considerably, and this is especially the case when a large percentage of lime or magnesia is present.

Some clays (commonly called marls) contain from 15 to 30 p.c. of lime, and although they may also contain as much as 6-8 p.c. of iron oxide, they fire to a light-yellow or buff colour. Such clays are largely used for making the well-known yellow facing bricks, which were at first made chiefly from the marls of the Thames basin, the Paris basin, &c., and are now made from artificially prepared mixtures of clay or chalk and limestone. The presence of certain soluble salts (chiefly sulphates of calcium or magnesium) in clays often produce serious discolouration on firing, owing to the deposition of these salts on the surface during the drying and firing of the ware. To prevent this action, it is usual to mix with the clay barium carbonate, to combine with the whole of the sulphuric acid present, and so convert the soluble salts into insoluble ones. When clays are fired in a reducing atmosphere, the red ferric oxide is converted into blue ferrous oxide, and the resultant ware is consequently bluish in colour. Blue bricks are made from certain clays, containing generally from 6 to 10 p.c. of iron oxide by firing in this way.

The presence of clay in soils exerts an important action on the growth of plants. Ammonia is retained by clay in such a manner that it cannot be removed except by an excessive amount of washing; in fact, clay will remove ammonia and many organic substances from manure, and still retain them in a form readily available for plants.

Kaolinite $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$. A comparatively rare crystalline mineral which occurs in Anglesey, in Colorado, and a few other localities in the form of minute hexagonal plates, having a perfect basal cleavage, and belonging to the monoclinic system. Kaolinite was formerly supposed to form the base of all clays, but this view is no longer held, and the term should be restricted to the crystalline mineral described above.

Kao-lin, *China clay*. The Chinese term 'kao-lin' (literally meaning 'high ridge') was applied to the white earth from which porcelain was made, and it corresponds to the English china clay, so called because it is used for the making of 'china,' or porcelain. These terms are now applied to all the purer residual clays which contain a high percentage of hydrated aluminium silicate ($\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$), and which consequently give on analysis 33-40 p.c. alumina (Al_2O_3), 45-60 p.c. silica (SiO_2), 11-14 p.c. water, with very small percentages of iron oxide, soda, potash, lime, magnesia, &c. Clays of this class are worked in Cornwall and Devon, at St. Yrieix near Limoges, Zettlitz in Bohemia, in the United States, in South Africa, &c. As mined, the clay generally contains a large percentage of quartz-sand and mica, and it is refined by washing. In Cornwall the china clay is usually the result of the weathering of pegmatite, and the felspar of the parent rock is often decomposed to a depth of 60 to 100 feet. In this condition it is known as *china clay rock*, and the workman breaks down the crumbling surface with a pick and then directs a stream

of water over this to wash down the material, which is passed into tanks where the suspended matter settles out, the quartz, clay, and mica being deposited according to the sizes of the particles, and so separated from each other. The china clay is allowed to dry to a stiff paste in the tanks, and is then removed to the drying kilns, where it dries until it can be cut into blocks ready for shipment. It is a soft, friable, sectile, white substance, showing irregularly shaped granules under the microscope, and possessing only a moderate plasticity when mixed with water. China clay is used in the manufacture of porcelain and white earthenware, in paper making, and the *filling* of calico, and also in the manufacture of alum, aluminium sulphate, and ultramarine. The fine mica separated from the china clay in the washing is used for weighting coarse papers, paper boards, &c.

Ball clay, *Potter's clay*. The name given to certain sedimentary clays which fire to whitish or light-buff colour, and which possess high plasticity and tensile strength when in a moist condition. They are worked in Devonshire and Dorset, and in some parts of the United States, &c., and are chiefly used in the manufacture of white earthenware. They are generally finer in grain than china clay, contain more organic matter and other impurities, and are consequently more plastic in a moist state, and fire to a vitreous mass at a lower temperature. They usually also contain a higher percentage of silica than china clays.

Pipe clay. A rather loose term, which is applied to white clays which contain a relatively high percentage of silica, and which have been used without admixture for several hundred years for the making of tobacco pipes and also for common pottery. These clays are of various geological origins, and in some localities the highly silicious clay found in pockets in limestone formations, and resulting from the decomposition of argillaceous limestone and chert rock, is used in this way. Ball clay is also used for the same purposes, and is sometimes consequently spoken of as pipe clay.

Plastic clay. This term has been specially applied to those beds of the Lower Tertiary or Eocene strata, which occur between the London clay and the chalk, and which may be recognised at Woolwich, Reading, Blackheath, Bognor, and in the neighbourhood of Paris, &c. This clay is mottled red or purple, and fires to a red colour. Some of our earliest pottery was manufactured from this clay, and it is still worked in Hampshire, in the Isle of Wight, and elsewhere.

Slate clay occurs in Devon, Cornwall, &c., differing considerably in different districts. It is massive, interspersed with mica, and of a greenish or greyish colour. It is sometimes hard and *slaty*, being readily cleavable into slabs, whilst in another form, the *killas* of the Cornish mines, it has an earthy fracture, is soft and frangible, and weathers to a more or less plastic clay. It is chiefly used for the manufacture of common bricks and tiles, and, when fairly free from lime, magnesia, and iron, for fire-bricks.

Common clay is the term often applied to

the ordinary surface and drift clays which have been used for centuries for making common pottery and bricks.

Fireclays. As the name implies, these clays are of a very refractory nature, and although, strictly speaking, practically all the pure residual clays come under this head, the term 'fireclay' has been restricted in use to certain coal-measure shales which have a high fusion point, and which are used mainly for the manufacture of firebricks, gas retorts, glass pots, furnace linings, &c.

These fireclays usually underlie the coal seams, and are often worked in conjunction with the coal. Certain districts are particularly noted for the quality of their fireclays, and in England the Stourbridge coal-measure shales have long been considered of the highest quality, and fireclay-mines are extensively worked in the Stourbridge district. Good fireclays are also found and worked in the Lancashire and Yorkshire, Derbyshire, and Glasgow coal-fields. The fireclay shales are mostly greenish-grey in colour, compact, dense, and of varying degrees of hardness. On exposure to the weather they usually crumble down, and in time become converted into plastic clay. The weathering process may be greatly accelerated by grinding the shale, but this is only done when the clay is to be used for the more expensive fireclay goods. Only those coal-measure shales which contain small percentages of oxide of iron, lime, and magnesia, are sufficiently refractory to be used as fireclays, and although no definite fusion-point has been fixed, it seems advisable that no clay having a fusion-point lower than 1500° should be classed as a fireclay. In the manufacture of fireclay goods, the partially weathered or ground fireclay is usually mixed with a certain proportion of 'ganister,' coarse sand, burnt clay, or other refractory material which produces in the fired ware a certain open texture, which enables it better to withstand rapid changes of temperature. Certain silicious fireclays and other coal-measure clays are used in the manufacture of salt-glazed drain pipes, and also for making common culinary ware, buff-coloured tiles, terracotta, glazed bricks, &c.

Chemical analysis of clay. From 1-2 grams of finely powdered clay, dried at 120° , are weighed into a platinum crucible, and mixed with about six times its weight of a fusion mixture consisting of potassium and sodium carbonates in equimolecular proportions. The mixing is best performed by first stirring together the clay with about the same bulk of fusion mixture by means of a dry glass rod, and then adding more and more fusion mixture with repeated stirring, until the whole is thoroughly mixed. The glass rod should then be rubbed in a little fusion mixture, which is added to the mass in the crucible. The covered crucible is gradually heated over a Bunsen burner (a Teclu burner may be advantageously used) until the whole mass is in a state of tranquil fusion. The crucible is allowed to cool, and afterwards the bottom is raised just to dull redness, twice successively, in order to facilitate the removal of the mass from the crucible. After cooling, a few drops of distilled water are added, and the crucible very gently warmed until the mass detaches itself. The contents of the crucible

are then washed into a large platinum dish (a porcelain dish may be used without seriously impairing the accuracy of the estimation), covered with water, and then warmed until the fused mass is completely softened. Hydrochloric acid is then added, a few drops at a time, until all effervescence ceases. The contents of the dish are evaporated on a water-bath, with constant stirring at the later stages, to ensure a fine powdery residue from which the last traces of hydrochloric acid are readily driven off. When cold, the contents of the dish are moistened with moderately strong hydrochloric acid, and allowed to stand for one hour; water is then added, and the dish again heated on the water-bath. The clear liquid is poured through a filter, and the residue in the basin, which consists of silicic acid, is washed repeatedly by hot water until it remains white when moistened with hydrochloric acid. The residue is then transferred to the filter, and washed with hot water until the filtrate no longer gives a precipitate with silver nitrate solution. The filter and contents are then placed in a platinum crucible and dried, and afterwards gradually heated, and finally ignited strongly until the paper is completely incinerated, and the weight constant. In order to ensure the complete separation of the silicic acid, it is necessary to evaporate the filtrate down to dryness, and treat exactly as before, and this process may be repeated again if very great accuracy is required. After filtering, the filter paper and residue are dried and added to the original silicic acid residue before ignition. The contents of the crucible are then weighed as silicon dioxide (SiO_2). If the clay contains titanic acid (as many clays do), this will accompany the silica. In order to determine the former, the contents of the crucible are covered with strong hydrofluoric acid, a few drops of sulphuric acid added, and the crucible warmed on the water-bath until all the silicon fluoride and the sulphuric acid have been driven off. The residue is then weighed as titanic oxide (TiO_2), which should be identified by the violet-coloured bead with microcosmic salt.

The filtrate is made up to definite volume, and divided into two parts, one for the determination of the iron, and the other for the determination of the alumina, calcium, and magnesium. The iron is estimated as ferric oxide, and determined either by reduction with zinc and titration with potassium permanganate solution, or by the iodometric method.

The other portion of the filtrate is heated on the water-bath, and ammonia added drop by drop, with repeated stirrings, until there is a slight excess of ammonia present. The liquid is then boiled for a moment and filtered. The precipitate is washed twice with hot water; washed back into a dish, and dissolved in hydrochloric acid; reprecipitated and filtered as before, and finally washed with hot water until the filtrate gives no precipitate with silver nitrate solution. The washing should be repeated immediately the previous washing has disappeared from the filter, and a jet of hot water should be directed into the precipitate so as to break it up as much as possible. The filter paper and contents are then dried, the residue removed into a platinum crucible, the paper separately incinerated, and then placed in the

crucible, and the whole strongly ignited until the weight is constant. The contents are then weighed as alumina (Al_2O_3) and ferric oxide (Fe_2O_3), the amount of ferric oxide separately determined as above being deducted from the total, leaving alumina only (art. ALUMINIUM). The filtrate from the alumina and ferric oxide is concentrated, and ammonium oxalate solution added while hot. The precipitate is filtered off, thoroughly washed with hot water, dried, strongly heated, and weighed as CaO . The filtrate from the above is then concentrated, and the magnesium precipitated by sodium phosphate and ammonia. The precipitate is filtered off, dried, and ignited until the weight is constant. The ignited residue consists of $\text{Mg}_2\text{P}_2\text{O}_7$, and the weight must be multiplied by 0.3624 to give the amount of magnesia (MgO) contained.

Determination of the alkalis. The method introduced by Lawrence Smith (Amer. J. Sci. [2] 50, 269) is the most trustworthy, and is based on the decomposition of silicates by fusion with calcium carbonate. In practice, the dried and finely powdered clay is mixed with its own weight of ammonium chloride, and four times its weight of calcium carbonate. These latter materials must be as free as possible from alkali. The ammonium chloride used is prepared by subliming the commercial salt; and the calcium carbonate is prepared by dissolving the purest calcite obtainable in hydrochloric acid, and precipitating with ammonia and ammonium carbonate. The precipitation is carried out in a large porcelain dish, and, after settling, the clear liquid is poured off, and the precipitate washed by decantation until free from chlorides. A special platinum crucible is used for the fusion, about 8 cm. long, and 2 cm. diameter at the top, tapering to $1\frac{1}{2}$ cm. at the bottom. About 0.5 gram clay is weighed out, and mixed by rubbing in an agate mortar with the same weight of ammonium chloride, and afterwards 3 grams of calcium carbonate are added, and the whole thoroughly mixed. The mixture is then transferred to the crucible, and the mortar is cleaned out with about 1 gram of calcium carbonate, which is added to the mixture in the crucible. The covered crucible is supported in an inclined position, and very gradually heated over a small Bunsen flame for about 15 minutes, until no more ammonia is given off, and then the temperature is raised until the lower three-fourths of the crucible is a dull-red, and this temperature is maintained for 1 hour. The crucible is cooled and the contents removed (by tapping the inverted crucible) into a porcelain or platinum dish. If the sintered mass sticks to the crucible, a little water should be added, and the crucible gently warmed until the mass detaches itself, and the whole can be washed into the dish. About 60 c.c. of distilled water are added, and the covered dish heated on a water-bath for 30 minutes, the water lost by evaporation being replaced, and the larger particles reduced by rubbing with an agate pestle. The clear liquid is decanted through a filter, and the residue washed by decantation four times, and then transferred to the filter and washed until the filtrate gives no precipitate with silver nitrate. The filtrate contains the alkalis as chlorides.

The calcium is precipitated by the addition of ammonia and ammonium carbonate to the filtrate, which is heated and filtered. The residue, which contains some alkali, is dissolved in hydrochloric acid, again precipitated by ammonia and ammonium carbonate, and filtered. The combined filtrates are then evaporated to dryness in a platinum dish, and the ammonium salts removed by careful heating over a moving flame. The residue is dissolved in water, and any traces of calcium left are precipitated by the addition of ammonia and ammonium oxalate. After standing 12 hours, the liquid is filtered off, evaporated to dryness in a weighed platinum dish, and gently heated. The alkali chlorides remaining in the dish are weighed, and the potassium determined by dissolving the chlorides in water and precipitating the potassium as potassium platino-chloride. The sodium is determined by difference.

Rational analysis of clay. To determine the relative amounts of clay substance, quartz, and undecomposed felspar, dry the clay to constant weight, and weigh about 5 grams of the dried and finely powdered clay into a porcelain dish; add 50 c.c. of concentrated sulphuric acid and 100 c.c. of water, and then heat the mixture for 3 hours on a water-bath, and afterwards on a sand-bath, until the acid commences to fume. After cooling add water, and decant the clear liquid into a 2-litre beaker. To the residue in the dish add 10 c.c. of Lunge's solution (100 grams crystallised sodium carbonate, and 10 grams sodium hydroxide, dissolved in 1 litre of water), boil for 5 minutes, dilute with water, and decant into the beaker. Treat the residue in the dish similarly with concentrated hydrochloric acid, and repeat the treatment with Lunge's solution and hydrochloric acid, diluting with water after each treatment, and decanting the clear liquid into the beaker. Then wash the residue on to a filter with dilute hydrochloric acid. Stir up the contents in the beaker, and allow to stand for an hour. Decant off the clear liquid, taking care to retain the residue in the beaker. Wash the residue into the dish, and repeat the treatment with Lunge's solution and acid as above, and pass through the filter. Wash with dilute hydrochloric acid, dry and ignite the filter paper and contents in a weighed platinum crucible. This residue is reckoned as felspar and quartz, and the loss suffered by the clay in this treatment as clay substance.

To determine the quartz and felspar, add about 5 c.c. of water, 4 drops of sulphuric acid, and 15 c.c. of hydrofluoric acid to the residue in the crucible, and heat the whole carefully on a sand-bath until nearly dry. Add more hydrofluoric acid, and again heat as before. After cooling, dissolve the mass in water, wash into a dish, and add ammonium chloride and ammonium hydrate to precipitate the hydroxides of aluminium and iron. Filter, wash with hot water, heat and weigh. This weight is multiplied by 5.451 to obtain its equivalent in potash felspar, and the difference between this and the weight of the original residue is taken as quartz.

Many ceramic chemists calculate the rational constitution of the clay from the ultimate analysis, taking the potash as derived

entirely from undecomposed felspar (reckoned as $K_2O \cdot Al_2O_3 \cdot 6SiO_2$), the alumina and iron as derived from felspar, and the clay substance (reckoned as $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$) and the silica as derived from the clay substance and quartz.

CLAY IRONSTONE *v.* IRON, ORES OF.

CLAY SLATE *v.* SLATE.

CLAYTON CLOTH RED, *v.* AZO-COLOURING MATTERS.

CLAYTON YELLOW *v.* PRIMULINE AND ITS DERIVATIVES.

CLEVEITE. A variety of uraninite, consisting of a uranate of uranyl, and oxides of lead and the rare earths. Usually obtained from Norway and Sweden. Hillebrand (Bull. U.S. Geol. Survey, 78, 43, 83) found the percentage of rare earths to be about 13, and that on heating with sulphuric acid, over 2 p.c. of nitrogen was evolved. Ramsay (Chem. Soc. Trans. 1895, 1107) proved that the gas evolved was not nitrogen, but helium (*q.v.*). Only half the helium is evolved by heat alone, and, moreover, in some cases the disengagement of the gas is accompanied by considerable evolution of heat (Proc. Roy. Soc. 1898, 64, 140).

CLICHY WHITE. A white lead manufactured at Clichy, in France (*v.* *White lead*, art. LEAD).

CLOTHBROWN, -ORANGE, -RED, -SCARLET, *v.* AZO-COLOURING MATTERS.

CLOVE OIL *v.* OILS, ESSENTIAL.

CLOVER. The name by which several leguminous forage plants are known. The chief species are: white clover (*Trifolium repens*, Linn.); red clover (*T. pratense*, L.); alsike clover (*T. hybridum*, L.); crimson clover (*T. incarnatum*, L.); yellow suckling clover (*T. dubium*, Sibth.); mammoth red, or zigzag clover (*T. medium*, L.); hop clover, or hop trefoil (*T. procumbens*, L.). All the above belong to the true clovers, to the genus *Trifolium*. Also included as clover are: yellow clover, or trefoil (*Medicago lupulina*, L.); Bokhara clover, or melilot (*Melilotus alba*, Desn.); Japanese clover (*Lespedeza striata*, Hook. et Arn.); and Soola clover, or sulla (*Hedysarum coronarium*, L.). The following table gives the average composition of various clovers at the time of flowering (Kellner):—

	Water	Protein	Fat	Sol. carbo- hydrates	Fibre	Ash
<i>T. repens</i>	81.5	4.4	0.8	6.9	4.3	2.1
<i>T. pratense</i>	79.0	3.4	0.7	9.4	5.9	1.6
<i>T. hybridum</i>	81.8	2.8	0.7	7.0	6.2	1.5
<i>T. incarnatum</i>	81.5	2.8	0.7	7.0	6.1	1.9
<i>T. procumbens</i>	80.0	3.5	0.8	8.4	5.7	1.6
<i>Melilotus alba</i>	79.7	4.1	0.8	7.4	5.7	2.3

The following are analyses of hay from various clovers:—

	Water	Protein	Fat	Sol. carbo- hydrates	Fibre	Ash
<i>T. repens</i>	9.7	15.7	2.9	39.3	24.1	8.3
<i>T. pratense</i>	16.5	13.5	2.9	37.1	24.0	6.0
<i>T. hybridum</i>	16.0	13.6	3.1	34.5	25.7	7.1
<i>T. incarnatum</i>	16.7	12.0	2.4	35.5	26.2	7.2
<i>T. procumbens</i>	16.0	15.4	3.4	33.2	24.5	7.5
<i>Melilotus alba</i>	15.7	16.7	2.8	27.9	30.3	8.0
<i>Lespedeza striata</i>	9.1	13.7	4.0	47.5	21.6	4.1

White or Dutch clover is a low, creeping perennial plant, valuable for grazing. Its growth in pastures is encouraged by phosphatic and potash manuring, but discouraged by

nitrogenous manures. In America, it is said that its blossoms salivate horses, and that consequently much clover in pastures is an objection where horses graze. White clover furnishes most excellent pasturage for bees, the honey which it yields being colourless and of high quality.

Red clover or broad clover is usually grown as a biennial, but will sometimes stand longer. It is often grown as a hay crop, or for cutting for green forage. It is the variety most susceptible to 'clover sickness,' and on many soils can only be grown safely once in 10 or 12 years.

A variety of red clover, *T. pratense* var. *perenne*, known as 'cow grass,' is not so prone to clover sickness, and lasts longer. It is, however, of slower growth, and usually yields but one crop per year of hay.

Alsike clover has whitish and pinkish flowers, and is a perennial; it is hardly susceptible to clover sickness.

Crimson clover, or 'trifolium,' is also a somewhat slow-growing crop, and is an annual.

Yellow suckling clover is a smaller plant than the other clovers, and is usually only grown in mixtures with rye-grass, &c. It is an annual.

Zigzag clover, known in America as mammoth red clover, ripens later than red clover, and is taller and ranker.

Bokhara clover, or large white clover, is a biennial, with small white flowers. This plant is remarkable for its strong odour, more pronounced when dried, of coumarin; animals do not eat it readily until they become accustomed to it.

Soola clover is a perennial resembling red clover, but is richer in soluble carbohydrates (*v.* Scurti, Chem. Zentr. 1910, i. 1632).

As the table of analyses shows, clovers are remarkable for the large amounts of nitrogenous matter and of ash which they contain. Of the former, however, a considerable proportion is of a non-protein nature, particularly in the immature plants. In the case of red clover, for example, it has been found that about 40 p.c. of the total nitrogenous matter is present as amides in very young plants, and that the proportion diminishes with growth, until, when the plants are in full bloom, it is about 20 p.c., when fully ripe it sinks to about 12 p.c.

The ash of clovers is remarkable for its richness in lime and its poverty in silica (in which grasses and cereal straws are so rich).

The following are Wolff's analyses of various clover ashes:—

	K ₂ O	Na ₂ O	MgO	CaO	P ₂ O ₅	SO ₃	SiO ₂	Cl
Red clover	34.5	1.6	12.2	34.0	9.9	3.0	2.7	3.7
White "	19.4	7.8	10.0	33.2	14.1	8.8	4.5	3.2
Alsike "	33.8	1.5	15.3	31.9	10.1	4.0	1.2	2.8

The very high ratio of lime to phosphorus pentoxide in the ash is noticeable.

Clover hay has proved very successful as a constituent of the rations of fattening oxen and sheep.

Out of about 200 feeding experiments with nearly 1000 cattle, conducted in Britain between 1833 and 1908, 17 included clover hay in the daily ration. The average daily increase in live weight per head of the whole was 1.803 lbs., while the consumption of total digestible matter per 1 lb. live weight gained averaged 9 lbs. In the 17 cases where clover hay formed a portion of the food, the figures are 2.1 lbs., and 7.47 lbs.

respectively (Ingle, Journ. High. and Agri. Soc. of Scotland, 1909).

With sheep, the results are equally significant. 2390 sheep fed in various ways, between 1844 and 1909, gave an average weekly increase per head of 2.06 lbs., and consumed an average of 7.43 lbs. total digestible matter per 1 lb. increase in live weight; while 384 sheep receiving cloverhay as part of their ration, gave an average weekly increase of 2.58 lbs. per head, and consumed only 6.20 lbs. of total digestible matter per 1 lb. increase in live weight (*ibid.* 1910).

H. I.

COAL v. FUEL.

COAL GAS v. GAS, COAL.

COBALT. Sym. Co. At. wt. 58.97.

Cobalt usually occurs combined with arsenic or sulphur, and almost invariably associated with nickel and other metals. Free cobalt occurs only in meteorites.

The most plentiful and important ore of cobalt is *smaltine* or *tin white cobalt*, consisting of arsenide of cobalt, nickel, and iron. It occurs abundantly at Schneeberg and many other localities where bismuth is found (*v.* BISMUTH), in Bohemia, at Balmoral near Pretoria, near Sudbury in Ontario, very pure at Tunaberg in Sweden, and free from nickel in Colorado. As triarsenide, it forms *skutterudite* CoAs_3 . Sulpharsenide of cobalt occurs as *cobalt glance*, *grey cobalt*, or *cobaltine*, abundantly at Vena (Sweden) and in Norway; in smaller quantities in Silesia and Cornwall. As hydrated arsenate it forms *cobalt bloom* or *erythrite* $\text{Co}_3\text{As}_2\text{O}_8\cdot\text{Aq.}$, found frequently as a peach-coloured incrustation on other arsenical ores, being produced by their decomposition. As sulphide, cobalt occurs in small quantities in *cobalt pyrites* and in *linnallite*.

Black earthy cobalt is a hydrated oxide of cobalt and manganese. It is essentially a variety of *wad* (hydrated manganese oxide), containing sometimes as much as 40 p.c. of cobalt. Surface deposits containing oxides and sulphides of cobalt and of nickel occur at New Caledonia, with veins of chrome ore and nickel and magnesium silicates; it is smelted on the spot and exported as a regulus to England. Cobalt occurs in small quantities in many other minerals; in pyrites and in certain iron ores; as oxide in black oxide of manganese; as arsenide in *mispickel*, sometimes to the extent of 10 p.c.; in selenide of lead, and in *cerite*, and in some peats and coals.

At the present time the most important source of cobalt, whence almost the whole of the cobalt of commerce is obtained, is the district surrounding Cobalt city, near the shores of Lake Timiskaming in North Ontario. Here very rich silver ores are found, containing frequently 2000 oz. silver per ton, and sometimes as much as 60 p.c. These ores also contain a high percentage of cobalt and nickel, chiefly as arsenides, and, after extraction of the silver in Canada, are exported to nickel and cobalt refiners.

Extraction.—The methods adopted by manufacturers for the extraction of cobalt from the ores vary with the nature of the ores. The ores are first concentrated by fusing with a suitable flux, whereby silicious matter and a portion of the iron are removed. In the case of the Ontario ores, the speiss consists chiefly of arsenides of

cobalt, nickel, iron, and copper. The speiss is then calcined, the iron is oxidised to ferric oxide, part of the arsenic is removed, a little less being left than is required to combine with the iron. The mass is then dissolved in hydrochloric acid, and lime is added, whereby the iron is precipitated as arsenate and hydroxide. The liquid is then treated with sulphuretted hydrogen to precipitate copper and other heavy metals, excess of the gas evaporated off, and the cobalt precipitated as oxide by the addition of bleaching powder. The nickel in the solution is subsequently precipitated by potash or lime.

In the case of New Caledonian ores, consisting chiefly of sulphides, the treatment of the concentrated ore is somewhat different. The *matte*, consisting chiefly of sulphides, is carefully calcined at a moderate temperature, and converted into sulphates. These are dissolved in water, and the iron precipitated by careful addition of the requisite quantity of sodium carbonate. The copper and heavy metals are separated by sulphuretted hydrogen, and after boiling off the excess, the cobalt is precipitated by sodium hypochlorite (bleaching powder cannot be used, owing to the sulphates in the solution), and the nickel in the remaining liquid precipitated by sodium carbonate.

In Herrenschildt's process for the treatment of New Caledonian ores, these are treated with a solution of ferrous sulphate, when cobalt, nickel, and manganese pass into solution, and iron remains in the residue. Copper is first separated, and then the cobalt, nickel, and manganese precipitated by sodium sulphide. The manganese is extracted by ferric chloride, the nickel and cobalt sulphides roasted to sulphates, and converted into chlorides by calcium chloride. A part of the solution is treated with lime water, and the suspended precipitate oxidised by chlorine and added to the other portion, whereby the cobalt is precipitated and nickel chloride remains in solution.

Metallic cobalt is not at present used to any extent in the arts, though its utility is becoming more fully recognised. Commercially it is always prepared by heating the oxide with charcoal; it then contains small quantities of carbon. Pure cobalt is prepared by heating cobalt oxalate $\text{Co}(\text{CO}_2)_2$, when the carbon and oxygen pass off as carbonic anhydride, leaving the pure metal as a powder. A button of the fused metal may be obtained by fusion of the oxalate alone, or of the oxide mixed with charcoal under a layer of powdered glass containing no lead or other reducible metal; the fusion is preferably performed in a lime crucible at the highest temperature of a furnace. Pure cobalt may also be prepared by electro-deposition with platinum electrodes (Winkler, *Zeitsch. anorg. Chem.* 8, 1). Cobalt is also produced as a grey metallic powder by igniting the oxide at a red heat in a current of hydrogen. If too low a temperature has been used, the metal produced is *pyrophoric*, igniting and becoming reoxidised in contact with the air.

Properties.—Cobalt is a brilliant silver-white metal, similar in properties to iron. It is the most magnetic metal after iron, and retains its magnetism at high temperatures; above 1115° it passes into a non-magnetic variety.

Pure cobalt is harder and more tenacious

than iron, its breaking weight being about 50 kilos. per sq. millimetre. Valenciennes states that cobalt, after fusion and annealing, may be rolled into spiral bands like good iron (Compt. rend. 70, 607). Cobalt melts at 1530° (Copaux), *i.e.* about the temperature at which English hammered iron fuses. Its sp.gr. is 8.8, and hardness, 5.5. Its specific heat (20°–100°) is 0.104; specific resistance, 5.5; and the temperature coefficient of resistance, 0.0055. It is slowly soluble in hydrochloric and sulphuric acids, with evolution of hydrogen, quickly soluble in nitric acid; it is not attacked by hot or cold alkali, but if used as anode in the electrolysis of alkaline electrolytes, passes into a colloidal solution of cobaltous oxide. It exhibits also the *passive* state, similar to that of iron and other metals, but the tendency to do so is slight. Cobalt occludes from 60 to 150 times its own volume of hydrogen, the amount varying with the mechanical condition of the metal. The powdered metal combines, when heated, with chlorine, bromine, and iodine. It decomposes steam at a red heat, and, if finely divided, ignites when heated in oxides of nitrogen, and in a current of ammonia gas at 500° forms a nitride Co_4N_2 . When finely divided cobalt is heated to 150°–200° in carbon monoxide at 100 atmos. pressure, orange-red crystals of *cobalt carbonyl* $\text{Co}(\text{CO})_4$ are formed, melting at 51°, soluble in alcohol or ether, but insoluble in water, and decomposing above 52°, yielding $\text{Co}(\text{CO})_3$ which further decomposes (Mond, Chem. Soc. Trans. 1910, 798) (*v.* COBALT CARBONYLS).

Cobalt may be deposited as a fine lustrous coating on metals by the electrolysis of a neutral solution of the double sulphate of cobalt and ammonium, using a current of about 6 amperes per sq. foot of cathode surface, and an anode of cobalt (A. Gaiffe, Compt. rend. 1878). The presence of ammonium chloride appears to hinder, whilst ammonium sulphate assists, the deposition. The deposit of cobalt is harder, more tenacious, and of greater beauty than that of nickel (Troost).

(For the properties of cobalt containing other metals, *v.* Alloys of cobalt.)

Detection.—All ores and compounds of cobalt impart a blue colour to a bead of borax on fusion; if present in too great excess, the bead appears black. Heated on charcoal with reducing flux, all substances containing cobalt produce metallic particles which are attracted by a magnet (distinction from all other bodies except iron and nickel).

Salts of cobalt, when *strongly* heated with alumina before the blowpipe, give a fine blue colour (Thenard's blue). Sulphuretted hydrogen produces no precipitate in an acid solution, but gives a black precipitate of sulphide in alkaline solutions, the precipitated sulphide being insoluble in dilute acids. In a solution containing free acetic acid, potassium nitrite produces a yellow precipitate of potassium cobaltinitrite $\text{K}_3\text{Co}(\text{NO}_2)_6$; the whole of the cobalt being thus precipitated on standing in a warm place for some time. If a mineral acid is present, it should first be neutralised by potassium hydroxide.

Potassium thiocyanate with cobalt salts gives a red colouration, and, on the addition of alcohol and ether, forms a deep blue ethereal layer.

Cobalt is also precipitated as a red precipitate by the addition of a solution of nitroso- β -naphthol to its alcoholic or acid solutions. As nickel is not thus precipitated, this forms a useful means of separation of the two metals, the sulphides being dissolved in *aqua regia*, evaporated to dryness, taken up with a little water and hydrochloric acid, and precipitated as above.

Estimation.—Ores containing cobalt are usually very complex; they almost invariably contain nickel and many other metals from which the separation is difficult. The following scheme will serve for the estimation of both cobalt and nickel in any mineral, though in the case of certain ores it may be somewhat simplified.

From 2 to 7 grams of the finely ground ore are roasted in a porcelain crucible in a muffle. The residue is boiled with hydrochloric acid containing a little nitric acid until the metallic oxides are dissolved; the solution is diluted, nearly neutralised with ammonia, and boiled with sodium acetate solution, whereby the iron and aluminium are precipitated as acetates containing the greater part of the arsenic (as arsenate of iron) and a little nickel and cobalt. The solution is filtered, and the precipitate redissolved in hydrochloric acid and reprecipitated as before, the precipitate being this time free from nickel and cobalt. The two filtrates are mixed, just neutralised with ammonia, and treated with sulphuretted hydrogen gas; cobalt, nickel, zinc, copper, bismuth, &c., are thus precipitated as sulphides, leaving the manganese and the alkaline and earthy metals in solution. The precipitate is filtered, washed, dried, and roasted, the oxides so produced dissolved in hydrochloric acid, and treated with sulphuretted hydrogen; the copper, bismuth, lead, &c., are thus precipitated and filtered off.

The solution is boiled till free from sulphuretted hydrogen, and the two metals coprecipitated by the addition of potash to the boiling solution; the precipitate is filtered and washed, nearly dried, and separated as far as possible from the filter. The precipitate is digested in a dish with dilute hydrocyanic acid, then with potash solution, and again with hydrocyanic acid, and warmed until no further solution occurs. A minute quantity of residue is left, consisting of paracyanogen and a small quantity of the oxides of nickel and cobalt; it is added to that still remaining on the filter paper, and the whole washed, dried, heated, and weighed.

The solution containing the two metals is boiled to expel the excess of acid, and consists of cobaltcyanide of potash and double cyanide of nickel and potash. Precipitated yellow mercuric oxide is added, and the solution boiled for some time. The nickel is thus precipitated, partly as cyanide and partly as sesquioxide. It is filtered, washed, dried, heated, and weighed as nickel protoxide NiO . The filtrate is nearly neutralised with nitric acid, and a neutral solution of mercurous nitrate added in excess. The cobalt is thus precipitated as mercury cobaltcyanide, which is washed, dried, and heated in an open crucible until of constant weight. The product consists of Co_2O_3 .

From the proportions of cobalt and nickel thus found, the amount of each in the residue on the filter paper, &c., which has been weighed

may be calculated, and added to the amounts directly determined.

In other methods, the copper, &c., are first precipitated by sulphuretted hydrogen, iron by ammonia, and the nickel and cobalt precipitated as sulphides. The sulphides are redissolved, and in (1) the total nickel and cobalt estimated by electro-deposition; in (2) the cobalt is first precipitated and the nickel alone determined.

The cobalt in the above solution may also be determined by precipitation as potassium cobalt-nitrite, dissolving the precipitate in warm dilute sulphuric acid, evaporating nearly to dryness, and electrolysing after addition of ammonium oxalate and excess of ammonium carbonate (Coppaux, Bull. Soc. chim. iii. 29, 301).

The solution containing the sulphides of nickel and cobalt may also be estimated after freeing from excess of acid by boiling with barium carbonate, and adding excess of bromine water. After 10 minutes the cobalt is completely separated as sesquioxide (Taylor, Proc. Man. Phil. Soc. 46, 1).

Various volumetric methods have been suggested, but none appears to be perfectly satisfactory.

Alloys of cobalt. Cobalt unites with incandescence on fusion with *antimony* or *arsenic*, forming brittle iron-grey alloys.

With *arsenic* the freezing-point curve indicates the existence of compounds, Co_5As_2 ; Co_2As ; and Co_3As_2 . Smaltine CoAs_2 forms tin-white octahedra; and *skutterudite* CoAs_3 occurs as greyish-white octahedra. The arsenides are attacked by oxidising agents, and all containing over 38 p.c. arsenic are non-magnetic.

Antimony and cobalt are completely miscible in the liquid state. Three classes of alloys exist; magnetic alloys with less than 67 p.c. antimony; alloys of from 67 to 80.27 p.c., which on heating form CoSb ; and alloys above 80.27 p.c., which by acids yield a compound, CoSb_2 , as a grey crystalline powder (Ducellicz, Compt. rend. 147, 1048).

Cobalt has a marked effect on the electrical properties of *copper*; 3.5 p.c. gives an alloy with a temperature coefficient of the resistance of only 0.00077. Two series of mixed crystals appear to exist, 0-10 p.c., and 95-100 p.c. copper, and alloys within these limits consist of conglomerates of the two sets of mixed crystals. Some of the alloys are very ductile. As in many of the cobalt alloys at high temperatures, the cobalt is present as a non-magnetic form (β), which changes to the magnetic (α) form on cooling. Alloys containing 99 p.c. of copper are stated to be magnetic (Sahmen, Zeitsch. anorg. Chem. 57, 1).

Tin and cobalt are perfectly miscible as liquids, and, according to Ducellicz (Compt. rend. 148, 502), all alloys are mixtures of CoSn and Co_2Sn , with one another, or with either of the components. Below 57.6 p.c. tin, the alloys are magnetic and brittle; above 66.8 p.c. tin, the alloys are less brittle and non-magnetic; all are much harder than either component. A compound Co_2Sn of m.p. 1151° has also been described.

With *gold* a brittle alloy is produced, that containing 1 part gold and 17 parts cobalt is dark-yellow and very brittle; all the alloys are magnetic. With *platinum* a fusible alloy is

produced; and a silver-white magnetic amalgam with *mercury* is used in dentistry.

Alloys with *aluminium* containing less than 68.5 p.c. cobalt are non-magnetic, the freezing-point curve indicates a compound CoAl . Cobalt and nickel do not appear to form a compound; the freezing-point curve is almost straight, the composition of the solid being almost identical with that of the liquid in all cases.

Addition of *iron* has no appreciable effect on the melting-point of cobalt, the curve being almost horizontal to 5 p.c. cobalt, the crystals having the same composition as the fused mass. Two series of non-magnetic, which transform into four series of magnetic crystals, appear to exist (Tammann, Zeitsch. anorg. Chem. 45, 205). Steels containing up to 60 p.c. cobalt show perlitic structure, and the mechanical properties are only slightly affected by the cobalt.

Lead, *silver*, or *bismuth* are only partially miscible with cobalt when molten, and no definite alloys appear to be formed.

With *silicon* in the electric furnace, steel-grey metallic-looking silicides are formed, Co_2Si and CoSi_2 . Both are stable and hard, and attacked by hydrofluoric acid and *agua regia*. A very hard magnetic *boride* is prepared in a similar manner; and by the action of phosphorus on cobalt chloride at a low red heat a hard brittle *phosphide*, Co_2P_3 , not affected by heat or acids, is produced.

It is possible to combine cobalt or nickel with manganese with the production of valuable alloys. For this purpose commercial manganese or ferro-manganese may be used, the presence of iron not being injurious. From 2 to 5 p.c. of the manganese is added in small portions to the molten metal; much gas is evolved after each addition, and the metal is poured into moulds when tranquil (*v. Huntingdon*, J. Soc. Chem. Ind. 1882, 258).

It is stated that when in the molten condition cobalt and nickel take up both carbon and oxygen, but evolve the greater part of the latter substance on cooling, leaving a porous metal containing carbon. A method has been patented whereby this carbon is said to be eliminated. The porous cubes of metal are immersed in a 4 p.c. solution of alkaline manganate or permanganate, dried and melted in a crucible at a high temperature. The carbon is said to be thus oxidised and removed, and the metal takes up a small quantity of oxygen. As soon as the metal flows easily, a little black flux and charcoal, or a small quantity of aluminium, or the calcium zinc produced in Caron's process, is added, and the oxygen thus removed (Dingl. poly. J. 1884, 254-315).

Oxide of cobalt is used for the preparation of the salts of cobalt and of smalt, and by enamellers and porcelain manufacturers for the production of the finest blue glaze and colour on porcelain, glass, and other vitrifiable substances. The presence of $\frac{1}{35555}$ of this substance imparts a bluish tinge to clear glass.

The presence of other oxides has an injurious effect on the colour produced by this substance (*v. Smalt*); it is therefore necessary, for the more delicate work, to ensure its complete freedom from such impurities.

When heated strongly with magnesia, it produces a pink mass; with alumina, a fine blue

(Thenard's blue); and with zinc oxide, a green (Rinnmann's green). *Zaffre* consists of a very impure oxide of cobalt, produced by roasting the ore. It is usually mixed with 2 or 3 parts of fine sand or ground quartz, and is used for the same purpose as smalt for the coarser work.

Cobalt blue, Cobalt ultramarine, Thenard's blue, Azure blue. The composition of this pigment varies considerably, according to the method of manufacture. It consists sometimes of the oxides of cobalt and aluminium; at other times it contains phosphate or arsenate of cobalt.

It is best prepared by first precipitating a solution of a cobalt salt, usually the nitrate, free from iron and nickel, with potassium or sodium phosphate, or with sodium arsenate. The gelatinous violet precipitate is thoroughly washed and well mixed with 3-5 volumes of freshly precipitated, well-washed alumina (when cobalt arsenate is employed, a larger proportion of alumina may be added), precipitated from a solution of alum free from iron by the addition of sodium carbonate. The mixture is dried until it becomes brittle, and calcined at a cherry-red heat for 30 minutes in a well-covered clay crucible. When the desired blue colour has been developed, the mass is ground with water and dried. In order to prevent the possibility of entrance of reducing gases, which much injure the value of the product, Regnault recommended the addition of a little mercuric oxide before the ignition. This becomes decomposed and evolves oxygen, which effectually prevents reduction, while the mercury escapes as vapour (Regnault, Cours Elém. de Chimie, 3, 150).

A similar but less fine colour is produced by the simultaneous precipitation of the oxides of cobalt and aluminium by the addition of sodium carbonate to a mixture of cobalt nitrate and alum; the mixed precipitate is washed and treated as above.

According to the process recommended by Binder (Technologiste, 5, 55), the oxide of cobalt is precipitated by the addition of the requisite quantity of ammonia to a solution of pure cobalt chloride. The washed precipitate is mixed with alumina as before, dried, and calcined at a red heat in a clay crucible for two hours.

Thenard's blue is of a fine ultramarine colour; the presence of excess of cobalt imparts a somewhat greenish tinge. It has, however, the disadvantage of appearing violet by gaslight. It is one of the most permanent blue pigments, being unaltered by acids or alkalis, and is largely used as an oil and water colour, but works better as water colour. It is non-poisonous, and has the advantage of miscibility with other pigments without alteration.

Ceruleum, Cæline, Bleu céleste, is a corresponding colour containing oxide of tin and usually calcium sulphate. Its general composition is said to be oxide of tin, 49.66; oxide of cobalt, 18.66; calcium sulphate and silica, 31.68; and a pigment of this nature is obtained by precipitating a solution of cobalt nitrate with sodium stannate, and heating the precipitate as above.

It is a fine light-blue pigment of slightly greenish tinge, of greater density than Thenard's blue, and retains its colour in artificial light.

New blue. A blue pigment of shade varying from a pale-greenish blue to a deep-turquoise blue, largely used for enamels, consists of aluminates of cobalt and chromium produced by the action of alum on carbonates and hydroxides of cobalt and chromium.

Cobalt green, Rinnmann's green. The constitution of this pigment corresponds with that of Thenard's blue, with the substitution of zinc oxide for alumina.

It may be prepared by mixing a solution of pure cobalt sulphate (or nitrate) into a paste with zinc oxide, and heating in a muffle furnace for 3 or 4 hours, until the desired colour is obtained. Pigments of a more uniform nature are produced by the precipitation of a mixture of solutions of zinc and cobalt salts, by means of sodium carbonate, phosphate, or arsenate, drying and heating the precipitate. The phosphate is said to give a purer and brighter green than the carbonate.

R. Wagner (Technologiste, 18, 409) gives the composition of fine green pigments as varying from 71.68 p.c. zinc oxide and 11.62 p.c. cobalt oxide, to 88.04 p.c. zinc oxide and 11.52 p.c. cobalt oxide, the quantity of phosphoric oxide also varying greatly.

Rinnmann's green is a fine permanent pigment; its colour varies through many shades, according to the proportion of zinc present, the darker greens containing less of that substance. It is non-poisonous and unacted upon by dilute acids or alkalis, but is attacked by ammonia. It has also the advantage of not affecting or being unaffected by other pigments. Rinnmann's green, on account of its high price, and the number of other permanent greens, finds little use as a pigment. Another permanent green pigment used in porcelain painting is said to be prepared by the calcination of a dried mixture of the following proportions of the freshly precipitated substances: 20 cobalt carbonate, 40 alumina, 20 chromium oxide.

Cobalt bronze is a phosphate of cobalt and ammonia, of a violet colour, with a bronze-like metallic lustre.

Cobalt silicates. A cobalt silicate is produced by the addition of sodium silicate (soluble glass) to a cobalt salt. It produces a blue pigment well suited for painting on glass and porcelain.

Smalt. *Bleu d'azur, Bleu de Saxe.* This important substance consists of a silicate of cobalt and potash.

In the preparation of smalt in Saxony, smaltine is principally used. In Norway and Sweden the principal ore is cobaltine. The general process is identical for both ores.

The selected ore is powdered, freed from the lighter earthy impurities by washing, and placed, in charges of about 3 cwt., in a layer of 5 or 6 inches thick on the bed of a reverberatory furnace or in a muffle. It is then roasted, and the sulphur and arsenic expelled as oxides, the latter being condensed in chambers through which the fumes are passed. The roasting must be discontinued when only sufficient arsenic is left to combine with the less oxidisable metals, especially copper and nickel, while the greater part of the cobalt is converted into oxide. In order to ascertain whether the roasting has proceeded sufficiently, a small portion is occasionally tested and the process stopped when the

finest tinted glass is produced. The material is then ready for fusion for 'smalt.'

The fluxes used consist of powdered quartz and potassium carbonate. They must be of great purity, as the presence of lime and many other substances impairs the beauty of the colour. The quartz is first heated to redness, plunged into water, and, thus disintegrated, is powdered in a mill. It is then suspended in water and allowed to subside for a short time, and the liquid, which contains most of the iron and other impurities still suspended, is poured off; this operation is repeated until a pure quartz powder is obtained.

The proportions of the ingredients used vary extremely according to the richness of the ore and the colour required. The potassium carbonate used generally amounts to about one-third of the weight of ore and quartz together. White arsenic is usually added to oxidise any ferrous-salt, and thus prevent the injurious effect of that substance on the smalt, and to otherwise heighten the colour of the product. The exact amount of each of these substances is found by a test fusion and comparison with a smalt of the required colour.

The smalt furnace is similar to a glass oven; it usually contains eight crucibles. The pots are of very refractory clay, free from lime, and capable of holding $\frac{3}{4}$ cwt. When charged, they are strongly heated, and the mass fuses in about 8 hours; it is frequently stirred to render it homogeneous, and to break the crust which forms on the surface. At a white heat combination occurs, the quartz and potash react with the production of fusible potassium silicate, which dissolves the cobalt oxide, forming the blue 'smalt,' while the mixed arsenides of nickel, copper, and iron, with the small quantity of cobalt arsenide which is always present, fuse and form a brittle metallic-looking *speiss* beneath the smalt. This usually contains about 3 p.c. of cobalt and a considerable quantity of nickel, and is used for the preparation of the latter substance and of cobalt oxide. The mass is left at a white heat for some time without stirring, to allow the *speiss* to settle, and is ladled out with long-handled iron ladles into vessels of cold water. It is thus rendered granular, brittle, and easy to pulverise. When nearing the bottom of the crucible, the ladle contains both *speiss* and smalt; the former, being much more fusible, is poured first from the ladle, from beneath the smalt, into a niche in the side of the furnace, whence the dense fumes of arsenic, &c., which it evolves pass up the chimney.

The blue glass is next powdered with granite stampers, or ground between granite millstones under water, and the product passed through a series of depositing vats. In the first vat it remains for a short time only, thence it passes to a second for a somewhat longer time, to a third for about 15 minutes, to a fourth and fifth for a corresponding period, and finally to a sixth vat, where it is allowed to deposit completely. The deposit in the first vat is returned to the mill and reground, that in the second and third is the best marketable smalt, whilst in the fourth and fifth vats a lighter-coloured deposit, sold under the name *eschel*, is produced. The deposit in the last vat is not marketable, and is usually resmelted.

The marketable deposits are again washed, deposited, dried, powdered, and sifted. About three-fifths of the glass taken from the pots is thus available. The presence of other oxides than those of cobalt and potash, even in small quantities, exerts a powerful influence on the colour of the smalt. Baryta produces an indigo tinge; sodium, calcium, and magnesium produce a reddish shade; iron, a blackish green, very prejudicial to the brighter-coloured smalts; manganese violet, nickel violet, but less intense; copper, zinc, bismuth, and antimony, dull shades.

The composition of smalt varies considerably; the silica is usually from 56-70 p.c.; potash, 12-22 p.c.; and cobalt, 6-16 p.c. The following analyses by Ludwig (J. pr. Chem. 1850, 51, 129) are typical:—

	Norwegian deep-coloured smalt	German deep-coloured	German pale coarse
Silica . . .	70.86	66.20	72.12
Potash and soda	21.41	16.31	20.04
Cobaltous oxide .	6.49	6.75	1.95
Alumina . . .	0.43	8.64	1.80
Ferrous oxide .	0.24	1.36	1.40
Arsenious acid .	trace	—	0.08
Water and carbonic acid .	0.57	0.92	0.16
	100.00	101.18	97.85

Smalt is a very permanent blue pigment, largely employed for the production of blue colours with vitreous substances and in painting, both for delicate and coarse work. It was formerly much used for colouring starch, paper, &c., but for this and many other purposes it is now almost superseded by the far less permanent artificial ultramarine.

Cobalt yellow consists of potassium cobalt-nitrite, prepared by the addition of potassium nitrite to a solution of a cobalt salt acidulated with acetic acid. Its composition varies with the proportions used and the strength of the solution. Erdmann and Sadtler state that when precipitated from a solution containing much acetic acid it consists of $K_3Co(NO_2)_6$ with a variable amount of water.

Cobalt yellow is a bright yellow crystalline powder, very free from impurities, unacted upon by cold water or cold acids, and but slowly blackened by sulphuretted hydrogen.

It forms a fine pigment for artistic purposes. When used for painting porcelain it produces the usual blue colour on baking, which, on account of the purity of the substance, is of great beauty.

Salts of cobalt. The soluble salts of cobalt are prepared by solution of the oxide, carbonate, or metal in the various acids. They are generally pink and deliquescent, forming pink solutions when dilute, but when dried, or in concentrated solution, they are blue. For this reason, solutions of nitrate and other salts of cobalt are used as sympathetic inks, such writing being almost invisible until brought near a fire, when the letters appear blue. They gradually reabsorb moisture and again become invisible. They are largely used for neutralising the

yellow colour of porcelain, and giving a pure white body, the porous clay being for this purpose soaked in solution of cobalt salts.

When ammonia is added to a solution of a cobalt salt, oxygen is absorbed; giving rise under various conditions to many complex series of salts containing ammonia and different oxides of cobalt.

Cobaltous chloride CoCl_2 is prepared by dissolving the oxide or carbonate in hydrochloric acid, and evaporating the solution. According to the temperature at which it crystallises, it may contain 6, 4, or 2 molecules of water of crystallisation, the latter at the higher temperatures.

Cobaltous chloride is soluble in water or alcohol. A strong solution, or a weaker solution containing strong hydrochloric acid, is of a blue colour.

Cobaltous sulphate $\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$ is prepared by solution of the oxide or carbonate in dilute sulphuric acid. It crystallises in red crystals, isomorphous with magnesium sulphate, soluble in 24 parts of cold water.

Cobaltous nitrate $\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ is a red deliquescent crystalline salt prepared by dissolving the oxide in nitric acid. It is very soluble in water, the solution being used as a reagent in blowpipe analysis.

COBALT BLOOM. *Erythrite*; *Hydrated cobalt arsenate* (v. COBALT).

COBALT BLUE or **THENARD'S BLUE** v. COBALT.

COBALT BRONZE v. COBALT.

COBALT CARBONYLS. Cobalt forms two carbonyls: the *tetracarbonyl* $\text{Co}(\text{CO})_4$, and the *tricarbonyl* $\text{Co}(\text{CO})_3$.

Cobalt tetracarbonyl. This compound is prepared as follows: Cobalt oxalate is carefully heated until completely converted into the oxide. It is then washed free from traces of chlorides which hinder the formation of the carbonyl, and dried at 120° . The oxide is placed in the apparatus described under 'carbonyls,' and reduced to cobalt by means of hydrogen, at a temperature of 300° and a pressure of 5 atmospheres. After the reduction, the hydrogen is displaced by carbon monoxide, the pressure being increased and the temperature lowered. For the production of the carbonyl, a minimum pressure of 40 atmospheres and a temperature of 150° is needed, and at pressures up to 250 atmospheres and temperatures between 150° and 250° , varying quantities of the carbonyl are collected in a tube attached to the outlet of the apparatus, and immersed in a freezing mixture.

The tetracarbonyl forms orange-coloured crystals of sp.gr. 1.73, which melt at 51° , and decompose above that temperature.

The molecular formula is $\text{Co}_2(\text{CO})_8$. The compound is insoluble in water, but is soluble in most organic solvents, and in nickel tetracarbonyl. It is not attacked by aqueous acids but concentrated acids and the halogens decompose it, forming the corresponding salt, carbon monoxide, and hydrogen

In contact with air a deep violet-coloured compound is formed, which is most probably a hydrated basic carbonate. The crystals are best preserved in a sealed tube in an atmosphere of hydrogen or carbon monoxide.

When the tetracarbonyl is heated at 60° , one quarter of the carbon monoxide is evolved at a regularly decreasing rate, leaving a compound having the formula $\text{Co}(\text{CO})_3$ in the form of black crystals, which are decomposed above 60° into cobalt and carbon monoxide, no intermediate product being formed.

When the tetracarbonyl is heated at 100° , one quarter of the carbon monoxide is evolved almost instantaneously, the rest coming off very irregularly and comparatively slowly (Mond, Kirby, and Cowap, Chem. Soc. Trans. 1910, 97, 798).

COBALT GLANCE. *Grey cobalt*; *Cobaltine*; *Sulpharsenide of cobalt* (v. COBALT).

COBALT GREEN or **RINMANN'S GREEN** v. COBALT.

COBALT PYRITES v. COBALT.

COBALT SPEISS v. COBALT.

COBALT ULTRAMARINE or **COBALT BLUE** v. COBALT.

COBALT YELLOW v. COBALT.

COBALTINE v. COBALT.

COCAÏNE v. VEGETO-ALKALOIDS.

COCATANNIC ACID v. TANNINS.

COCCINE v. AZO-COLOURING MATTERS.

α -COCCINIC ACID, COCCININ, v. COCHINEAL.

COCCULUS INDICUS or **INDIAN BERRY** is the fruit of the *Anamirta paniculata* (Colebar), [*A. Cocculus* (Wight and Arnott)] nat. ord. *Menispermaceæ*, a tree growing upon the coasts of Malabar, Ceylon, &c. The berry is about the size of a large pea and of a dark-grey colour. It possesses strong poisonous and narcotic qualities from the fact of its containing about one-fiftieth part of its weight of picrotoxin, and has been employed to increase the bitterness as also the inebriating effect of beer. It is, however, exceedingly deleterious to health, and the use of it for this purpose has been prohibited by the Legislature under heavy penalties.

Besides picrotoxin, Schmidt and Löwenhardt (Bull. Soc. chim. 14, 817) obtained from the seeds *cocculin* $\text{C}_{15}\text{H}_{25}\text{O}_{10}$, crystallising in white needles, sparingly soluble in hot water, insoluble in cold water, alcohol and ether. It is probably identical with Barth and Kretschy's *anamirtin* $\text{C}_{15}\text{H}_2\text{O}_{10}$ which they regarded as a constituent of picrotoxin.

Cocculus indicus berries contain *menispermine*, *paramenispermene*, and *picrotoxin* (v. PICTOTOXIN).

COCCUS CACTI, C. ILICIS, C. LACCAL, v. COCHINEAL.

COCHIN CHINA WAX v. WAXES.

COCHINEAL. This important natural dyestuff, which, in its native country, Mexico, was used as a dye and cultivated by artificial means at a remote period of history, was for a long time considered to be of vegetable origin. Cochineal, however, consists of the dried body of an insect, the *Coccus cacti*, which lives upon a species of cactus (the *Napalea coccinellifera* (S.-Dyck) or *Nopal*), a plant which is found in the wild condition, but which, for the sake of the insect, is cultivated in gardens which are termed *Nopleries*. The collection of the insects takes place before the commencement of the rainy season, and they are then brushed either into straw baskets or into basins of tinned iron. A number of insects are left upon each plant, and a new generation is produced, which is again gathered at a suitable

period. The insects are killed by immersion in boiling water, or are enclosed in a linen bag and placed in an oven; by the latter process the peculiar white down covering the insect is preserved, but in the former case is lost.

In Mexico and Central America two varieties of cochineal are known—the home-grown, or fine cochineal (*grana fina*); and the wild, or forest cochineal (*grana silvestra*). The former is more valuable than the latter, and is richer in colouring matter. Since 1830 the cultivation of cochineal was introduced into Spain and the Canary Islands, Algeria, and Java, but the most productive of these newer plantations were those of Java. Since the discovery of the coal-tar colours, the consumption of cochineal as a dyestuff has gradually decreased, and at the present time it is only employed in a minor degree. According to Liebermann, cochineal contains about 10 p.c. of colouring matter (Ber. 18, 1969).

Carminic acid, the colouring matter of cochineal, was first isolated by Pelletier and Caventou (Ann. Chim. Phys. [2] 8, 250), and was subsequently examined by Preisser (Annalen, 52, 375; J. Pharm. Chim. [3] 5, 191); and Arppe (Annalen, 55, 101); but Warren de la Rue (*ibid.* 64, 1) was the first to isolate this substance in a pure condition, and described it as a purple-brown mass, which, on grinding, yields a bright-red powder, easily soluble in water and alcohol, but not in ether. The mean of his analyses gave 54.13 p.c. of carbon, 4.62 p.c. of hydrogen, and 41.25 p.c. of oxygen by difference; and from these figures he deduced the formula $C_{14}H_8O_8$ or $(C_{14}H_8O_8)_2$.

Schützenberger (Ann. Chim. Phys. [3] 54, 52), on the other hand, was the first chemist who succeeded in obtaining carminic acid in a crystalline condition. He precipitated the colouring matter from an aqueous cochineal extract in the form of its lead compound; suspended this in water, and decomposed it with sulphuretted hydrogen. The liberated carminic acid dissolved in the water and was recovered from this solution by evaporation at a low temperature. The product, dissolved in alcohol, was treated with ether to precipitate certain impurities, and the liquid partially evaporated. On cooling, a crystalline mass was obtained, which Schützenberger considered to consist of two substances, carminic acid $C_9H_8O_8$, and oxycarminic acid $C_9H_8O_6$, the latter being distinguished by its solubility in ether.

Schaller (J. 1864, 410), who prepared carminic acid by the same method, assigned to it, however, the formula $C_9H_8O_6$.

The work of Hlaziwetz and Grabowski (Annalen, 141, 329) indicated that carminic acid was a glucoside which could be decomposed into a sugar and a new colouring matter, *carmine red*:

but according to Liebermann (Ber. 18, 1969; Will and Leymann, *ibid.* 18, 3182; and Von Miller and Rohde, *ibid.* 26, 2647), this is incorrect.

Coccinin, according to Hlaziwetz and Grabowski, is produced when carminic acid is fused with caustic potash. It crystallises from alcohol in straw-yellow needles or leaflets, dissolves in alkalis with a yellow colour, which, by air oxidation, develops first a green then

violet, and, finally, a purple tint. The analyses of this substance were in agreement with the formula $C_{14}H_{12}O_5$.

Rufiococcin.—By heating carminic acid with sulphuric acid to 130°–140°, Liebermann and van Dorp (Annalen, 163, 105) obtained a new colouring matter rufiococcin, $C_{16}H_{10}O_6$, and this consisted of a bright-red powder, sparingly soluble in hot water and ether, with a greenish-yellow fluorescence. On distillation with zinc-dust, it yielded a colourless crystalline hydrocarbon $C_{16}H_{12}$, m.p. 183°–188°, from which, by oxidation, a quinone melting at 250° could be produced.

Fürth, somewhat later (Ber. 16, 2169), prepared the same hydrocarbon by the distillation of both cochineal carmine and coccinin with zinc-dust.

Rufiocarmine $C_{16}H_{12}O_6$ can be obtained, according to Liebermann and van Dorp, by heating carminic acid with water in a sealed tube at 200°. It consists of a carmine-red powder, easily soluble in alcohol.

In view of the uncertainty existing as to the percentage composition of carminic acid, Schunck and Marchlewski (Ber. 27, 2980) submitted this substance to an elaborate process of purification, and, using in their operations as low a temperature as possible, obtained a product which crystallised from alcohol in red prismatic needles. Their analysis agreed closely with that required by the formula $C_{11}H_{12}O_6$, and the percentage composition approximated with the figures given by Warren de la Rue, and also by Schützenberger.

On the other hand, analyses by Miller and Rohde (Ber. 30, 1762) indicated the formula $C_{12}H_{11}O_7$ or $(C_{12}H_{11}O_7)_2$ as probable; but it now appears, according to the more recent work of Liebermann, Höring, and Wiedermann (Ber. 1900, 33, 149), that the correct formula of carminic acid is $C_{22}H_{22}O_{13}$.

The most simple method for the purification of carminic acid is that devised by Miller and Rohde. A solution of the crude colouring matter in five times its weight of water, is diluted with four times its volume of acetic acid. The filtered liquid, on standing over sulphuric acid, gradually deposits the carminic acid in a crystalline condition.

Carminic acid crystallises in red prisms, easily soluble in water and alcohol, with a purple-red colour. It possesses no melting-point, but darkens at 130°, and at 250° becomes quite black-coloured.

By the action of alcoholic potassium acetate, carminic acid (Perkin and Wilson, Chem. Soc. Trans. 1903, 83, 139) yields two potassium salts, viz.:

Monopotassium carminate $C_{22}H_{23}O_{12}K$ (probably $C_{22}H_{21}O_{13}K$) which is red-coloured; and

Dipotassium carminate $C_{11}H_{11}O_6K$ (probably $C_{22}H_{20}O_{13}K_2$) soluble in water, with a violet-red colouration.

Hexabenzoyl carminic acid $C_{22}H_{16}O_{13}(C_6H_5O)_6$, obtained by digesting carminic acid with benzoyl chloride (Liebermann, Höring, and Wiedermann) is an orange-coloured powder, easily soluble in benzene.

Octacetyl carminic acid $C_{24}H_{12}O_{13}(COCH_3)_8$? (probably $C_{22}H_{14}O_{13}(C_2H_5O)_8$) crystallises in golden-yellow needles, m.p. 155°–165°, and is

readily prepared by the short action of acetic anhydride in presence of zinc chloride or sulphuric acid on carminic acid (Miller and Rohde).

THE CONSTITUTION OF CARMINIC ACID.

Nitrococcussic acid was obtained by W. de la Rue from carminic acid by the prolonged action of boiling nitric acid. It was subsequently studied by v. Kostanecki and Niementowski (Ber. 18, 250), and was found to be identical with the *trinitrocresotinic acid*, of the following constitution:—

When carminic acid dissolved in 50 p.c. acetic acid is treated with an excess of bromine, and the solution digested at the boiling heat, two substances, known as α - and β -bromcarmines, are produced (Will and Leymann, Ber. 18, 3180).

α -Bromcarmine $C_{10}H_6Br_4O_3$, the more sparingly soluble substance, crystallises in colourless needles, and melts at 247° - 248° , with decomposition. When oxidised with potassium permanganate in alkaline solution, it gives *dibrommethylhydroxyaldehydobenzoic acid*,

and *dibrommethylhydroxyphthalic anhydride*

On treatment with hot caustic soda solution, α -bromcarmine yields, in addition to a purple-red colouring matter, dibrommethylhydroxyphthalic acid, and bromoform (Miller and Rohde). As a result of this reaction, these authors assigned to α -bromcarmine the constitution of a methylhydroxytetrabromdiketohydrindene

For Zincke (Ber. 20, 3227; 21, 2388) had previously shown that the dibromdiketohydrindene itself

under similar treatment yields both phthalic acid and bromoform.

β -Bromcarmine $C_{11}H_7Br_3O_4$ is obtained as a yellow amorphous powder, easily soluble in alcohol (Will and Leymann), and is best purified by means of its potassium salt. Crystallised from acetone, it separates in orange needles, melting at 232° (W. and L.) or 288° (Miller and Rohde). By the action of bromine in the presence of 50 p.c. acetic acid solution, it is

converted into α -bromcarmine. As a result of their investigation, Miller and Rohde ascribed to β -bromcarmine the constitution of a *methyl-dihydroxytribrom-a-naphthaquinone*, possessing one of the following formulæ:—

This suggestion was supported by the fact that bromoxynaphthaquinone (1), on treatment with bromine and caustic soda solution, is converted into dibromdiketohydrindene (2) (Zincke, l.c.)

A further point in support of this view was obtained by a study of the behaviour of β -bromcarmine with zinc-dust in alcoholic solution. Thus the acetyl compound of the reduction product, m.p. 206° , gave, on analysis, numbers agreeing with those of the acetyl derivative of a *methyl-dibrom-dihydroxy-naphthaquinone*, possessing the following formula:—

From a consideration of the points above enumerated, Miller and Rohde considered that the constitution of carminic acid could be represented by one or other of the following expressions:—

As, however, such formulæ require $C=64.7$ p.c., $H=3.92$ p.c., figures which are much higher than those given by the analysis of carminic acid itself, these authors suggested the addition of two molecules of water of hydration, as shown below:

A substance of this constitution would require $C=55$ p.c., and $H=5$ p.c.

Somewhat later, Liebermann and Voswinkel (Ber. 30, 688) studied the oxidation of carminic acid with alkaline potassium permanganate at the ordinary temperature, and in this way succeeded in producing two important acids.

Cochinealic acid $C_{10}H_8O_7$, crystallises in colourless needles, which melt at 224° - 225° with evolution of CO_2 . It is tribasic, at 260° is converted into *hydroxymethylphthalic anhydride* (1); when heated with water in a sealed tube at 210° yields symmetrical *cresotinic acid* (2)

and in the same manner at a lower temperature, 170°, gives *α*-coccinic acid (3). The constitution of cochinealic acid was therefore as follows:—

α-Coccinic acid C₉H₉O₅. The second product of the oxidation, which, as already indicated, can also be prepared from cochinealic acid, proved to be identical with the hydroxyuvitic acid of Oppenheim and Pfaff (Ber. 7, 929). It consists of colourless needles, m.p. 239°.

Liebermann (*ibid.* 30, 1731), whilst agreeing with the diketohydrindene constitution which had been assigned to *α*-bromcarminine by Miller and Rohde, considered that *β*-bromcarminine was an indone rather than a naphthoquinone derivative, and could be better represented as follows:—

It was probable, indeed, that carminic acid itself was a hydrindene or bishydrindene derivative, and the following constitutions were suggested for it:—

In a more recent paper, however, Liebermann and Voswinkel (Ber. 37, 3344) consider that carminic acid is possibly a tetrahydrate of *α*-dimethylidihydroxynaphthacenequinonedicarboxylic acid

and it was observed that a dimethyltetrahydroxynaphthacenequinone

prepared by these authors not only possessed weak tinctorial property of a cochineal-like character, but in several respects closely resembled carminic acid itself.

A valuable contribution to the subject was made by Dimroth (Ber. 1909, 42, 1611) who studied the oxidation of carminic acid with potassium permanganate at 0° in presence of sulphuric acid. The solution thus obtained gave nothing to ether, but on heating for three-quarters of an hour at 90°, it evolved carbon dioxide, and ether then extracted carminazarin.

Carminazarin crystallises from water in garnet-red needles, decomposing at 240°-250°. It possesses the constitution (1), and is very similar to isonaphthazarin (2).

Its alkaline solution, when treated with a stream of oxygen, is quickly decolourised with formation of 5-6-dicarboxy-4-hydroxy-*o*-tolylglyoxylic acid

A further point of resemblance of carminazarin to isonaphthazarin is shown by its behaviour with nitric acid in glacial acetic acid, for whereas the latter gives tetraketotetrahydronaphthalene, the former yields the analogous Carminazarinquinone crystallising in colourless prisms,

and which, when heated with water or acetic acid, passes back to carminazarin.

The intermediate product formed by the oxidation of carminic acid with permanganate at 0°, and which, on heating, is transformed into carminazarin, is termed by Dimroth *carminiquinone*. The constitutions assigned to this substance (1) and to carminic acid (2) are given below:—

Carminic acid is, therefore, not a symmetrical compound, and the nature of the group C₁₀H₁₅O₇ has not yet been determined. Finally, it is considered by Dimroth that the *coccerin* (see above) of Hlaziwetz and Grabowski, and which is prepared by fusing carminic acid with potassium hydrate, has probably the constitution of a tetrahydroxymethylnaphthalene

Rohde and Dorfmueller (Ber. 1910, 33, 1363) further examined β -bromocarmine, and obtained results which support the naphthaquinone constitution assigned to it by Miller and Rohde (*l.c.*), but disprove Liebermann's contention that it is a derivative of indone. By reduction with zinc-dust and acetic acid and subsequent acetylation, β -bromocarmine gives the compound $C_{17}H_{14}O_6Br_2$;

colourless needles; m. p. 208° .

Simultaneous hydrolysis and oxidation converts this into the substance

orange prisms; m. p. 258° ; and it thus appears that by the latter treatment an hydroxyl has probably entered the quinone nucleus. The diacetyl derivative melts at 233° . When distilled with zinc-dust, this product, and also β -bromocarmine itself, give naphthalene.

TECHNICAL PREPARATIONS OF COCHINEAL.

Ammoniacal cochineal.—When a solution of carminic acid in ammonia is allowed to stand for some time, there is formed a new compound, which appears to consist of carminic acid in which one of the hydroxyls has been replaced by an amino-group. The formula assigned to this substance by Schützenberger is $C_9H_8NO_4$. This reaction, long known, has been utilised for the production of a new colouring matter termed *ammoniacal cochineal*, or *carminamide*, and this comes into commerce either as cakes or in the form of a paste.

The first variety is usually prepared by allowing one part of cochineal to stand in a closed vessel for 3 months with three parts of ammonia. The clear liquid is decanted, treated with about half its weight of gelatinous alumina, evaporated, and, when the mass has become thick, it is cut up into cakes and dried.

The paste is manufactured in a somewhat similar manner, the ammonia, however, being only allowed to react for 8 days. The clear liquid is then evaporated to about one-third its bulk without addition of alumina (Crookes, Dyeing and Calico Printing).

Ammoniacal cochineal dyes much bluer shades than cochineal itself, and is sometimes employed in conjunction with the latter. Its use is now very limited, but it finds some application in the blueing of bleached cotton.

Cochineal carmine (see under LAKES).

DYEING PROPERTIES OF COCHINEAL.

Cochineal has been little employed in cotton dyeing, but was very largely used in silk dyeing

and wool dyeing. It has now been practically replaced by the azo-scarlets.

Two shades of red are obtained upon wool with cochineal, namely, *crimson*, which is produced by means of aluminium sulphate, and a very fiery *scarlet*, for which stannous and sometimes stannic chloride are employed.

For crimson, wool is mordanted with aluminium sulphate and tartar, and is then dyed in a separate bath with cochineal. The employment of calcium salts in the dyeing operation is not beneficial. Fairly good shades of crimson can also be obtained by mordanting and dyeing in a single bath with aluminium sulphate, oxalic acid, and cochineal. For scarlet, wool can be mordanted with stannous chloride and tartar, and dyed in a separate bath with cochineal. A single-bath method, employing stannous chloride, oxalic acid, and cochineal, has, however, been very largely employed for this purpose. On the other hand, preparations of stannic chloride, known as 'tin spirits,' 'scarlet spirits,' and 'nitrate of tin,' are and have been much employed by dyers of cochineal scarlet. Though, when used alone, stannic chloride does not give such brilliant shades as the stannous mordant, a mixture of both is considered to be beneficial.

For very yellow shades of scarlet, yellow colouring matters can be added to the cochineal dye-bath, and of these 'flavine' has been considerably employed.

Cochineal red on wool possesses considerable fastness to light, but has the defect that weak alkalis and soap cause it to acquire a duller or more bluish shade.

Wool mordanted with potassium dichromate gives with cochineal a good purple colour, whereas with ferrous sulphate and tartar, purplish slate or lilac colours can be produced. These mordants, however, are not employed in practice.

A good crimson shade is produced by mordanting silk with alum, and dyeing with an extract of cochineal. In scarlet dyeing, silk is preferably first dyed yellow, then mordanted with 'nitromuriate of tin,' and finally dyed in a second bath with the assistance of cream of tartar. Silk can also be dyed in a single bath with cochineal, stannous chloride and oxalic acid.

COCHINEAL CARMINE v. LAKES.

COCHINEAL RED, -SCARLET v. AZO-COLOURING MATTERS.

COCHINEAL WAX and FAT. The wax is obtained by extracting the cochineal with benzene, and consists almost entirely of a substance to which Liebermann gave the name *coccerin*. After the removal of the coccerin, the fat is extracted with ether; it consists of myristin and an oil containing fatty acids. The following are the percentages of coccerin in various samples of cochineal (extracted whole with benzene):

Silver cochineal	. 1.0	p.c.
Mexican silver cochineal	. 1.7	"
Teneriffe silver cochineal	. 2.0	"
Zaccatille	. 0.5	"
Teneriffe black cochineal	. 0.7-1.0	"
Mexican black cochineal	. 1.5	"
Granilla	. 4.2	"

By powdering the cochineal before extraction, the percentage is increased by about one-half; except in the case of Granilla, where the granules are exceedingly small. The percentage of myristin is on the average about 1.5-2.0, and of fluid fat and fatty acids 4.0-6.0, so that the average total quantity of wax and fat contained in a silver cochineal is about 12 p.c. After recrystallising from benzene or acetic acid, coccerin forms thin glistening plates of melting-point 106°. It is sparingly soluble in all cold solvents, and nearly insoluble in alcohol and ether. It has the constitution $C_{20}H_{80}(C_{21}H_{61}O_2)_2$. On saponification with alcoholic potash, it gives cocceryl alcohol $C_{30}H_{50}(OH)_2$ and cocceric acid $C_{31}H_{62}O_3$. The alcohol forms a white crystalline powder of m.p. 101°-104°. The acid melts at 93°, and is soluble in hot alcohol, benzene, &c.; its ethyl ether melts at about 70°. The myristin $C_8H_7(OC_{14}H_{27}O)_3$ forms colourless crystals of m.p. 55°, easily soluble in warm alcohol, &c.; on saponification it gives glycerol and myristic acid $C_{14}H_{25}O_2$ of m.p. 54°, and b.p. 248° at 100 mm. (J. Soc. Chem. Ind. 4, 585).

COCHINEALIC ACID v. COCHINEAL.

COCINIC ACID v. HENDECATOIC ACIDS.

COCOA. The cocoa tree is an evergreen shrub, indigenous to Mexico and the tropical regions of Central America, whence it was introduced into Europe by the Spaniards. It belongs to the natural order *Sterculiaceae*, and comprises several species, that most highly valued and cultivated being the *Theobroma cacao*, so called by Linnæus, from *θεός* (the god) and *βρώμα* (food), in allusion to the esteem and almost veneration in which the beverage prepared from its seeds was held by the natives of Central America, and 'cacao,' the name by which it was originally known. The seeds were used as a kind of money even down to the time of Humboldt's visit to Mexico.

The tree grows to a height of from 12 to 40 feet, the average being about 25 feet, but in plantations it rarely exceeds 18 feet. It flourishes best in a moist and warm climate, in latitudes between 25° north or south of the equator, and at altitudes up to 1000 feet. It is now cultivated more or less extensively in Brazil, Caraccas, Central America, Ecuador, Essiquibo, Grenada, Guayaquil, Peru, Trinidad, Venezuela, and in the West Indies (particularly Jamaica, Dominica, and St. Lucia); also in Ceylon, the East Indies, the Philippines, Mauritius, Madagascar, San Thomé, Gold Coast, Cameroons, and to some extent in Australia.

The cocoa tree begins to bear fruit when 3 years old, and attains its full productiveness when 7 or 8 years old, but a healthy tree will bear for 40 or 50 years. Fruit is produced all the year round, but harvesting usually takes place only twice a year—from February to April, and again in October and November.

The fruit consists of an elongated pod, in shape between a melon and a cucumber, measuring from 5 to 12 inches in length, and from 2 to 4 inches in diameter, with a thick pericarp varying in colour from yellow or red to purple, according to the variety. There are from 20 to 40 or more seeds in a pod (though the number is smaller in the West Indian varieties) arranged in 5 longitudinal rows, and embedded in a rose-coloured mucilaginous pulp. When

fresh they are usually white (some varieties purple), and have a bitter taste, but after drying and exposure to the air and light they acquire a yellow, red, or brown colour, and become hard, brittle, and less bitter. They are ovate, compressed, and about the size and shape of haricot beans or olives.

After removal from the pods, the seeds or beans are either freed at once from adhering pulp and dried in the sun (or occasionally by artificial means), to produce 'unfermented cocoa,' or they are removed to the 'sweating' or curing house to undergo a process of fermentation before drying. Unfermented cocoa is distinguished by its pale skin, which separates with difficulty from the kernel. Owing to its bitter taste, it is suitable only for use in cocoa mixtures containing starch and sugar. It is quite unfit for chocolate making, and commands a lower price than fermented cocoa.

To produce fermented cocoa, the beans were formerly buried in the ground, or in trenches covered with plantain leaves, but in order to avoid the consequent adherence of earthy matter, they are now generally buried in casks or boxes, or heated in piles in sheds, and turned over once or twice daily. The temperature rises considerably during fermentation, and the process requires great care and skill, as on it the commercial value of the finished beans chiefly depends.

The objects arrived at in the 'sweating' operations are the loosening of the adherent pulp, the removal or modification of the bitter principle, the development of an agreeable aromatic odour, and the colouration of the beans to a rich mahogany tint. The fermentation process generally lasts from 2 to 7 days. In some parts, as Trinidad and Jamaica, red earth is often employed to assist in the removal of the mucilage from the beans, which are afterwards rubbed clean and dried. Occasionally Venetian red is used to impart a uniform red tint to the finished beans.

In the drying operation the beans are spread out in trays and systematically turned so as to expose every part of the bean to the light, and, when thoroughly air-dried, are in a suitable condition for shipment.

The preliminary processes of manufacture consist in (a) *sifting* out sand, dust, and small stones; (b) *picking* out by hand the empty beans and foreign matter, as larger stones, grass, wood &c.; (c) *roasting*; and (d) *cleaning*, by breaking up the beans and removal of the husks or shells. Berhardt (Chem. Zeit. 1889, 32) has found, from the results of actual factory work, that the losses in these operations amount to 2 or 3 p.c. in sifting; nearly 1 p.c. in picking; about 5 p.c. in roasting; and 12 or 13 p.c. in cleaning; making a total loss of over 20 p.c.

The roasting process, which requires great care, skill, and experience on the part of the operatives entrusted with it, is conducted in rotating cylinders heated by coke fires or by means of superheated steam in pipes lining the cylinders, to a temperature varying from 500° to 600°F. (260° to 315°C.). Uniformity of roasting is facilitated by grading the beans in the same operation to a uniform size. The beans are then cooled, gently crushed in a 'kibbling mill,' to fracture the crisp husk and break down the kernel into its natural angular

fragments or 'nibs,' after which the nibs, husks, and hard rod-shaped germs are separated by winnowing and sieving, and the nibs graded into different classes according to size.

The object of roasting is to develop to the fullest extent the characteristic aroma and flavour of the cocoa. This is probably due to the development of a volatile principle in the nature of an essential oil, somewhat analogous to the caffol of coffee (*v. infra, Cocoa-red*).

The roasted husks or shells constitute on an average about 12 or 13 p.c. of the weight of the whole bean, varying from 7 or 8 p.c. in the thin-walled beans of Ceylon and Java to 18 p.c. in those of Trinidad and the West Indies, which have a much thicker shell. The shells form a low-priced product extensively used, after grinding, in the cheaper grades of cocoa and chocolate, and occasionally, under the name of 'cocoa tea,' as a beverage which has the taste and flavour of weak cocoa. Cocoa shells have proved to be a useful addition to feeding stuffs, especially for milch cows, and gave good results on the experimental farms of Canada when used as manure. (For analysis of cocoa shells, see table below.)

The nibs enter into commerce as such, but although in this form the consumer may be assured of the purity of the article, yet, owing to the large proportion of fat in them (about half their weight) and the difficulty of disintegrating them even by boiling water, they are hardly suitable for popular use as a beverage.

For the manufacture of the various forms of prepared cocoa, the nibs are ground by means of millstones or steel mills so constructed as gradually to reduce the cocoa to the finest and smoothest possible condition. If the cocoa is to go into consumption as ground nibs in powder, the stones or rollers are kept cool during the operation, but if, as is usual, the ground cocoa is afterwards to be made up into any of the numerous forms of prepared cocoa or chocolate, the stones or rollers are usually kept heated during the grinding. This causes the fat to melt, and the whole is reduced to a liquid mass, which is run into moulds and cooled so as to form blocks, which are sold as such or kept as stock for subsequent conversion into prepared cocoa or chocolate.

The leading types of manufactured cocoa are *flake cocoa*, *rock cocoa*, and cocoa powders sold under such names as 'soluble' cocoa, and 'extract' or 'essence' of cocoa. *Flake cocoa* is prepared simply by grinding the whole beans or the nibs only in steel mills somewhat resembling those used for grinding coffee. *Rock cocoa* is made in the form of a paste by grinding in a mill with heated stones or rollers, and with the addition of sugar and starch.

The admixture of starch or other gelatinising substance tends to mask the presence of the fat and to render the cocoa more readily miscible with boiling water. These mixtures, sold under such names as 'homeopathic,' 'Iceland moss,' &c., are frequently described as 'soluble cocoa,' but this is a misnomer, since the absence of a sediment in the cup is due, not to solution of the cocoa, but to the formation of an emulsion, which holds the cocoa in a finely divided state suspended in the liquid. In some of these, as

'granulated cocoa,' 'cocoatine,' &c., sugar is added as well as starch.

The large proportion of fat (about 50 p.c.), being found by many to be difficult of digestion, is reduced in preparations intended for use as a beverage, not only by the addition of sugar and starch (which incidentally reduces the proportion of cocoa present), but also by the actual abstraction of fat to form the so-called 'essence' or 'extract' of cocoa.

The partial extraction of the fat is accomplished by submitting the pure cocoa paste enclosed in strong canvas bags to a pressure of 1200-1400 lbs. per square inch in hydraulic presses heated to 70°-80°. The cocoa butter flows out through a special orifice, and is afterwards solidified into blocks or slabs ready for use in surgical and pharmaceutical preparations, for soap making, and in the manufacture of chocolate confectionery. The commercial value of cocoa butter (which is twice that of the raw cocoa) is no doubt an inducement to its removal, in addition to the alleged purpose of making the cocoa more digestible.

To prepare the so-called 'essence' or 'extract' of cocoa, the cakes of compressed cocoa, now containing only about 25 p.c. of fat, are turned out in a nearly dry condition, and ground to a fine powder. Some cocoa powders are said to be rendered more digestible by treatment with alkalis, which soften the cellulose tissue and act upon the fat so as to produce a more perfect emulsion than that obtained by other 'soluble' cocoas prepared with starch; also there is less tendency to separation of the melted fat in the cocoa beverage. Another method is to soften the tissue by heating in closed vessels with or without water to a temperature of 150°. In some preparations, as 'solidified cocoa,' the fat is not removed, whilst a preparation of cocoa practically free from fat is obtained by extracting the roasted and ground beans with ether or benzene. The ordinary flavouring materials are vanilla and cinnamon, but other spices and artificial vanilla are occasionally used.

The principal constituents of cocoa are fat ('cocoa butter'), alkaloids, albuminoids, starch, tannin, cocoa-red, and mineral matter.

ANALYSES OF RAW COCOA NIBS.

	Bell	Boussingault
Moisture	5.23	7.6
Fat	50.44	49.9

Ash	2.75	4.0
(Tartaric acid)	—	3.4
	100.00	100.0

The fat, cocoa butter, or cacao butter, *oleum theobromæ*, is the principal food constituent of cocoa, and forms from 45-55 p.c. of the husked bean. It has a pleasant taste and odour, suggestive of chocolate. At ordinary temperatures it is a yellowish-white, somewhat brittle solid, melting below the temperature of the body, viz. 23°-33°, and solidifying at 21°-23°; sp.gr. from 0.95 to 0.97 at 15°, and 0.856 at 100°; iodine number from 33 to 38; saponification value, 193-195; refractometer reading (Zeiss) at 40° is 46.47.8; and index of refraction, between 1.4565 and 1.4578 at 40°. It is readily soluble in ether, chloroform, turpentine, and boiling alcohol, from which it crystallises out almost completely on cooling. Chemically, it is a mixture of the glycerides of stearic, palmitic, oleic, and arachidic acids (Benedikt, *Analyse der Fette und Wacharten*). It is sometimes adulterated with such substances as coco-nut oil, cotton seed, and sesame oils, stearin, tallow, and paraffin wax. Illipé oil is often used as a substitute for cocoa butter (which it closely resembles in certain respects) in the manufacture of chocolate.

Alkaloids.—Theobromine $C_7H_9(CH_3)_2N_4O_2$, or dimethylxanthine, is the principal alkaloid in cocoa, and is closely related to the alkaloid of tea and coffee, caffeine (trimethylxanthine), which is also present to a small extent in cocoa. Theobromine crystallises in white microscopic needles, having a bitter taste, and is present in cocoa to the extent of about 1.5 p.c. The published analyses show variations from 0.4 to 3.3 p.c., due to the different methods of analysis employed. One of the best methods is that of Decker, as modified by Welmans and Fromme (*Pharm. Zeit.* 47, 798, and 858; and *Apoth. Zeit.* 18, 68). The caffeine is usually included with the theobromine, from which, however, it can readily be separated by means of cold benzene, in which caffeine is soluble, but theobromine practically insoluble. The amount of caffeine varies from 0.1 to 0.3 p.c. (see art. THEOBROMINE).

Albuminoids.—These have been but little studied, but Stutzer (*Zeitsch. angew. Chem.* 1891, 368) has classified the nitrogenous constituents of cocoa as follows:—

(1) Non-proteids, substances soluble in neutral water solution in presence of copper hydroxide (theobromine, ammonia, and amino-compounds).

(2) Digestible albumen, insoluble in neutral water solution in presence of copper hydroxide, but soluble when treated successively with gastric juice and alkaline pancreas extract.

(3) Insoluble and indigestible nitrogenous substances.

According to Stutzer's analyses, the proportion of albuminoids in cocoa powder manufactured without chemicals is between 17 and 18 p.c., of which 10 p.c. is soluble or digestible albumen, the remainder (over 40 p.c. of the whole) consisting of insoluble and indigestible substances. Forster, however, maintains that the proportion of digestible albuminoids reaches as high as 80 p.c., his experiments being made on the human subject, whilst Stutzer's were conducted under laboratory conditions (*Hyg. Rundschau*, 1900, 314).

Starch, as in oleaginous seeds generally, is not very abundant. It has been variously

estimated from 2 to 20 p.c. of the nib, but many of the results are too high, owing, no doubt, to the conversion of cellulose into sugar when the acid method for the starch conversion is employed. The diastase method is preferable in the presence of cellulose. The average amount of starch is from 4 to 5 p.c., or about 8 p.c. calculated on the fat-free bean. The starch grains are nearly spherical, with a very indistinct nucleus. They have a tendency to unite in small groups of 3 or 4, and rapidly lose the colour imparted by iodine. The average size is about 0.005 mm.

Tannin.—An astringent principle resembling tannin exists in the raw bean, but, according to Mitscherlich and Bell, it is rapidly oxidised to 'cocoa-red,' to which the characteristic colour of cocoa is due. Bell (*Foods*, i. 79) states that this astringent principle is different from the tannin of tea and coffee, and that its rapid change to cocoa-red, even during the process of analysis, renders its quantitative estimation difficult. It is precipitated by basic acetate of lead, and can be obtained after removal of the lead by sulphuretted hydrogen. It gives a green precipitate with ferric chloride not unlike caffeic acid under similar treatment.

Cocoa-red is not present in the fresh seeds, which are nearly white, but arises from the oxidation of the natural tannin of the seed. It consequently appears in different quantities in different kinds of cocoa. On hydrolysis it decomposes into glucose, tannin, and a resinous substance. By many the peculiar taste and aroma of cocoa are associated with the formation of cocoa-red, which increases in amount during the process of fermentation, drying, and roasting, simultaneously with a corresponding increase in flavour, thought to be due to the development of a volatile principle or essential oil. Details of methods for its extraction and estimation are given in Zipperer (*Die Schokoladen Fabrikation*) and Blyth (*Foods*).

Mineral matter. The ash in cocoa nibs varies from 2.5 to 4.5 p.c., the average, according to Zipperer, being 3.6 p.c. in raw, and 3.9 p.c. in the roasted kernels. The shells contain two or three times this amount. Approximately half the ash (which is rich in potash and phosphates) is soluble in water. The ash is naturally lower than the average when starch or sugar has been added, and higher when fat has been abstracted, or when the cocoa has been adulterated with husks or coloured with pigments. The shell is rich in alkaline carbonates and silica as compared with the nib. A high alkalinity in the ash of cocoa powders indicates treatment with alkalis as described in the preparation of the so-called 'soluble' cocoas. The composition of the ash of cocoa nibs and husks is shown in the table given below.

Whilst cocoa ranks higher than tea or coffee as a nutritious beverage, its value as a substitute for solid food has been greatly exaggerated. In its content of alkaloid and tannin substances, it stands midway between tea and coffee, and, like them, it should be considered a stimulating beverage rather than a true food.

The following tables will serve to show the composition of cocoa nibs, shells, the ash, and several kinds of commercial cocoas:—

COMPOSITION OF COCOA SHELLS (WEIGMANN).

Commercial varieties	Moisture	Nitrogenous substances	Theo-bromine	Fat	Nitrogen-free extract	Cellulose	Ash	Sand	Total nitrogen
Caraccas	12.49	13.18	0.58	2.38	40.30	16.33	9.06	6.26	2.11

Adulterants. Besides sugar and starches (particularly coco-nut oil) to replace the abstracted cocoa butter, farinaceous substances, ground cocoa shells, and pigments such as ferric oxide, ferruginous earth, &c.

COCOA-NUT OIL GROUP. Under this name the writer comprises a number of vegetable fats which differ from all other vegetable fats by their high saponification values in conjunction with high Reichert-Meißl values. The considerable proportion of volatile fatty acids which the fats belonging to this group contain, brings them into relationship with the milk fats of mammals. They differ, however, from the latter essentially in that they do not contain any butyric acid. The high proportion of volatile fatty acids contained in the members of these groups differentiates them from other fats which are also characterised by high saponification values, but do not contain volatile acids.

The fats belonging to the cocoa-nut oil group are the following: (a) Muriti fat, from *Mauritia vinifera* (Mart.); *Acroemia vinifera* (Oerst.); (b) mocaya oil, from *A. sclerocarpa* (Mart.); *Cocos sclerocarpa*, *C. aculeata* (Jacq.); *Bactris minor* (Gart.); (c) cohune oil, from *Attalea cohune* (Mart.); (d) maripa fat, from *Palma (Attalea) maripa* (Aubl.); (e) aouara-kernel oil, from *Astrocaryum vulgare* (Mart.); (f) palm-nut oil, from the kernels of *Eleis guineensis* (Linn.; Jacq.); (g) cocoa-nut oil from *Cocos nucifera* (Linn.) and *Cocos butyracea* (Linn.); (h) fat from *Cocos acromoioides*.

It may be pointed out that aouara-kernel oil and palm-nut oil differ considerably from the corresponding fats contained in the fruit flesh surrounding the seeds (see PALM OIL).

All these fats are derived from trees belonging to the palm family. The two most important fats are cocoa-nut oil and palm-kernel oil. The latter will be described subsequently (v. PALM KERNEL OIL).

Cocoa-nut oil is the fat obtained from the kernels of the cocoa-nut, especially from those of the two species *Cocos nucifera* (Linn.), and *C. butyracea* (Linn.).

Cocos nucifera grows on all coasts and islands of the tropics; in fact, it may be considered a cosmopolitan of the tropical coast-lines in both hemispheres. The cocoa-nut tree is indigenous to the islands of the Malayan Archipelago, whence the nuts were carried by sea currents towards the east to the Pacific Islands and the coasts of Central America, and towards the west to Ceylon and the east coast of Africa.

Being well protected by the 'eoir' (fibres), the seeds are able to germinate on all shores (islands and even coral reefs) where they may be deposited.

The cocoa-nut tree forms large forests, especially on the coast-line of Ceylon, Java, and the Philippines. On account of its manifold uses, the tree has been cultivated early in the history of mankind, and the fruits were, therefore, gathered, as it were, on a commercial scale, not only in the localities named, but also in the South Sea Islands, Madagascar, Mauritius, Ceylon, Zanzibar, the east and west coast of Africa, the Antilles, and the coast-lines of tropical South America.

Cocos butyracea is indigenous to Brazil, and yields, together with *Cocos nucifera* (as also with the other *cocos* species mentioned above), the chief quantities of cocoa-nut fats which are consumed locally. The cocoa-nut oil which is exported to Europe is mainly derived from *Cocos nucifera*.

The cocoa-nut tree flowers when about 6 or 7 years old, and begins to bear fruit from an age of 8 years up to an age of 60 years. The nuts contain a fleshy endosperm, built up from a milky juice, rich in oil. At the period of maturity of the fruit the milky juice has disappeared almost completely, and the endosperm forms the well-known cocoa-nut kernel, inside which the remainder of the milky juice, cocoa-nut milk, is enclosed. The kernel contains from 30 to 40 p.c. of fat, and about 50 p.c. of moisture.

Since the earliest times in the history of mankind, the kernels have been used by the natives of the South Sea Islands, and especially of India, as one of their chief articles of food. The mode of preparing the oil, as practised centuries ago, was of the most primitive kind. The kernels were cut into small pieces and exposed in piles to the sun, when the oil would run off spontaneously. Improved methods consisted in converting the kernels into pulp, placing the latter in vessels perforated with holes, and exposing them to the sun, when the oil would run through the holes. The oil was then collected and carried in bamboo sticks to the market, a practice which up till a few years ago still obtained in the outlying parts of the Philippines. In order to render the process independent of the heat of the sun, as in the rainy season, the kernels were, at a later stage of evolution laid on hurdles, formed from bamboo staves and cocoa-nut leaves, and dried over a slow fire, the fuel for which was derived from the shell of the kernels. In India, where the nuts became at an early date an extensively used food product, the nuts were split into halves by a blow with a sharp instrument, the cocoa-nut milk was poured off, and the halves exposed to the sun to dry, whereby the kernels became readily detachable from the shell. The dried kernels were then triturated and expressed, or the pounded kernels were thrown into boiling water, when the oil rose to the top, and was ready to be skimmed off. The residual mass was used as cattle food ('cocoa-nut poonae'). This process was carried out with special care at Cochin and the coast of Malabar. Hence the reputation of Cochin cocoa-nut oil for best quality has been maintained to this day.

As large proportions of moisture left in the kernel readily lead to putrefaction, a further step in the preservation of the fat was found in drying the kernels thoroughly, so as to remove the bulk of the water. The absence of moisture rendered the growth of fungi impossible, and thus prevented excessive hydrolysis and subsequent rancidity. The process of producing the dried kernel—*copra*—developed into a manufacturing process.

Cocoa-nut oil became first known in Europe in the 18th century, but was not imported in any notable quantities before the year 1820. At present three qualities of oil are distinguished in commerce: (1) *Cochin oil*; (2) *Ceylon oil*; (3) *Copra oil*.

(1) *Cochin oil* represents the finest and whitest quality, and is obtained, as stated above, by boiling the kernels with water and skimming off the oil.

(2) *Ceylon oil* is prepared in a similar manner in the plantations of Ceylon. This oil is not of such high quality as Cochin oil, owing

mainly to the want of care on the part of the natives, as compared with that exercised by the natives of the Malabar coast. Hence Ceylon oil represents, as a rule, a second quality of cocoa-nut oil, and is characterised by a somewhat higher percentage of free fatty acids than is found in Cochin oil. At present, however, in some plantations in Ceylon, managed by Europeans, the same care is exercised as in Cochin, and some brands of Ceylon oil are now imported which yield little in quality to Cochin oil.

(3) *Copra oil* is the oil prepared in modern factories in Europe, United States, Australia, from copra (*i.e.* the dried kernels), which are imported in enormous quantities into these countries. The conversion of the kernel into copra must not only be looked upon as a convenient method for reducing the cost of freight, but, as pointed out above, is pre-eminently a cheap process for preserving the cocoa-nut oil as far as possible.

At present great care is bestowed on the preparation of copra; it is used in growing proportions for the production of edible cocoa-nut oil (*see* EDIBLE OILS), and cocoa-nut stearin (*see* CHOCOLATE FATS). In commerce we differentiate 'sun-dried copra' and 'kiln-dried copra.' The sun-dried copra was considered the better quality, as it gives a white cocoa-nut oil, with only a slight yellow tinge, and could be readily converted into an edible oil. Kiln-dried copra is obtained by a more rapid process, the kernels being dried over a bamboo grating heated by burning underneath it the shells. In these primitive kilns, the fumes obtain ready access to the copra itself, and not only burn it occasionally, but impart to the copra a peculiar empyreumatic smell and a dark colour. Hence copra thus dried yields a yellowish oil which proves refractory in the refining process. At present, however, notable improvements are being introduced in the kiln-drying process, (rotary driers, vacuum driers), so that it may be expected that in the near future kiln-dried copra will take its place next to, or rank equally with, sun-dried copra. Sun-dried copra contains on an average 50 p.c. of fat; in kiln-dried copra the percentage rises to 63 and even 65 p.c. Copra dried by means of hot air contains even as much as 74 p.c.

The copra is treated in oil mills in a similar manner to that in which oleaginous seeds generally are worked up. The meal is expressed twice at a temperature of 55°-60°. The practical yield varies from 63 to 66 p.c., according to the contents of oil in the copra. The expressed oil contains a notable quantity of free fatty acid, the amount depending on the quality of the raw material.

Although the trade in cocoa-nut oil and cocoa-nut products may be said to be still in its infancy, the great importance it has reached may be gathered from the following figures: in the year 1907 the value of the imports, exports, and home consumption, in the United Kingdom amounted respectively to 857,879*l.*, 424,860*l.*, and 433,019*l.*

In our climate cocoa-nut oil is, at the ordinary temperature, a solid white fat of bland taste, having the peculiar, though not unpleasant, odour of cocoa-nut. The odorous substances in cocoa-nut oil consist chiefly, according to Haller

and Lassieur (Compt. rend. 1910, 151, 697), of methylheptylketone and methylonylketone. These two ketones, together with certain undefined volatile substances, are removed in the process of refining cocoa-nut oil for edible purposes. In order to obtain cocoa-nut stearin (chocolate fat), the liquid glycerides are removed by expression in hydraulic presses, when 50-80 p.c. of the liquid glycerides are expressed. Inferior copra oils also are frequently subjected to the same process, and thus a commercial cocoa-nut stearin is obtained, which, on account of impurities, can only be employed in the manufacture of composite candles and night-lights. The lower qualities of cocoa-nut oil are used in enormous quantities in the manufacture of soap.

Cocoa-nut oil contains large proportions of myristin and, especially, of laurin, small quantities of palmitin, stearin, and triolein, and of caprin, caprylin, and caproin.

The saponification value of cocoa-nut oil lies between 246 and 260; the Reichert-Meissl value of the oil is 7-8; its iodine value about 8-10. Owing to its peculiar chemical composition, cocoa-nut oil is not readily saponified by weak caustic leys. It requires for saponification alkaline leys of high strength, which, however, so easily convert it into soap, that it is only necessary to stir the fat and caustic alkali together at 30°-35°, and allow the mixture to stand. After a short time saponification takes place, with liberation of heat. (Soapmaking by the 'cold process.')

Soaps so formed are very hard, and combine with a large amount of water without becoming soft. The soaps are further distinguished by their remarkable property of requiring large quantities of salt to throw them out of their aqueous solution. Hence they are used as 'marine soaps.'

J. L.

COCOSITOL *v.* INOSITOL.

CODEÏNE *v.* VEGETO-ALKALOIDS.

COD LIVER OIL is obtained from the liver of the cod, *Gadus morrhua* (and of the dorsch, the young of *G. morrhua*, formerly considered a separate species, *G. callarius*). The cod appears annually at certain times in enormous shoals on the coasts of the northern seas, chiefly on the coasts of Norway, Scotland, Newfoundland, the east of the United States and of Canada, the west coast of the United States and the coasts of Japan and Siberia. The best-known and oldest fishing-grounds are those of Norway, where the fish make their appearance at regular intervals of the year.

In the early years of the manufacture of cod liver oil, the livers were heaped up in barrels and allowed to undergo a process of spontaneous putrefaction, whereby the liver cells burst and the oil exuded. The oil so obtained was contaminated with decomposition products of the liver, and possessed that rank odour and nauseous taste with which even nowadays popular prejudice associates medicinal cod liver oil. Of late years the manufacture of cod liver oil has been carried out in a scientific manner, and the best oil is at present obtained by steaming the livers in the freshest state obtainable. The livers are washed immediately they are taken out of the body of the fish, and placed in jacketed vessels in which they are heated to a

temperature of 70°-80°, when the cells burst and the oil flows off. This oil is known as 'raw medicinal oil,' and is consumed as 'congealing oil' in those countries where the Pharmacopœia permits congealing oils. The British Pharmacopœia prescribes, however, a non-congealing oil, which will not "set" at the freezing-point. It is prepared by cooling the crude medicinal oil below zero and filtering it at a temperature of -10°. The 'stearine' is sold as fish stearin of best quality for soap-making purposes. All unsound livers, and those which have been exposed for some time to the atmosphere, are then worked up for 'brown oil.' This oil is, of course, a genuine cod liver oil, but is (or should be considered) unfit for consumption, and is mostly used up in leather industries, under the name 'brown cod oil' or 'cod oil.'

The pure medicinal oil is pale yellow or light yellow, and the best qualities have a slight fishy odour only, and a by no means unpleasant taste. Such oil has a sp.gr. of about 0.922-0.93 at 15°, and a saponification value of 175-190, and an iodine value of 140-175. The best qualities have an iodine value of about 175, for the longer the livers have been exposed, the lower will be the iodine value, so that this value alone may indicate, preliminarily, a good medicinal oil. The chemical composition of the cod liver oil glycerides is not yet completely known. Small quantities of palmitin occur in the oil, and are the cause of the separation of 'stearine.' The older statement that small quantities of lower saturated fatty acids, such as those of acetic, butyric, valeric, and capric acids occur in cod liver oil must be rejected, these statements being due to the fact that the cod liver oil in which those volatile fatty acids were found had already undergone decomposition. The greater number of the liquid fatty acids in cod liver oil are not identified. Among the unsaturated fatty acids there occurs undoubtedly *clupanodonic acid*; this can be identified and isolated by means of its octobromide, which does not melt at 200°, and decomposes, with blackening above that temperature.

The therapeutic value of cod liver oil which was attributed to the organic bases occurring in badly rendered cod liver oil must (in the author's opinion) be ascribed rather to the easy manner in which cod liver oil is digested than to any specific constituent, for the purest cod liver oil practically represents a mixture of pure glycerides with a small amount only of cholesterol and other unsaponifiable substances.

Like all liver oils, cod liver oil may be identified by the colour test which it gives with concentrated sulphuric acid in a solution of carbon tetrachloride or carbon disulphide. The better a cod liver oil is in quality, the fainter is the sulphuric acid colour test; this points to the fact that the colour test is due to small quantities of foreign substances which are dissolved by the oil from the tissues of the liver. J. L.

CELESTIN v. STRONTIUM.

CELÉINE, CÉRULEAN BLUE, CÉRULEUM v. COBALT; also PIGMENTS.

CÉRULEÏN, *Anthracene green* (v. ALIZARIN AND ALLIED COLOURING MATTERS).

CÉRULIGNOL $C_8H_7 \cdot C_6H_5 \cdot (OH)OCH_3$. A colourless oil of a burning aromatic taste, and a smell resembling creosote, obtained from beech

pine and fir tars. Boils at 240°-241°; sp.gr. 1.0564 at 15°. It is somewhat soluble in water, freely soluble in alcohol, ether, and acetic acid. It is coloured red by sulphuric acid, and dark-brown by potassium hydroxide in contact with the air. In alcoholic solution it gives with barium hydroxide a characteristic deep-blue colouration. Ferric chloride in alcoholic solution gives a green, in aqueous solution a deep-red, colouration. Cœrulignol is decomposed on treating with hydrochloric acid at 145°, according to the equation

CÆRULIGNONE (*Cœrivret*)

A steel-blue crystalline solid obtained by oxidising pyrogalloldimethylether in acetic acid solution with potassium dichromate (Hofmann, Ber. 11, 335). It combines with primary amines to give deep-blue dyestuffs (Liebermann and Flatau, *ibid.* 1897, 234; Moir, Chem. Soc. Proc. 1906, 110; 1907, 307) (v. CÆDRINET).

COFFEE. The beverage known as 'coffee' is prepared from the seeds (dried, roasted, and ground) of *Coffea arabica* (Linn.), an evergreen shrub, indigenous to North-East Africa, and Arabia. The use of coffee has been known from time immemorial in Abyssinia, whence it spread to the neighbouring Mahometan countries (where its use was at various times forbidden as being an 'intoxicating' beverage), and subsequently to all parts of the civilised world. It did not find its way into Europe, however, until the beginning of the 17th century. It was introduced into England in 1652, and rapidly spread in popular favour in spite of heavy taxation and attempts to suppress the 'coffee houses,' for political reasons, until its importation reached a maximum of 37½ million lbs. in 1847. Since then the consumption has declined, due, no doubt, chiefly to the greatly extended use of tea, and partly to the introduction of coffee substitutes. At the present time (1911), the consumption of coffee in the United Kingdom is less than 30 million lbs., or less than ¾ lb. per head. In the principal coffee-drinking countries of the world the consumption of coffee per head of the population is as follows: Holland, from 14 to 15 lbs.; United States of America, 12 lbs.; Scandinavia, nearly 12 lbs.; Germany, 7 lbs.; and France, 4 lbs.

The coffee tree belongs to the natural order *Cinchonaceæ*, which embraces, according to Lindley and Paxton, two species, *C. arabica* and *C. paniculata* (Aubl.). Other botanists distinguish many other species, as *C. microcarpa*, *C. umbellata*, *C. acuminata*, *C. subsessilis*, *C. laurina*, *C. racemosa*, *C. bengalensis*, *C. indica*, &c. Some of these are probably only varieties. However this may be, four species distinct from each other are now grown: (1) Arabian or Mocha coffee, having short upright branches with a brittle leaf, and seeds usually single in the berries. (2) Jamaica coffee, bearing longer and more pliable branches, a tougher leaf, and seeds almost always double in the berries. (3) East India or Bengal coffee, of which the leaf is smaller than the Jamaica variety, and the berry very small. (4) Liberian coffee (*C. liberica*) is taller and has larger leaves and fruit than the preceding varieties, but owing to its coarse

flavour, it was not until recently of much commercial use. It has, however, rapidly attained importance on account of its hardy habit and power of resistance to disease, and is now largely cultivated by grafting on to its stem the more delicate and highly esteemed Arabian coffee. Trees growing wild in the Cingalese jungle attain a height of 14-18 feet; but under cultivation and subjected to systematic pruning, the plant rarely exceeds 6-9 feet. Within the tropics the coffee tree succeeds best at 1200-3000 feet above the sea-level, but grows at a height of 6000 feet. When the mean temperature is about 70°, it may be grown as far as lat. 36°. It is cultivated in the West Indies, Mexico, Central America, Brazil, and Cayenne; in Western Africa, Egypt, Mozambique, and Natal; in Arabia, India, Ceylon, Siam, Sumatra, Java, Celebes, and other parts of the Eastern Archipelago, Fiji, and the islands of the Pacific. At the present time more than three-quarters of the world's supply comes from Brazil.

The coffee consumed in the United Kingdom comes principally from Costa Rica and British India as regards the finer qualities, and the inferior grades from Brazil.

The manner of forming plantations varies somewhat in different countries. The surface soil should be good and the subsoil not too stiff. Perhaps the best soil is that known in Brazil as 'terra roxa,' a topsoil of red clay 3 or 4 feet thick, with a subsoil of gravel. Virgin forest land is as a rule, found very suitable. Shelter from wind is most important, and a wet soil is fatal. Steep slopes are unsuitable owing to rain wash. The loss due to this cause should be repaired by good manure, well-rotted dung and ground bones being the best. The young plants may be reared in nurseries, whence they are transplanted to their permanent position, or they may be gathered out of the old plantations; the age at which this is done varies, as in Brazil where the shrub is usually two years old on its removal, or as in the West Indies where it is planted out at 6 months. Fruit is produced in the fourth year, and continues to be gathered for several years.

The tree blossoms and bears fruit practically all the year round, and the fruit takes about 4 months to ripen. There is thus in some places an almost perpetual crop, but, as a rule, there are two principal harvest seasons in the year.

The coffee fruit consists of a bilobed berry somewhat resembling a small elongated cherry (by which term it is described commercially). The fleshy pericarp changes colour, as the fruit ripens, from green through yellow and red to a deep crimson. When dried, it blackens and becomes hard and brittle, resembling a shell or husk. Beneath the skin of the pericarp is a saccharine and somewhat glutinous pulp containing the seeds, which are usually double, lying face to face, but sometimes occurring singly. Each seed or 'bean' is enclosed in two membranous coverings—an outer, consisting of tough buff-coloured tissue, technically known as 'parchment,' which becomes loose and readily separates on drying; and an inner film of thin white tissue, closely adherent to the bean, and known as the 'silver skin.'

The principal methods in vogue for gathering

and preparing the coffee berries for commerce are as follows. In Arabia, Egypt, and the Antilles, the berry is left on the tree till completely dried, when it is easily shaken down and the dry outer envelope and the parchment removed by pounding in a mortar, beating with a flail, or simply rubbing in the hands. In many other places the berries are gathered by hand as soon as ripe but not dry, and are spread out on the ground in layers from 4 to 6 inches deep. These are exposed to the sun's heat for 3 or 4 weeks, with frequent turning by means of spades, when the bean becomes easily removable from the fruit by gentle trituration. As this process of drying sometimes imparts to the coffee a disagreeable flavour owing to putrefactive changes in the pulp, recourse is frequently had to artificial heat. The most modern method is to 'pulp' the berries by crushing between rollers so as not to injure the beans, which are then subjected to a fermenting process in tanks, with or without the addition of water, after which they are separated from the pulp by 'washing,' and dried, either by the sun or by artificial means. Coffee beans in the form of 'cherry' rarely enter into commerce, but frequently retain the parchment and silver skin, which, however, before roasting, are removed by rollers and separated by winnowing. They are then graded into different sizes by special machinery, which also separates the round or 'pea-berries' from the ordinary flat-faced beans. The colour of coffee beans varies from a pale-yellow passing through various shades of green to a slatey grey. The following table will indicate the variations in size:—

	No. of seeds in a measure holding 50 grams of water.
Fine brown Java	187
Fine Mysore	198
Fine Neigherry	203
Costa Rica	203

Fine long-berry Mocha	217
Good ordinary Java	223
Fine Ceylon plantation	225
Good average Rio	236
Medium plantation (Ceylon).	238
Manilla	248
Ordinary Mocha	270
West African	313

Coffee undergoes important changes in the process of roasting, the object of which process is to develop its aroma and to destroy its toughness so that it may easily be reduced to powder. Great care is necessary to ensure an equable roasting of all the beans, and to attain the exact point at which torrefaction should cease. If, on the one hand, rawness is not removed, the flavour of the bean is not developed, and the coffee is hard to grind; on the other hand, if too much heat is permitted, carbonisation takes place, and a strong empyreumatic flavour is produced, which renders the coffee infusion nauseous.

The roasting process is conducted in cylinders (preferably of strong wire gauze to permit of the escape of steam and other volatile products as fast as they are formed) heated by coke fires or gas. The loss in weight is from 15 to 18 p.c., of which about one-half is due to moisture,

and the rest chiefly to volatile products derived from the fat, and from the sugar during the conversion of the latter into caramel. There is also some loss of caffeine. At the same time, an empyreumatic oily substance is developed, known as *caffool*, which, in spite of its small amount, imparts to roasted coffee much of its characteristic aroma. The most favourable temperature for developing the maximum aroma during roasting is a little above 200°. After roasting, it is most important that the beans should be rapidly cooled, and this is effected by spreading them on a large sieve through the meshes of which they cannot pass, but through which the air is forcibly drawn by means of a powerful exhaust connected with a closed chamber immediately below the sieve. Since the essential oil rapidly escapes after the bean is broken up, coffee should not be ground until required for infusion.

O. Bernheimer (Wien. Akad. 81, [2] 1032, 1042) found that during the roasting of coffee, water vapour is first given off, then suddenly an evolution of carbonic anhydride, and distillation of volatile substances commences. The distillate consists of an aqueous liquid and a solid part. The former contains caffeine, caffel, acetic acid, quinol, methylamine, and acetone; the latter consists of fatty acids, chiefly palmitic. Pyrrol escapes during roasting. Of fatty acids, 0.48 p.c. of the coffee employed was volatilised; of caffeine, 0.18 p.c.; and of caffel, 0.05 p.c.

Bernheimer found that raw coffee beans (50 kg.) roasted in a revolving drum yielded a liquid distillate (5 litres) and a solid portion (680 grams) floating thereon. The uncondensable vapours contained carbonic anhydride, and, on passing them through dilute hydrochloric acid, a resinous body was deposited, having the appearance of pyrrol-red.

A. *Liquid distillate*.—The crude liquid distillate filtered from solid particles has a yellow colour and the fragrant odour of coffee. On agitating it with ether, and evaporating the ethereal extract over the water-bath, a dark heavy oil was obtained, smelling like coffee, and yielding, on redistillation, first a few drops of liquid having the odour of acetone, afterwards, for the most part, acetic acid and water. The thermometer then rose quickly to 200°. above which point there passed over an oil smelling like coffee, the temperature at the same time rising to 300°. Above this point there passed over a very small quantity of liquid, which

immediately solidified to a mass having the buttery aspect and rancid odour of the higher fatty acids. This portion, and the liquid which passed over from 200° to 300°, were neutralised with sodium carbonate, whereupon a thick dark-coloured oil was thrown down, which was separated from the supernatant liquid by means of a tap-funnel, and washed with water rendered very slightly alkaline by potash.

The alkaline wash waters contained no fatty acids, but, when acidified with sulphuric acid and agitated with ether, they yielded a substance which, after evaporation of the ether, filled the liquid with a pulp of crystals, and after precipitation crystallised in colourless needles, exhibiting the characters of *quinol* (m.p. 171°), converted into quinquhydrone by the action of ferric chloride.

The oil above mentioned, designated by Bernheimer as *caffool*, was dried over calcium chloride and fractionally distilled, the greater part passing over from 195° to 197°. The distillate smells very strongly of coffee, is apparently insoluble in cold water, but imparts to it the characteristic odour; slightly soluble in hot water, very slightly in aqueous potash, very easily in alcohol and ether, the alcoholic solution giving, with ferric chloride, a red colouration, which does not disappear on addition of sodium carbonate. Analysis led to the formula $C_8H_{10}O_2$. Caffeol is oxidised by chromic acid mixture, without formation of any definite products. By fusion with potash it yields salicylic acid. The portion of the crude liquid distillate not taken up by ether, when concentrated over the water-bath, yielded groups of needle-shaped crystals, exhibiting the composition and properties of *caffeine* $C_8H_{10}N_4O_2$ (0.28 p.c. of the coffee). The mother liquor was found to contain *methylamine* and *trimethylamine*.

B. *Solid distillate*.—The black mass floating on the crude liquid distillate was found, by a preliminary examination, to consist of a mixture of the higher fatty acids. By saponification, and treatment of the product by Heintz's method of separation, this mixture yielded, as chief constituent, *palmitic acid* melting at 60°, and a very small quantity of another acid having a melting-point a few degrees higher than that of lauric acid.

The chemical composition of coffee has been investigated by many chemists with various results. The following table gives analyses by O. Levesic (Arch. Pharm. [3] 8, 294) of some of the principal commercial varieties of coffee:—

—	Gummy matter	Caffeine	Fat	Tannic and caffeotannic acids	Cellulose	Ash	Potash	Phosphoric acid
Finest Jamaica plantation	25.3	1.43	14.76	22.7	33.8	3.8	1.87	0.33
Finest green Mocha	22.6	0.64	21.79	23.1	29.9	4.1	2.13	0.42
Ceylon plantation	23.8	1.53	14.87	20.9	36.0	4.0	—	0.27
Washed Rio	27.4	1.14	15.95	20.9	32.5	4.5	—	0.51
Costa Rica	20.6	1.18	21.12	21.1	33.0	4.9	—	0.46
Malabar	25.8	0.88	18.80	20.7	31.9	4.3	—	0.60
East Indian	24.4	1.01	17.00	19.5	36.4	—	—	—

Commaile (Mon. Sci. [3] 6, 779) found in undressed Mysore coffee:

Hyroscopic water (extremes of 24 determinations) . . .	6.3 to 15.7
Fatty matters	12.68
Glucose	2.60
Dextrin	—
Legumin-casein	1.52
Albumen	1.04
Total quantity of caffeine . . .	0.42 to 1.31
Ash	3.882
Coffee extract with cold water . .	24.97
" " " warm water	37.20
Coffee extract with alcohol of 60 p.c.	22.15

Drägerdorff gives the following results of analyses of 25 different samples of coffee from Ceylon, Java, Malabar, Mocha, Mysore, and other places:—

	Maximum per cent.	Minimum per cent.	Mean per cent.
Caffeine	2.21	0.64	1.16
Ash	4.87	3.83	4.41
Phosphoric acid	0.72	0.28	0.42

The principal constituents of coffee are alkaloids (caffeine and caffeineine), caffetannic acid, cellulose, fat, gum, protein, sugar, water, and mineral matter.

Caffeine $C_8H_{10}(CH_3)_3N_4O_2$, trimethylxanthine, is identical both chemically and physiologically with theine, the alkaloid of tea, and is closely related to theobromine (dimethylxanthine), the principal alkaloid of cocoa (*q.v.*). According to Payen (Ann. Chim. Phys. [3] 16, 108), caffeine is present as a caffetannate. Gorter (Annalen, 1908, 358, 327) states that caffeine occurs in coffee combined with potassium as potassium caffeinechlorogenate $C_{32}H_{36}O_{12}K_2(C_8H_{10}N_4O_2)_2 \cdot 2H_2O$. When pure it consists of white silky needles, slightly bitter and odourless, almost insoluble in ether, sparingly soluble in cold water and alcohol, but more soluble in hot water, and readily soluble in chloroform, by means of which it may be extracted from coffee. The crystals begin to sublime below the boiling-point of water.

Caffeine is found also in guarana leaves, kola-nut, maté or Paraguay tea and to a small extent in cocoa as well as in coffee and tea, and gives to these their exhilarating qualities. Taken in excess, caffeine is a poison. In coffee it is present to the extent of from 0.6 to 2.2 p.c., the average being 1.1 p.c. Lendrich and Nottbohm (Zeitsch. Nahr. Genussm. 1909, 18, 299) report nearly 3 p.c. of caffeine in certain African coffees, whilst in Madagascar and other islands off the east coast of Africa a variety of coffee has been found entirely devoid of caffeine. A coffee has recently been placed on the market after being deprived of practically the whole of its caffeine.

Numerous methods have been proposed for the estimation of caffeine. That of Lendrich and Nottbohm is detailed in the Analyst, 1909, 214. A good method, sufficiently accurate for ordinary purposes, is that given in Jour. Anal. Chem. 4, 4, 390.

Another alkaloid, *Caffeineine*, having narcotic properties, is stated by Paladino (Gazz. chim. ital. xxv. 1895) to be present in coffee in very small quantity.

Caffetannic acid presents certain of the

characteristics of tannin (which, however, is not found in roasted coffee) and to it the bitter taste of coffee is chiefly due. It is very susceptible to change, and its composition has been much disputed. According to Gorter (*vide supra*), it is a mixture of a new acid discovered by him and called *caffalic acid*, with chlorogenic acid. A method for its estimation in coffee has been devised by Krug (U.S.A. Dept. of Agric. Div. of Chem. Bull. 13, 908). According to Bell, caffetannic acid is present in coffee to the extent of from 3 to 5 p.c., and when distilled with manganese dioxide and sulphuric acid yields quinone.

Cellulose.—In coffee this is of a very hard and horny character, and difficult to define under the microscope, especially after roasting, although the chief characteristics of the cellular tissue are more or less retained. Coffee cellulose is dissolved by an ammoniacal solution of copper oxide, and gives a blue colour with sulphuric acid and iodine. Remnants of the silver skin are always present even after roasting, and its structure, a thin membrane with adherent, thick-walled, spindle-shaped, and hollow cells, is quite peculiar to coffee.

Fat forms a considerable constituent of coffee, varying from 10 to over 20 p.c. A loss occurs in roasting, due to the separation of volatile fatty acids. When pure, coffee fat is white, inodorous, and of the consistency of butter, melting at 37.5°.

Protein, chiefly in the form of insoluble albuminoids, occurs in coffee to the extent of from 10 to 14 p.c., the soluble albuminoids constituting about 2 p.c. There is but little difference in this respect between raw and roasted coffee.

Sugar.—König and Bell found from 5 to 9 p.c. of sugar in raw coffee, but this practically disappears in roasting, being almost entirely converted into caramel. Herfeldt and Stutzer (Zeitsch. angew. Chem. 1895, 469) state that sugar is not present as such in the raw bean, but only in the form of a glucoside. Bell, however, found that when the saccharine extract of the beans is boiled with a little dilute sulphuric acid, a quantity of glucose is obtained nearly equivalent to the weight of dry extract operated upon, a result inconsistent with the existence of sugar as a glucoside. Bell considers that this sugar is not present as sucrose, since it is not inverted even after prolonged boiling with acetic acid. On the other hand, the chemists of the United States Department of Agriculture have isolated cane sugar in considerable amount as pure, well-defined crystals (*v. Bulletin*, 13). It is usually accompanied by some invert sugar probably formed during the process of extraction, and a small percentage of dextrin. Starch is absent in the coffee bean.

Water.—The moisture in raw coffee varies from 8 to 14 p.c., the average being about 11 p.c. After roasting, it rarely exceeds 3 p.c., and frequently falls as low as 0.5 p.c.

Mineral matter.—The total amount of ash varies from 3.5 to 4.0 p.c. in raw, and from 4.0 to 5.0 p.c. in roasted coffee. The composition of the ash is shown in the following table (U.S.A. Dept. of Agric. Div. of Chem. Bull. 13, 904):—

Constituents	Mocha	Maracaibo	Java	Rio
Sand	1.44	0.72	0.74	1.34
Silica (SiO ₂)	0.88	0.88	0.91	0.69
Ferric oxide (Fe ₂ O ₃)	0.89	0.89	1.16	1.77
Lime (CaO)	7.18	5.06	4.84	4.94
Magnesia (MgO)	10.68	11.30	11.35	10.60
Potash (K ₂ O)	59.84	61.82	62.08	63.60
Soda (Na ₂ O)	0.48	0.44	—	0.17
Phosphoric acid (P ₂ O ₅)	12.93	13.20	14.09	11.53
Sulphuric acid (SO ₃)	4.43	5.10	4.10	4.88
Chlorine (Cl)	1.25	0.59	0.73	0.48
	100.00	100.00	100.00	100.00

The principal constituents are potash, magnesia, lime, and phosphoric acid. Ludwig, in his analyses of various parts of the Brazilian coffee tree, shows that the silica increases from the root upwards to the leaves and pericarp of the fruit, after which it declines in the parchment skin, and is nearly absent in the bean (Arch. Pharm. [3] 1, 482). Graham, Stenhouse, and Campbell inferred that sodium compounds are entirely absent in coffee (*vide* table in Bell's Food Adulteration, 46), but although this is not absolutely correct, the amount, as shown in the above table, is very minute.

Adulteration of coffee is very common, and the number and variety of the adulterants is almost unlimited.

Colouring is frequently employed in order to disguise damaged beans and give them the appearance of superior quality, a practice analogous to the 'facing' of tea. The substances most commonly employed are, for the raw beans, chrome yellow, yellow ochre, indigo, Prussian blue, azo-dyes, and soapstone for polishing; and for the roasted beans, burnt amber, oxide of iron, Venetian red, ferruginous earth and clay. The inorganic colouring matters are best sought for in the ash or in the sediment obtained by shaking the beans in cold water; indigo and Prussian blue by their usual reactions; and other organic colouring matters after extracting them with alcohol.

Glazing is a process resorted to for the alleged purpose of improving the keeping properties of the roasted beans, and the substances used, a mixture of egg albumen with glucose or gum, are said to have the effect of clarifying the infusion. The improved appearance of the beans and increased weight due to the retention of moisture, are probably also important considerations. The latter result is sometimes attained by the addition of sugar before roasting, or by actually steaming the beans and coating them with glycerine, palm oil, or vaseline, to prevent evaporation of moisture. Bertarelli (Zeitsch. Nahr. Genussm. 1900, iii. 681) describes the adulteration of roasted coffee beans with a solution of borax, which not only gives the beans a glossy appearance, but also adds as much as 12 p.c. to their weight.

Coffee substitutes comprise a large number of vegetable substances, roasted and ground, and having for their object either the production of a stronger infusion than can be obtained from coffee alone, or the simulation of coffee in order

to give weight by the use of thick-walled vegetable tissue of hard or leathery consistency. The former, of which chicory is the type, includes acorns, beet refuse, biscuits, bran, cereals (barley, buckwheat, maize, malt, oats, rye, and wheat); caramel (burnt sugar); carrots, dandelion root, figs, lupin seeds, mangolds, parsnips, peas, beans, and other leguminous seeds, turnip, &c.; whilst the latter comprise such substances as coffee husks, cassia seeds, date stones, grape stones, locust or carob beans, sawdust, vegetable ivory dust, &c.

Imitation coffee.—Although adulteration is naturally more prevalent in ground coffee than in the beans, yet the latter are frequently prepared artificially and on a large scale from the above adulterants (generally without any admixture of coffee), held together by means of gum, molasses, or stiff clay, and skilfully moulded into the form of coffee beans.

The detection of the adulterants above referred to is best effected by means of the microscope. By simply digesting with water, a ready means is afforded of differentiating between the pale soft-walled tissues of cereals and roots and the dark-coloured and hard-walled tissue of coffee. The former may readily be detected and identified by the presence and characteristics of their starch, coffee (and chicory) being practically free from starch. The use of bleaching reagents is of great assistance in the microscopical examination, and reference might usefully be made to the drawings and photographs reproduced in the works of Bell, Leach, Vilhers et Collin, and Wiley, and in the Coffee Report of Graham, Stenhouse, and Campbell, referred to below.

The chemical differences between coffee and its adulterants are also strongly marked, as mixtures usually give high aqueous extract and sugar, and low fat and caffeine. The density is a useful factor in detecting the sophistication of coffee, and, in particular, the artificial moistening of the berries. In the Paris Municipal Laboratory, Regnault's volumometer, as modified by Dupré, is used for this purpose. According to the French chemists, the density of raw coffee varies between 1.041 and 1.368, and that of roasted coffee between 0.500 and 0.635.

By far the most important adulterant of coffee is *chicory* (*q.v.*), but owing to the public preference for an admixture of chicory with coffee, it is now regarded in the light of an adjunct to rather than an adulterant of coffee,

provided its presence in the mixture is disclosed. Chicory has little in common with coffee except a considerable proportion of sugar, which is converted into caramel in the roasting, and thus imparts to the infusion a bitter taste and aroma somewhat resembling that of coffee. This and the stronger infusion obtained as well as the comparative cheapness of chicory and similar substances, has, no doubt, led to the present extensive use of chicory and other coffee substitutes.

An elaborate research into the nature of coffee and chicory, with a view to the detection of adulteration, was made at the instance of the Commissioners of Inland Revenue in 1852 by some of the leading botanists and chemists of the day, viz. Lindley and Hooker, and Graham, Stenhouse, and Campbell, and the results, chemical and physical, as well as microscopical, embodied in their reports are of great practical value even at the present time.

The following table by Graham, Stenhouse, and Campbell, shows the sp.gr. at 60°F. of solutions made by treating one part of each of the substances named (roasted and finely ground) with 10 parts of water (by weight), raising the mixture to boiling-point, where it is maintained for half a minute, then filtering and cooling :—

SPECIFIC GRAVITIES OF SOLUTIONS AT 60° F.

One Part of Substance to 10 Parts of Water.

Spent tan	1002.1
Date stones	1002.9
Lupin seed	1005.7
Acorns	1007.3
Peas	1007.3
Mocha coffee	1008.0
Deans	1008.4
Neilgherry coffee	1008.4
Plantation Ceylon coffee	1008.7
Java coffee	1008.7
Jamaica coffee	1008.7
Native Ceylon coffee	1009.0
Costa Rica coffee	1009.5
Parsnips	1014.3
Carrots	1017.1
Black malt	1021.2
Turnips	1021.4
Rye malt	1021.6
English chicory	1021.7
Dandelion root	1021.9
Red beet	1022.1
Foreign chicory	1022.6
Guernsey chicory	1023.2
Mangold wurzel	1023.5
Roasted figs	1024.9
Maize	1025.3
Bread raspings	1026.3

It will be seen from the above table that the low sp.gr. of the coffee infusion distinguishes it from the roots and cereals, and when chicory is the only substance admixed with the coffee, its percentage may be calculated with approximate accuracy by a comparison of the density of the infusion of the mixture with the average densities of coffee and chicory given in the above table.

The same observers lay stress on the relative colouring power of roasted coffee and chicory, the latter being four and a half times as great as the former. This property affords a simple device for detecting the presence of roasted

chicory or other substances containing caramel when admixed with coffee. A few grains of the sample are placed on the surface of cold water in a glass, without stirring, when, if roasted chicory or similar substance be present, each particle emits a yellowish-brown coloured cloud, which is rapidly diffused in streaks through the water till the whole acquires a brownish colour, whilst pure coffee gives practically no colour to the water in similar circumstances. The chicory readily sinks, whilst nearly the whole of the coffee floats.

If examined under the microscope, the sediment of chicory which reaches the bottom of the vessel will be found to exhibit the characteristic loose, large cells, with dotted vessels and branching lactiferous ducts. Even to the touch the difference is evident, for, whilst chicory under these conditions will feel soft and smooth, the coffee grains remain hard and gritty.

A. Winter Blyth (Foods; their Composition and Analysis, 359) gives the following summary of the influence of chicory on the coffee mixture :—

(1) It decreases the gum, the latter seldom rising in chicory to more than 15 p.c., whilst in coffee it has not been found less than from 21 to 28 p.c.

(2) It increases the sugar, roasted coffee having seldom so much as 2 p.c. of sugar; whilst chicory, when roasted, has at least 8 or 9 p.c.

(3) It decreases the fatty matter, the fat of chicory ranging from 1 to over 2 p.c., that of coffee being about 14 to over 20 p.c.

(4) It decreases the tannic and caffeotannic acids, chicory being destitute of tannin.

(5) It decreases the caffeine, chicory possessing no alkaloid.

(6) It profoundly modifies the constitution of the ash, especially by introducing silica, which is not found to any great extent in coffee ash.

Graham, Stenhouse, and Campbell laid stress upon the presence of silica as a means of detection of the admixture of chicory. Their analysis, showing the principal differences in the composition of the respective ashes, gives :

	In coffee ash	In chicory ash
Silica and sand	—	10.69 to 35.85
Carbonic acid	14.92	1.78 „ 3.19
Ferric oxide	0.44 to 0.98	3.13 „ 5.32
Chlorine	0.26 „ 1.11	3.28 „ 4.93

There is a marked difference in the proportion of ash soluble in water, that from coffee amounting to from 75 to 85 p.c., and in chicory from 21 to 35 p.c.

Negro or *Mogdad* coffee consists of the seeds of *Cassia occidentalis*. It contains no caffeine nor starch, and its infusion more nearly approaches the character of genuine coffee than any other known coffee substitute.

Mussaendar coffee is derived from the seeds of *Gaertnera vaginata*. It contains no caffeine.

French coffee is a description commonly applied to a mixture of coffee with burnt sugar and a large proportion of chicory. As the latter ingredients readily absorb moisture on exposure to the air, such mixtures are usually preserved in tins.

Various fraudulent coffee substitutes have

been imposed upon the public by specious advertising under fancy names, and as possessing certain desirable qualities not found in coffee. Such are *Kunst kaffee*, consisting of roasted roots or cereals, and often moulded into the form of coffee beans; *Pelotas coffee* and *Coffee surrogate*, made from ground acorns; *Date coffee* from date stones, or torrifed dates mixed with a small proportion of coffee; and many others.

The grosser forms of adulteration above referred to are much more prevalent in the coffee-drinking countries of the continent of Europe and in the United States of America than in the United Kingdom. J. C.

COGNAC v. BRANDY.

COKE MANUFACTURE AND THE RECOVERY OF BY-PRODUCTS.

Introduction.—Previous to the early nineties, practically the whole of British coke was made in the old beehive oven, which, as will be seen in the following, is a semi-combustion process, involving the loss of the whole gas and by-products, together with a portion of the possible coke yield. With the gradual disappearance of the old prejudices against coke made in by-product ovens, the latter and much more highly economical process began to assert itself, and in 1898, 1·25 million tons of coal were being carbonised in by-product coke ovens; in 1905 the quantity of coal so treated reached 3·31 millions; and in 1909, 7·5 millions. With this rapid adoption of the by-product coking process, it is necessary to confine the following article to a description of modern coking methods viewed from a by-product standpoint, with only a passing reference to the wasteful beehive process.

History of the by-product coking process.—The earliest reference which we can find of any observation being made on coal as a source of by-products is that contained in the memoirs of Johann Joachim Becher, dating about the end of the 17th century; Becher states that he has found means for treating coal 'so that it no longer smoakes nor stinks,' and in doing so made a tar equal to the Swedish.

The use of coke in iron smelting became general within 50 years of Becher's discovery, and a French metallurgist, De Gensanne, describes a process working at Sulzbach near Saarbrücken prior to 1768, where coal was coked for iron smelting, tar being recovered as a by-product; Stahl is said to have been the inventor of this process, and he produced therefrom an 'oil,' bitumen, sal-ammoniac, and lampblack.

In 1781 Archibald, Earl of Dundonald, was granted a patent for 'allowing coals to burn or ignite without flaming, so by their own heat to throw off the tar or oils that they contain.' Dundonald stated that the only method whereby tars could be obtained prior to his discovery, was by a distillation in closed retorts, where the admission of external air was prevented, and where other coals were required for heating besides the coals contained in the closed vessel. It is interesting to note that Dundonald was perfectly aware of distillation in closed retorts, which is the basis of modern by-product coking methods, and it is also evident that Dundonald's knowledge of closed retorts was 16 years previous to the introduction of coal gas for street and household illumination in 1797.

In 1838 Frederick Neville obtained protection for an invention which consisted in heating ordinary gas retorts by the waste heat from beehive coke ovens, the distilled gases from the retorts being passed through condensing and scrubbing appliances. William Newton, in 1852, introduced the use of an aspirator or pump for withdrawing the gases from coke ovens through condensers and scrubbers. Newton likewise mentions the use of acids for removing the ammonia from the gases. In 1860 W. H. Kingston patented a coke oven provided with external furnace, from which the heat evolved by the combustion of an auxiliary supply of coal was conducted round the oven through a system of flues; the evolved gases were passed through a series of pipes and condensing vessels for the recovery of the by-products. Kingston's patent is especially noteworthy, since he recognises that the true method for the recovery of by-products from coal lies in heating the coal in closed chambers, and not in chambers to which air is admitted.

In 1856 Knab erected a coal-distillation plant at Commentry, on the closed-retort system with bottom flues, but made no attempt to recover by-products. Later Knab was joined by Carvès, who introduced an improved method of heating by side flues in addition to the bottom flues, thus obtaining a more even distribution of temperature and a quicker rate of carbonisation. Carvès likewise first utilised the gases from which the by-products had been extracted in the side-wall flues, in addition to the auxiliary coal as employed by Knab. The Knab-Carvès ovens at Commentry gave the following results:—

Large coke	70·00
Breeze	1·50
Dust	2·50
Graphite	0·50
Tar	4·00
Ammoniacal liquor	9·00
Gas	10·58
Loss	1·92

100·00

Further plants on the Carvès system were erected at Bessèges and Terre-Moire, near St. Etienne, between the years 1866 and 1873, and were still further improved; the Carvès ovens working at Bessèges in 1880 were built with carbonising chambers only 24 inches wide, to facilitate rapid heat penetration and quick carbonisation. In 1881 Mr. H. Simon of Manchester introduced a recuperator, whereby the air necessary for the combustion of the gas in the side-wall flues of the Carvès oven was preheated by the waste gases escaping from the flues, and thus the rate of carbonisation was still further increased, the combined work of the two investigators resulting in the well-known Simon-Carvès oven, which may be held to be the precursor of the modern by-product coking retort.

Following on the success of the Simon-Carvès process, other coke-oven patents were filed, viz. Semet-Solvay, 1880; Hüssener, 1881; Lürmann, 1882; and Brunck, 1883; but although development was rapid on the Continent, little was done in this country before the nineties, owing to the prejudice of iron smelters against by-product coke; that this

prejudice has now disappeared will be seen from the rapid adoption of the process, indicated by the figures at the beginning of these notes. The by-product coking plants which have generally found acceptance in this country are the Otto-Hilgenstock, Simon-Carvès, Koppers, Seneet-Solvay, Simplex, Coppée, and Hüssener.

Non-by-product and by-product ovens compared.—Prior to the establishment of the by-product coking process, the type of oven universally employed was that known as the beehive. This oven consists of a fireclay chamber, beehive shape in elevation and circular in plan, provided with a loose brick charging door at ground level, and with an exit flue in its crown for carrying the waste gases to the chimney. The coal is charged into the oven by spades, through the charging door, to a height of 2 feet 6 inches to 3 feet, is then ignited, and the charging door bricked up and plastered, a small hole 6 inches square being left for the admission of air. The surface of the coal burns and sets up distillation of the under layers, the evolved gases passing upwards and burning above the coal with the air drawn in at the door; this operation of distillation and immediate combustion proceeds until the whole of the volatile constituents of the coal have been evolved, which for a 10-ton charge occupies 70 hours. The coke is then quenched with water and withdrawn by rakes.

It will be seen that by this process, the whole of the volatile products, that is to say, benzols and ammonia together with the permanent gases, are burned immediately they are evolved within the coking chamber itself; further it is not possible to so regulate the combustion of these gases without burning a portion of the coke in addition; in actual practice, from 15 to 20 p.c. of the coke is burned to waste. For the reason, too, that the coke is quenched inside the oven, the temperature of the latter is lowered, so that before the next charge can be coked, considerable expenditure of heat is necessary to raise the oven to coking temperature. The removal of the coke by hand-rakes is also tedious and expensive.

With the object of overcoming the main drawbacks of the beehive oven, Coppée introduced a non-by-product retort of rectangular form, from which the coke could be discharged *en bloc* by a ramming machine and quenched outside the oven, thus expediting the operation and greatly increasing the yield. In Coppée's oven the gases evolved from the coal are drawn into flues in the side walls where they are burned, and in this way combustion within the coking chamber and loss of coke, as in the beehive oven, is avoided.

The by-product retort is built on the same lines as the Coppée, that is to say, it is a rectangular chamber heated by flues in the side walls, and the coke is discharged by a ramming machine; the essential point of difference lies in the fact that in the Coppée the whole of the gases containing the by-products are drawn immediately they are evolved into the side-wall heating flues, where they are burned; in the by-product retort, the gases and products are drawn from the oven through cooling and washing plant for the recovery of the tars, ammonia, and benzol, and the permanent gas only is burned in the flues after the said products

have been extracted. In the Coppée, the whole of the permanent gas is burned in the heating flues; in the by-product oven, only one-half to two-thirds of the gas is utilised in the flues, the remainder being available for lighting or power purposes.

The following diagrams illustrate the essential differences in the three types of oven:

FIG. 1.—BEEHIVE.

FIG. 2.—COPPÉE.

FIG. 3.—BY-PRODUCT RETORT.

It will be seen, therefore, that in addition to effecting the theoretical coke yield, and a large output, the by-product retort yields valuable by-products and a considerable yield of power or lighting gas. The value of products per 100 tons of coal at their present market value is as follows:—

	Gross value		recovery		Net value	
	£	s. d.	£	s. d.	£	s. d.
1 ton sulphate of ammonia	12	0 0	2	10 0	9	10 0
4.5 tons tar at 18s.	4	1 0	0	9 0	3	12 0
300 gallons crude benzol at 5d.	6	5 0	1	17 6	4	7 6

Per 100 tons of coal 17 9 6
Per ton of coal = 3s. 5.94d.

The by-product process described in detail.—The by-product retort usually measures from 30 to 33 feet in length, from 5 feet 9 inches to 7 feet 6 inches in height, from 17 to 22 inches

TABLE SHOWING THE RETURN FROM CARBONISING A COAL CONTAINING 30 P.C. VOLATILE MATTER, *i.e.* A THEORETICAL COKE YIELD OF 70 P.C. IN THE THREE TYPES OF OVEN.

Beehive	Coppée	By-product retort
Combustion within coking chamber, quenching inside oven	Coking chamber heated externally by gas from which by-products not extracted: quenching outside oven	Coking chamber heated externally by gas from which by-products have been extracted: quenching outside oven
Yield of dry coke = 56 p.c.	70 p.c.	70 p.c.
" tar —	—	4.0 to 4.5 p.c.
" sulphate of ammonia —	—	1.0 to 1.2 p.c.
" benzol —	—	2.5 to 3.0 gallons of crude benzol testing 62 p.c. at 120° per ton of coal
Waste heat— In most cases not utilised but approximately equal to 0.75 ton of water evaporated per ton of coal carbonised	Always utilised: equal to 1 ton of water per ton of coal carbonised	Always utilised: equal to 1 ton of water per ton of coal carbonised
Amount of coke produced per oven per week = 7 to 10 tons	24 to 26 tons	24 to 26 tons
		Surplus gas if required for other purposes than steam raising, <i>e.g.</i> gas engines or illumination, 3000 to 5000 cubic feet per ton of coal

in width, and is built in batteries of from 25 to 60 ovens, capable of carbonising from 100 to 350 tons of coal per day. Each oven is provided with cast-iron or rolled-steel doors at each end, lifted by a small crane whenever an oven is discharged, and with three holes in the roof through which the coal is charged into the oven from the charging hoppers; a fourth hole is provided, through which the gases are led to an ascension pipe from which the gases pass to the by-product plant. The oven linings and combustion flues are constructed of silicious firebricks containing from 80 to 84 p.c. of silica, from 14 to 18 p.c. of alumina, and 2 p.c. of fusible constituents (iron oxide, lime, magnesia, and the alkalis). The design of the heating flues constitutes the main difference between the various types of oven; the Simon-Carvès, Semet-Solvay, Hüssener, and Simplex containing horizontal flues; the Otto-Hilgenstock, Otto-Hoffmann and Koppers prefer vertical flues (Figs. 4 and 5). In all cases the air required for the combustion of the gas in the heating flues is preheated either by passing it through recuperators in which it travels through a system of flues situated alongside the waste gas flues of the oven, or through regenerators similar to those employed in open-hearth steel furnaces, where the hot waste gases and air are alternately taken over the same surface (Fig. 6). Where a large supply of surplus gas is desired from a coking plant, the regenerative method of preheating the air is to be preferred, since it is more effective and less gas is required for heating the flues; the amount of surplus gas available from a Lancashire coal containing 30 p.c. of volatile matter, may be taken at 2000 cubic feet per ton, where recuperative heating is employed, and 5000 cubic feet per ton where regeneratives are used.

The coal is generally charged into the oven through the crown from small hoppers, carrying

the coal on rails from the storage bunker, the coal flowing into the oven being levelled by hand-rake or levelling machine. In cases where the coal employed is not of a strongly coking character, the fuel is stamped into a solid cartridge in a compressing machine and charged into the oven *en bloc* through the end doorway. The coke is discharged from the oven by a ram, generally electrically driven; often the levelling machine or compressor is built on the same carriage as the ram, and driven by the same motor. The coke is received from the ovens on a sloping bench, where it is quenched with water, and from which it slides into railway trucks, furnace barrows, or a conveyor. The heating flues of each oven discharge into a common flue, which leads the waste gases in the case of recuperator types to steam boilers; with regenerator-ovens, the gases are led direct to the chimney stack. The gases distilled from the coal collect above the level of the fuel and pass forward to the ascension pipe or stand pipe, which delivers the gas into the tar or hydraulic main, which receives the gases from the entire battery. A valve or damper is provided on each ascension pipe for shutting off each oven whilst the latter is being discharged and recharged. In the tar or hydraulic main the heavier tars or pitches are deposited, and in the 'dry' types of main, it is necessary to pump the thinner tars made at a later stage of the cooling, through the main to clear the pitch and prevent stoppages. From the main the gases are drawn by an exhauster (either steam or electrically driven), a Root's blower, or some form of aspirator, through coolers. These coolers are either plain pipes or cylinders offering a large amount of atmospheric cooling surface, or are water-cooled chambers; in these condensers, the bulk of the remaining tar, together with the greater proportion of the ammonia liquor, is precipitated.

FIG. 5A.—SECTION THROUGH SEMET-SOLVAY OVEN.

Fig. 6.—REGENERATIVE VERTICAL-FLUED COKE OVEN: THE OTTO-HILGENSTOCK.

From the condensers, the gases pass into the exhauster or aspirator, which then delivers them at a pressure into a tar-fog extractor. This vessel is employed to remove the last traces of tar which exist in the gas in an extremely fine state of division, and which no amount of cooling would remove. The tar extractor, of which the Pelouze Andouin and Livesay are types, operates by dividing the gas into numerous thin streams by means of very small gas passages, the agglomeration and removal of the tar particles being effected by the wire drawing and friction thus afforded.

From the tar catcher the gases pass into the

ammonia scrubber, where the last of the ammonia not recovered by the condensers is removed by contact with weak ammonia liquor and water. The types of ammonia scrubber generally employed are similar to those employed at gas works, and are either of the tower or rotary form. In the tower scrubber, the gases pass upwards through a mass of coke or other open material, meeting a downward current of water or ammonia liquor pumped in at the top. In the rotary scrubber, the gas is caused to impinge on revolving brushes or circular wooden screens, which dip into the water or liquor in the lower half of the vessel, and pass upwards

with wet surfaces into the upper half of the scrubber, where the gas is circulating, and solution of ammonia is attained. The gas then passes forward to the benzol scrubber, which is constructed on similar lines to that employed for ammonia removal, creosote or anthracene heavy oil being employed for the solution and recovery of the benzol vapour.

The gas having been freed from its tar, ammonia, liquor, and benzol, is then passed forward to the ovens, where it is fed into the heating flues, the surplus being passed forward to boilers, gas engines, or gas holder.

The tars and ammonia liquors made in the hydraulic main, condensers, tar catchers, and

ammonia scrubber are collected and run into separators or tanks, where the denser tar settles to the bottom, is withdrawn and despatched to the tar stores. The liquors which remain above the tar are run off to the sulphate of ammonia plant, where the liquor is pumped into overhead store tanks, whence it is allowed to flow by gravity through a preheater (heated by the waste gases from the sulphate plant), and thence into a distilling column, where it flows downwards, meeting in its travel an upward current of steam, which liberates the free or combined ammonia. In the lower half of the still, milk of lime is mixed with the liquor for the liberation of the ammonia from the fixed

FIG. 8.—SULPHATE OF AMMONIA PLANT.

salts; the whole of the ammonia, together with steam, sulphuretted hydrogen, carbonic acid, and hydrocyanic acid, pass upwards through the still and into a lead-lined vessel called the saturator, containing sulphuric acid. The ammonia combines with the acid to form ammonium sulphate, which, when the liquor in the bath becomes saturated, crystallises out and is removed either by copper scoops, a valve, or by steam injector. The sulphuretted hydrogen and other gases pass from the saturator to the preheater, where they serve to heat the liquor passing to the still; thence the gases travel to a condenser where they are cooled, and afterwards to purifiers where the sulphuretted hydrogen is removed by oxide of iron. The waste liquors, which should not contain more than 0.01 p.c. ammonia, are run into the sewers or watercourses, and are a frequent source of trouble to the river boards. By the Otto-Hilgenstock method of by-product recovery, to be described later, the production of these waste liquors is entirely obviated.

The recovery of crude benzol from its solution in creosote or anthracene is effected in a distilling column somewhat similar to that employed for the recovery of ammonia from liquor, the heating of the solution of benzol in the absorbent being effected by wet steam assisted by dry steam. The vapours, steam, and benzol pass from the top of the still to a water-cooled coil, where they are together condensed, the condensates being separated by reason of their different densities. The grade of crude benzol thus obtained varies with the class of absorbent oil employed with creosote, 62 p.c. of the product distils at 120° , with anthracene the benzol is richer, 80 p.c. distilling at 120° . For the rectification of crude benzol, the product is washed successively with strongest oil of vitriol, water, and caustic soda, and redistilled.

Development in by-product recovery.—Two successful attempts have been made to simplify the old system of treatment of coke-oven gases for the recovery of ammonia, viz. the inventions of the Koppers and Otto-Hilgenstock Coke Oven Companies. Koppers treats his gases by the old system up to the point of the tar-fog extraction. He then reheats his tar-free gas by passing it in pipes surrounded by the hot gases coming from the ovens in an apparatus called a heat exchanger, and then passes the heated gas direct into a sulphate saturator, into which is likewise passed the ammonia from the liquor made in the condensers, which is distilled in an ordinary ammonia still. In short, Koppers abolishes the usual ammonia scrubber and substitutes the sulphate saturator, thus making his sulphate direct on the gas main (Fig. 9). By thus using the sulphuric acid in the saturator for scrubbing out the ammonia, Koppers dispenses with the water utilised in the old scrubber, thereby reducing the total amount of liquor produced, and effecting an economy in the amount of steam required in the ammonia distillation.

A far more extensive simplification is effected by the invention of the Otto-Hilgenstock Co. of Dahlhausen, who dispense entirely with the old condensing plant and remove the tar from the gases by means of a tar spray at a temperature above the dew-point of the liquors. The

tar-free gases then pass direct into a saturator, where the whole of the ammonia is caught by sulphuric acid. The gases issuing from the saturator still contain their liquors in steam form, and the whole passes forward to the oven-flues, and the offensive and troublesome waste

liquors are thus got rid of. The Otto invention, by abolishing the condensing plant, liquor tanks, ammonia stills, lime mixers, and pumps, waste liquor tanks, &c., effects a great economy in ground space. It likewise saves nearly the whole of the steam required to distil the ammonia liquor

made by the old condensing process, and, by passing the whole of the ammonia through sulphuric acid, losses of ammonia, which are liable to occur in the old process of ammonia liquor distillation, are rendered impossible. The ammonium sulphate made by the Otto direct-recovery, tests from 25 to 25.5 p.c. of ammonia,

and contains only the merest traces of tar, viz. 0.05-0.1 p.c. (Fig. 10, 11, and 12).

The utilisation of coke-oven gas.—The large amounts of surplus gas obtained from the by-product coking process are gradually being diverted from use under steam boilers to more economic forms of application, and regenerative

ovens are now being erected as power stations, in addition to the facilities which they afford for economic coke manufacture and by-product recovery. At many collieries and iron works on the Continent, large gas-engine installations have been set down for the utilisation of coke-oven gas; and in England its use is being surely extended. The coke-oven plant erected by the Otto-Hilgenstock Coke Oven Co., for the Skinningrove Iron Co., Carlin How, Yorkshire,

provides sufficient surplus gas to develop 7000 horse-power.

The use of coke-oven gas as a town's illuminant is likewise receiving attention, and with the development of the incandescent mantle, which requires gas of calorific rather than of candle value, coke-oven gas comes into the category of ordinary coal gas. In the year 1910 Parliament granted powers for the supply of gas from Lord Ellesmere's Brackley coke

FIG. 11.—MODEL OF OTTO-HILGENSTOCK SYSTEM: PLANT ERECTED FOR THE SKINNINGROVE IRON CO.

ovens to the urban district of Little Hulton, the guarantees of quality and purity of the product being identical with the gas supplied to the Metropolis, that is to say, the gas has a minimum illuminating power of 14 standard sperm candles, tested by the Metropolitan No. 2 Argand burner, and a calorific guarantee of 550 B.T.U. gross. The average composition of the gas is: CO_2 , 2.5; O, 0.3; C_2H_4 , 3.8; C_2H_6 &c., nil; CO, 7.0; CH_4 , 31.0; H, 49.0; N, 6.4. E. B.

COLTANNIN v. TANNINS.

COLCHICINE v. VEGETO-ALKALOIDS.

COLCHICUM. *Meadow saffron.* (*Colchique*, Fr.; *Herbstzeitlose*, Ger.) The corm or seeds of *Colchicum autumnale* (Linn.), (Bentl. v. Trim. 288). This plant is found in meadows and pastures throughout Europe, where its crocus-like flowers, usually of a lilac hue, make their appearance in September and October.

Colchicum is a poisonous drug long known to medicine. It has been subject to repeated investigation with a view to isolate its active constituent or constituents. Among earlier inquiries are those of Melander and Moretti, 1810 (Bull. Pharm. 2, 217); Stoltze, 1818 (Berz. J. 19, 107; 20, 135); Pelletier and Caventou, 1820 (Ann. Chim. Phys. [2] 14, 69; J. Pharm. Chim. 6, 364); Buchner, 1832 (Rep. Pharm. 43, 376). Besides substances common to plants, such as starch, gum, cellulose, sugar, oil, resin, &c., the older workers detected a bitter extractive possessing physiological activity, and Pelletier and Caventou regarded it as containing gallate of veratrine. Geiger and Hesse, in 1833 (Annalen, 7, 274), showed, however, that the bitter alkaloidal compound, which they describe as crystalline, has properties quite distinct from veratrine, and they gave it the name *colchicine*. It is faintly alkaline, is sparingly soluble in water, but dissolves readily in alcohol or chloroform, the latter extracting it from its aqueous solution; the dry compound strikes a deep violet to blue colour with concentrated nitric acid, and its aqueous solution is precipitated brown by tincture of iodine, yellow by platinum chloride solution, and white by tannic acid. The corm yields less than 0.1 p.c. of colchicine. The subject is further studied by Asehoff (Arch. Pharm. [3] 89, 4); Bley (*ibid.* [3] 89, 18); Hübschmann (*ibid.* [3] 92, 330); and Oberlin (Ann. Chim. Phys. [3] 1, 108). The last-mentioned observer, by the action of dilute acids, succeeded in breaking up colchicine into a new alkaloid *colchicine* and other products. This compound was obtained in colourless laminae or needles, sparingly soluble in cold, more so in boiling water, readily in alcohol or chloroform, insoluble in ether or benzene. Full directions for extracting colchicine from the crude drug, and its conversion into colchicine are given by Hertel (Pharm. Zeit. 1881, 245), who observes that when exposed to the air, colchicine gives off ammonia and water, and is converted successively into two resins: *α-colchico-resin* $\text{C}_{51}\text{H}_{40}\text{N}_2\text{O}_5$ (?), and *β-colchico-resin* $\text{C}_{34}\text{H}_{36}\text{NO}_{10}$ (?). These resins are formed in the officinal wine of colchicum, but are not indications of therapeutical deterioration, for they possess equal medicinal value with the alkaloid from which they are derived.

Important contributions to the chemistry of colchicine and colchicine have more recently been

FIG. 12.—OTTO-HILGENSTOCK DIRECT RECOVERY PLANT ERECTED FOR THE SKINNINGROVE IRON CO.

made by Zeisel (Monatsh. 4, 162; 7, 557; 9, 1; 9, 865). After reviewing previous work, this observer assigns to colchicine the formula $C_{22}H_{25}NO_6$. It melts at about 145° and forms a characteristic crystalline compound with chloroform $C_{22}H_{25}NO_6 \cdot 2CHCl_3$ (Houde, Compt. rend. 98, 1442; Zeisel, *ibid.* 98, 1587). Colchicine is slightly basic, forming a gold salt $(C_{22}H_{25}NO_6)HAuCl_4$. Methyl colchicine $C_{22}H_{24}MeNO_6$ has also been obtained. In the conversion of colchicine into colchicineine $CH_3 \cdot OH$ is evolved, and the new alkaloid has the composition $(C_{21}H_{23}NO_6)_2 \cdot H_2O$. It melts at 139° – 141° , loses its water of crystallisation at 140° – 150° , becoming solid, and on further application of heat the anhydrous alkaloid softens at 161° and melts at 172° . Colchicine appears, therefore, to be a methylcolchicine. When colchicine is treated with concentrated hydrochloric acid, the reaction does not stop with the formation of colchicineine by the displacement of one methyl group; but this is accompanied by that of an acetyl radicle, leaving an acid $C_{19}H_{21}NO_5$ or $(C_{18}H_{20}NO_5)COOH$. In the further progress of the reaction, this compound loses another methyl group, giving rise to a second acid $(C_{17}H_{18}NO_5)COOH$, and finally by the displacement of two additional methyl groups, colchicineic acid $(C_{15}H_{14}NO_5)COOH$ is obtained. The second acid described is therefore dimethyl colchicineic acid, and the first acid trimethyl colchicineic acid; whilst colchicineine is regarded as acetyl trimethyl colchicineic acid, and colchicine, which does not possess acid properties, as the methyl ester of colchicineine. Colchicineine is basic, forming the gold salt $C_{21}H_{23}NO_6 \cdot HAuCl_4$, but it is also acid, or at least phenolic, giving rise to the copper derivative $(C_{21}H_{22}NO_6)_2Cu \cdot 5H_2O$. The acid property of colchicineine is further apparent in the readiness with which it combines with alkalis. By treatment with methyl iodide and sodium methoxide colchicineine may be converted into colchicine.

Colchicine has also been found to occur in other varieties of colchicum (Albo, Arch. Sci. Phys. Nat. Geneva, 1901, iv. 12, 222).

Colchicum is a favourite remedy in the treatment of gout and rheumatism. It acts as an irritant of the alimentary canal and kidneys, being a purgative and diuretic, and in large doses these symptoms become more and more violent until a fatal result follows. The action is cumulative (Mairet and Combemerle, Compt. rend. 104, 439, 515). *Post-mortem* examination of the stomach contents by treatment with alcohol, and purification of the extract obtained by fresh treatment with alcohol or with chloroform, and then the application of the nitric acid and other tests, may be adopted in cases where death is supposed to have been caused by colchicum. (Cf. Dannenberg (Arch. Pharm. [3] 9, 411; 10, 97), and Van Geldern (*ibid.* [3] 9, 32); Obolonski (Zeitsch. anal. Chem. 29, 493).)

Flückiger (Pharm. J. [3] 7, 372) recommends the colour reactions which an alcoholic extract of colchicum corms gives with mineral acids as a delicate means of detecting those acids. (For detection and estimation of colchicum, see also Kremel, Zeitsch. anal. Chem. 29, 727); Barillot (Bull. Soc. chim. [3] 11, 514); Prescott and Gordin (Chem. Zentr. 1900, ii. 784). A. S.

COLCOTHAR. The reddish-brown residue of ferric oxide obtained in the manufacture of fuming oil of vitriol from iron sulphate.

COLEMANITE. A hydrated calcium borate $Ca_2B_6O_{11} \cdot 5H_2O$, containing 50.9 p.c. boron trioxide. It is found in California at Death Valley in Inyo Co., and the Calico district in San Bernardino Co.; and although not discovered until 1882 and 1883, is now of some importance as a material for the preparation of borax and boracic acid. Cavities in the massive, white material are lined with beautiful, water-clear crystals with a profusion of brilliant facets; these are monoclinic, with a perfect, pearly cleavage parallel to the plane of symmetry. They are considerably harder (H. 4–4½) than borax; sp.gr. 2.42. The mineral forms, together with other borates and borosilicates, a bed 7 to 10 feet in thickness in sandstones and clays.

The compact minerals, *priceite* from Oregon and *pandermite* from Asia Minor, have very nearly the same composition, and they may be regarded as impure, massive varieties of colemanite. These also are mined as borates.

L. J. S.

COLLIDINE v. BONE OIL.

COLLIN. A preparation made by heating a solution of hide powder or gelatin with caustic soda and neutralising with acetic acid. Used in the analysis of tannin and tanning materials (Parker and Payne, J. Soc. Chem. Ind. 1904, 648; Wood and Trotman, *ibid.* 1904, 1071).

COLLODION v. PHOTOGRAPHY.

COLLODION COTTON v. EXPLOSIVES.

COLLOIDS. In 1861 Graham pointed out that substances which crystallise readily from water are characterised by a high power of diffusion and by the ability to pass through animal or vegetable membranes; substances, on the other hand, which cannot easily be obtained in the crystallised condition are characterised by a low power of diffusion and by inability to pass through animal or vegetable membranes. Graham termed substances of the first class, such as sucrose or sodium chloride, *crystalloids*; and those of the second class, such as starch, gum, or albumin, *colloids*. The separation of a colloid from a crystalloid is effected by dialysis, a process based on the inability of a colloid to pass through parchment or other membrane.

At the present time, the term 'colloid' is used in a sense somewhat different from that in which Graham employed it, and is to be interpreted as referring, not so much to a particular class of substances, as to a condition which a large number of chemical compounds may be made to assume. A 'colloidal solution,' therefore, is not necessarily a solution of a colloid (in Graham's sense); it is a solution the properties of which are, in many respects, similar to those of, say, a gum arabic solution, although the dissolved substance may be quite outside the class which Graham termed 'colloids'; it may be, for instance, ferric hydroxide, arsenious sulphide, or platinum.

Osmotic properties of colloidal solutions.—The osmotic pressure of a colloidal solution is extremely low. According to Duclaux, for instance, the osmotic pressure of an 8.86 p.c. ferric hydroxide solution is only 22.6 cm. of

water, which is about equal to the pressure given by a solution of sucrose containing one-thirtieth of a gram in 100 grams of water. It has, indeed, been suggested that the osmotic pressures which have been observed for colloidal solutions are due, not to the colloids themselves, but to small quantities of electrolytes associated with the colloids. While it is certainly true that the removal of the last traces of electrolytes from a colloidal solution is no easy matter, and that electrolytes are extremely active material from the osmotic point of view, still the most recent investigations indicate that colloidal solutions do possess a definite, if small, osmotic pressure. It appears, however, that the osmotic pressure of a colloidal solution is not completely defined, as is that of a crystalloidal solution, by concentration and temperature. Thus Moore and Roaf have found (*Biochem. J.* 1906, 2, 34) that the osmotic pressure of a given gelatin solution at a given temperature depends, to some extent, on its previous history, while Lillie has found (*Amer. J. Physiol.* 1907, 20, 127; see also Bayliss, *Proc. Roy. Soc. B.* 1907, 81, 269) that the osmotic activity exhibited by the colloid itself is modified by the presence of electrolytes in a remarkable degree. Concentration and temperature, therefore, are not the only factors which determine the osmotic pressure of a colloidal solution.

The depression of the freezing-point and the elevation of the boiling-point of water by a dissolved substance are quantitatively related to the osmotic pressure of the solution, and, like the latter, may be made the basis for a determination of the molecular weight of the solute. The freezing-point and boiling-point of a colloidal solution are, however, very slightly different from those of water itself, and the experimental error of the determination of the molecular weight of the colloid by this method is relatively large. In view, further, of the fact that the osmotic activity of a colloid depends on other factors than those of concentration and temperature, it is obvious that the values for the molecular weight of a colloid deduced from its effect on the freezing-point or boiling-point of water have a very limited significance. Such values have reference only to the particular condition of the colloid at the time of the determination.

Colloids in an electric field.—In 1892 Linder and Picton observed (*Chem. Soc. Trans.* 1892, 61, 148) that when two wires, connected with the terminals of a battery, are placed in a colloidal solution of arsenious sulphide, this substance is attracted by the positive pole and is gradually transported thither. Ferric hydroxide in colloidal solution is, on the other hand, attracted by the negative pole. It appears, therefore, that the particles of colloidal arsenious sulphide carry a negative charge, whilst those of colloidal ferric hydroxide carry a positive charge. Other colloids are similarly found to carry a definite charge; thus chromium and aluminium hydroxides, methylene blue, Bismarck brown and hæmoglobin, are electropositive; tannin, caramel, starch, platinum, gold, and indigo are electronegative. Very significant in this connection is Hardy's observation (*J. Physiol.* 1899, 24, 288), that protein is electronegative in an alkaline medium, but electropositive in an acid medium. A reversal of the electric charge on a

colloid has been observed in other cases also (see Burton, *Phil. Mag.* 1906, 12, 472).

Colloidal solutions and suspensions.—The behaviour of substances in colloidal solution, when exposed to the action of an electric force is very similar to the behaviour of suspensions in the same circumstances. When wires connected with the terminals of a battery are immersed in suspensions of quartz powder, gum mastic, or shellac, the suspended particles move towards the positive pole. These are facts which suggest a close relationship between colloidal solutions on the one hand, and mechanical suspensions on the other. This view is strongly supported by various other lines of evidence. Thus the majority of colloidal solutions exhibit the Tyndall phenomenon, *i.e.* the opalescence which is observed when a powerful beam of light is passed through a fluid medium containing definite suspended particles. Further, the ultramicroscope, devised by Zsigmondy and Siedentopf, makes it possible to detect the individual particles in colloidal solutions, even when the most powerful microscope fails to reveal any trace of heterogeneity. There are therefore good grounds for the view that there is a close relationship between colloidal solutions and mechanical suspensions.

There are, however, cases on record in which colloidal solutions, even when examined with the ultramicroscope, have been found free from distinct particles. On the other hand, evidence has been adduced (Lobry de Bruyn, *Rec. trav. chim.* 1904, 23, 155, 218) showing that solutions of a heavy crystalloid, such as sucrose, are non-homogeneous. Hence it is evidently impossible to draw a hard-and-fast line of division between colloidal and crystalloidal solutions, so far at least as the size of the solute particles is concerned. The smallest particle that can be detected with the ultramicroscope under the most favourable conditions is about 5×10^{-6} mm. in diameter, and it is estimated that the size of an ethyl alcohol molecule is 0.4×10^{-6} mm., so that in any case the interval between the region of colloidal solutions and that of average crystalloidal solutions is not great. So far as the size of the individual particle is concerned, colloidal solutions are intermediate between mechanical suspensions on the one hand and crystalloidal solutions on the other, but the inadvisability of regarding these three classes as absolutely distinct is clearly indicated by the fact that it is possible to prepare solutions of one and the same substance of various degrees of heterogeneity. Linder and Picton were able to prepare different 'grades' of arsenious sulphide solution; and in deciding whether a given solution of arsenious sulphide is a colloidal solution or merely a mechanical suspension, the verdict will depend on the criterion of heterogeneity which is employed.

The particles which are detected in a colloidal solution with the help of the ultramicroscope are seen to be in a state of constant motion—a phenomenon essentially the same as the Brownian movement exhibited by gamboge or fat particles suspended in water. The finer the particles the more rapid is their movement, and a study of the relationship between the size of the particle and its rate of movement has led to a calculation of the rate at which a particle of

molecular size would move. The value so calculated is in good agreement with the value deduced from the kinetic theory, and this agreement is regarded as amounting to a definite proof of the kinetic nature of heat.

Separation of colloids from their solutions.—Substances in colloidal solution pass through the finest filter paper, but if the close relationship between mechanical suspensions and colloidal solutions is borne in mind, it will be seen that the question whether filtration can be effected in the latter case as in the former reduces itself to the question whether filters with sufficiently small pores can be procured. The most successful attempts that have been made to solve this problem depend on the impregnation of a suitable supporting medium with a colloid such as gelatin or collodion. Filter paper, for instance, may be soaked in gelatin solution and then hardened with formaldehyde, or impregnated with a solution of collodion in glacial acetic acid and then dipped in water. As the concentration of the impregnating gelatin solution is increased, the permeability of the filter to colloids diminishes, so that a series of graded filters can be prepared which may be employed to sort out a number of colloidal solutions, according to the size of particles they contain (see Bechhold, *Zeitsch. physikal. Chem.* 1907, 60, 257). It is noteworthy that these 'ultra-filters,' as they are called, may be employed to separate oil-water emulsions (see Hatschek, *J. Soc. Chem. Ind.* 1910, 29, 125).

Another method of separating a colloid from its solution is to precipitate the colloid and then filter off in the ordinary way. It is found that in relation to precipitating or coagulating agents, the substances which form colloidal solutions may be divided into two classes—the one class resembling suspensions, the other behaving more like crystalloid substances. The colloids belonging to the first class are known as 'suspension colloids,' and they give non-viscous solutions which are coagulated by small quantities of electrolytes; these colloids are known also as 'non-reversible,' for when once they have been separated they do not again pass into solution by mere contact with water; their solutions can be obtained only by indirect methods. The colloids belonging to the second class are known as 'emulsion colloids,' and they give viscous solutions which are not readily coagulated by electrolytes; they are also termed 'reversible' colloids, because, even if separated from solution by any means, they will again pass into solution on mere contact with water.

The coagulation of suspension colloids, such as arsenious sulphide or ferric hydroxide, is brought about by extremely small quantities of electrolytes. When experiments are made to determine the minimum concentration of various electrolytes required to precipitate colloidal arsenious sulphide, it is found that this minimum concentration is of the same order for all salts containing cations of equal valency; the higher the valency of the cation, the smaller is the concentration of the electrolyte required to bring about coagulation. In relation to colloidal ferric hydroxide, on the other hand, the coagulating power of a salt is mainly determined by the valency of the negative ion; the valency of

the cation is relatively unimportant. The contrast in this respect between colloidal arsenious sulphide and colloidal ferric hydroxide is very interesting in view of the fact that the colloid particles of arsenious sulphide are negatively charged, while those of ferric hydroxide are positively charged. The full significance of this was first emphasised by Hardy (*Zeitsch. physikal. Chem.* 1900, 33, 385), who formulated the rule that the ion of an electrolyte which determines the coagulation of a colloidal solution is the one which has a charge opposite in sign to that on the colloid particles. The validity of this rule has been extensively confirmed. The 'coagulum' or 'hydrogel' obtained when a solution of a suspension colloid is precipitated by a salt contains some of the acidic or basic part of the salt. Thus the coagulum obtained when colloidal arsenious sulphide is precipitated with barium chloride, is found to contain barium, and in proportion as the coagulum retains barium, the filtrate becomes acid. The barium cannot be removed by continued washing with water, but may be replaced by an equivalent quantity of another metal by digesting the coagulum with a solution of the chloride of this metal.

If, as suggested by the facts just mentioned, the coagulation of a suspension colloid by a salt is essentially a neutralisation of electric charges, it may be expected that colloids of opposite electrical sign will precipitate each other. In harmony with this, it is found that while no coagulation occurs when colloidal solutions ('hydrosols') of the same electrical sign are mixed, precipitation immediately follows the addition of the solution of a positive colloid to the solution of a negative colloid, unless one of the colloids is in very large excess. For a certain proportion of the colloids, the precipitation of both is complete, but as the quantities deviate from this optimal ratio, precipitation is increasingly incomplete. The precipitation of egg albumin by solutions of various complex acids—e.g. molybdic, tungstic, and tannic acids—furnishes an example of the mutual coagulation of two colloids. Metaphosphoric acid, too, forms a pseudo-solution or hydrosol which precipitates albumin, while the crystalloidal orthophosphoric acid has no such effect.

The separation of emulsion colloids, such as serum protein, from their solutions, may also be effected by the addition of electrolytes, but the process is essentially distinct from the corresponding precipitation of suspension colloids; it is not electrical in character. When a number of alkali salts are arranged according to their efficiency in precipitating emulsion colloids, the order is practically the same as when they are arranged according to their efficiency in salting out an organic compound from water, or according to their power of lowering the solubility of gases in water. The precipitation of emulsion or reversible colloids by neutral alkali salts appears, therefore, to be closely allied to the process of 'salting out,' and this result of itself shows that solutions of reversible colloids approximate more closely to true solutions than do solutions of suspension colloids.

Not only are emulsion colloids themselves very slightly sensitive to electrolytes, but in presence of an emulsion colloid the precipitation

of a suspension colloid by salts is more or less inhibited. This is not due to an increase in the viscosity of the medium and consequent increase of resistance to sedimentation, for the protective effect is exhibited by quantities of the reversible colloid insufficient to cause any appreciable change in viscosity. It is probable that the emulsion colloid forms a thin envelope round each particle of the suspension colloid and so prevents the aggregation and subsequent flocculation of the particles.

Adsorption.—Reference has already been made to a difference of electrical potential as determining in some cases the relation between a colloid and its environment. There is, however, another factor which must be taken into account in the consideration of this question, and that is the relatively enormous surface of contact between the colloid and the surrounding medium. The evidence sketched in the foregoing paragraphs shows that a colloidal solution is really a two-phase system, consisting of a fluid medium in which are distinct suspended particles of extremely small size. Now, it is obvious that as a given quantity of matter is divided up more and more finely, its surface area increases regularly. The surface area, for instance, of a single sphere with a diameter of 1 mm. is 0.0314 sq. cm.; if the matter composing this sphere were broken up into a number of smaller spheres, each 0.0001 mm. in diameter, the total surface area of the spheres would be 314 sq. cm. It is evident, therefore, that in a colloidal solution with its fine suspended particles, there must be relatively a very large surface of contact between the colloid and its medium.

On the basis of the two-phase character of colloidal solutions and the large surface development of the colloid phase, the relation of colloids to each other and to various solid and dissolved substances may be regarded as being essentially of the nature of 'adsorption.' This term is used in reference to the observation that when a substance is introduced into a two-phase system, and provision is made for its distribution throughout the system, it is frequently found concentrated at the surface of one of the phases. The nature of this phenomenon will perhaps be best appreciated by contrasting it with cases in which the substance is distributed uniformly in each phase of the two-phase system. When iodine is shaken up with two immiscible liquids, such as water and carbon tetrachloride, a state of equilibrium is soon reached at which the concentration of the iodine is uniform throughout the aqueous phase, uniform also (but different) throughout the carbon tetrachloride phase. If c_1 is the concentration of iodine in the aqueous layer, and c_2 its concentration in the carbon tetrachloride layer, then c_2/c_1 , the 'partition coefficient,' is found to be a constant, independent of the absolute values of c_1 and c_2 . This is a rule applicable to the distribution of any substance between two immiscible liquids, provided the molecular condition of the substance is the same in each liquid. If, on the other hand, the molecular weight of the substance in the first liquid is n times its molecular weight in the second liquid, then c_2^n/c_1 is a constant, independent of the absolute values of c_1 and c_2 . If, con-

versely, the distribution of a substance between two liquids at various concentrations has been found to be such that c_2^n/c_1 is a constant, the conclusion may be drawn that the molecular weight of the substance in the first liquid is n times its molecular weight in the second liquid.

The distribution of a substance in a two-phase system which consists, not of two immiscible liquids, but of a solid and a liquid, is generally quite different in character. When, for instance, acetic acid solutions of various concentrations are shaken up with carbon, a state of equilibrium is rapidly attained, and it is found that some of the acetic acid has been taken up by the carbon. If c_s and c_l represent the equilibrium concentrations of the acetic acid in the solid and the liquid phase respectively, then the experiments show that $c_s^{2.25}/c_l$ is a constant. According to the foregoing paragraph, this would mean, on the assumption of a uniform distribution of the acetic acid throughout the carbon, that the molecular weight of acetic acid in the carbon must be less than half what it is in water. This conclusion must obviously be rejected, and the assumption of a uniform distribution of the acetic acid throughout the carbon is incorrect. The acetic acid must be concentrated at the surface of the carbon, a view supported by the rapidity with which equilibrium is established. The acetic acid is said to be 'adsorbed' by the carbon, and the phenomenon is termed 'adsorption.'

The distribution of a substance in a two-phase system where one of the phases is a solid with largely developed surface, is generally found to consist in an adsorption equilibrium. This is indicated, qualitatively, by the concentration of the substance in the solid phase increasing more slowly than its concentration in the liquid phase, and quantitatively by the validity of the formula $c_s^n/c_l = \text{constant}$. In this way it has been shown, to quote one or two examples, that the taking up of gases by charcoal, the removal of arsenious acid from solution by freshly precipitated ferric hydroxide, and the dyeing of silk with picric acid and numerous other colouring matters, are all cases of adsorption. The complexes formed, although not due to chemical combination in the strict sense, and although lacking the characteristics associated with a definite chemical substance, are frequently referred to as 'adsorption compounds.' As van Bemmelen especially has shown, colloids in the form of hydrogels have a very marked power of adsorbing other colloids, crystalloids and water, and evidence is accumulating in favour of the view that the behaviour of colloids in solution towards other substances is also to be interpreted in terms of adsorption.

The question may be asked: Is there any physical reason for the concentration of a substance at the surface of one of the phases in a two-phase system, such as a colloidal solution undoubtedly is? The answer is that if surface tension considerations only are taken into account, then it follows on thermodynamical grounds that the most stable relation between the two phases of a colloidal solution is the one characterised by a minimum surface tension. Hence if the substance present in the solution lowers the surface tension of the solvent, that

substance will accumulate in the surface layer of the solution. That such spontaneous accumulations may occur in the surface layers of solutions has been shown by Ramsden (Proc. Roy. Soc. A, 1903, 72, 156), who observed the formation of solid or highly viscous coatings on the free surfaces of protein and many other colloidal solutions.

Bearing of colloid chemistry on technical problems.—The rôle played by colloids in the operations of applied chemistry is of great importance. In the manufacture of starch, cellulose, glue, leather, caoutchouc, artificial silk, paper, and photographic plates, colloids are involved, and a knowledge of the general behaviour of colloids throws much light on these and other industrial operations. Many dyes give colloidal solutions, and dyeing, in a large number of cases at any rate, depends on the adsorption of the colouring matter by the fibre. The relation between hide and tannin appears to be of the same description, and the investigation of the tanning process from this point of view shows the definite bearing which colloid and adsorption phenomena have on this operation. The problem of sewage disposal also is closely related to colloid chemistry, and it has been found practicable to retain the colloids of the sewage in the form of adsorption compounds. The tints of coloured glasses are frequently due to the presence of metals in the colloidal state. This is notably the case with gold ruby glass, which owes its colour to the presence of ultramicroscopic particles of the metal. Colloid chemistry has an important bearing, too, on agricultural chemistry. Many of the properties of soils—for example, permeability, absorptive power, and moisture content—depend more on the size of the constituent particles than on their chemical composition. The retention by the soil particles of materials of nutritive value for plants is closely related to the phenomenon of adsorption already discussed. Colloids are of importance further in connection with the pottery trade. Highly plastic clays behave like colloids, and the treatment of clay with a colloid, such as tannin, notably increases the plasticity of the material.

Reference has been made above to the protective action of emulsion colloids, and this phenomenon is of frequent occurrence. The presence of such colloids, generally and vaguely referred to as 'organic matter,' may altogether prevent the flocculation and precipitation of insoluble compounds. In presence of gelatin, for example, silver nitrate gives with sodium chloride only an opalescence which is not altered by filtration. This is a fact of the greatest importance in connection with photographic emulsions. Closely related to this phenomenon is the use of glues and gums as retarders in the setting of plaster of Paris, and the inclusion of such materials in mixtures which have for their object the prevention of scale in boilers. Detailed references to the bearing of colloid chemistry on technical problems will be found in a monograph, *Die Bedeutung der Kolloide für die Technik* (Dresden, 1909), by K. Arndt, and in a paper on Colloid Chemistry and some of its Technical Aspects, by J. Alexander (J. Soc. Chem. Ind. 1909, 28, 280). J. C. P.

COLLOTYPE v. PHOTOGRAPHY.

COLOCYNTH. *Bitter apple.* (*Coloquinte*, Fr.; *Koloquinthe*, Ger.)

The fruit, peeled, dried, and freed from seeds, of the *Citrullus Colocynthis* (Schrader), a climbing plant of the gourd family, inhabiting the warm dry districts of the Old World—India, Persia, Arabia, Syria, and the African and European shores of the Mediterranean. (Cf. Bentl. a. Trim. 114.)

Colocynth was well known to Greek, Roman, and Arabian medicine, and in the form of solid extract enters into many of the purgative pills of modern pharmacy. It was chemically examined early in the last century, amongst others by Braconnot (Journ. de Phys. 84, 338); Vauquelin (J. Pharm. Chim. 10, 416); Herberger (Rep. Pharm. 35, 368); Bostiek (Pharm. J. 10, 289); and Meissner (Pereira, Mat. Med. 3rd ed. 2, 1737). It was, however, Walz, in 1858, who first isolated an active constituent, *colocynthin*, from the drug (Arch. Pharm. 96, 241; 99, 338; J. 1858, 531; 1861, 757). The alcoholic extract is treated with water, the aqueous solution precipitated by lead acetate and sub-acetate, and the clear liquid thus obtained, after being freed from lead by sulphuretted hydrogen, is precipitated by tannic acid. The precipitate dissolved in alcohol is freed from tannic acid by treatment with basic lead acetate, and the crude *colocynthin* thus obtained is finally purified by washing with ether. (Cf. Lebourdais, Ann. Chim. Phys. [3] 24, 58) and Henke Arch. Pharm. 221, 200.)

Colocynthin is a sticky mass, brittle when dry (Henke), is indistinctly crystalline (Walz). It has an intensely bitter taste, and acts as a drastic purgative. Walz assigns to it the formula $C_{56}H_{84}O_{23}$. Water and alcohol dissolve it, but it is insoluble in ether, chloroform, and most other solvents. Yield from the drug 0.6 p.c. (Henke). The aqueous extract reduces Fehling's solution. With concentrated acids, *colocynthin* gives colour reactions: with sulphuric acid, deep red; nitric acid, bright red; hydrochloric acid, bright yellow. According to Walz, *colocynthin* is a glucoside breaking up by treatment with dilute acids into glucose and a resinous product *colocynthein*. Johansson (Zeitsch. anal. Chem. 24, 154) also states that *colocynthin*, heated with dilute sulphuric acid, yields *colocynthein* together with elaterin and bryonin, and he describes colour reactions by which these products may be distinguished. Walz also obtained from the alcoholic extract of *colocynth* a crystalline substance, insoluble in water but soluble in ether, which he named *colocynthinin*.

Naylor and Chappel (Pharm. J. 79, 117) have prepared from the fruit of *Cucumis trigonus* (Roxb.) or pseudo-colocynth, a plant indigenous to India, a principle identical with or nearly related to *colocynthin* from *Citrullus Colocynthis*, and find that on hydrolysis it yields, amongst other products, *colocynthein*, elaterin, and dextrose. The same authors, by a modification of Henke's method, obtained *colocynthin* from *Citrullus Colocynthis* in a crystalline form.

Power and Moore (Chem. Soc. Trans. 97, 99) have cast doubt on the existence of the *colocynthin* and *colocynthinin* of previous investigators. In their research the pulp of the

fruit was examined separately from the seeds, and the following substances were isolated: *citrullol*, a dihydric alcohol $C_{22}H_{36}O_2(OH)_2$, m.p. 285° - 290° , yielding a diacetyl derivative, melting at 167° ; an amorphous alkaloidal substance possessing an extremely bitter taste and representing one of the purgative principles of the fruit; α -elaterin (see ELATERIUM); a small amount of hentriacontane $C_{31}H_{64}$, m.p. 68° ; a phytosterol $C_{27}H_{46}O$; and a mixture of fatty acids. The seeds, which represent 75.5 p.c. of the peeled fruit, were found to contain traces of an alkaloidal principle, a small amount of an enzyme hydrolysing β -glucosides, and fatty oil. The proportion of glucosidal substance in the fruit is found to be very small. The purgative action depends on at least two compounds, one of which is alkaloidal. After removal of the alkaloidal compound, the fruit still possesses marked purgative properties, but the substance to which these are due has not yet been obtained in a definite form.

It has been sometimes required to search for colocynth in beer (v. Dragendorff, Chem. Zentr. 1881, 285, 299). A. S.

COLOPTENE v. RESINS.

CHROMIMETERS, CHROMOMETERS, or **CHROMATIMETERS.** Under this heading are included those instruments (*colorimeters*) which are used for determining the relative intensity of colour in solutions, and those (*chromatimeters*, *tintometers*) which are used to obtain a numerical record of the hue and intensity of a colour.

Colorimetric measurements depend on obtaining equal intensity of colour in two columns of liquid, one of which contains a known amount of the substance to be estimated. This can be done either (a) by varying the concentration of one liquid, keeping the lengths of columns equal, or (b) by altering the length of one column, keeping the concentration the same.

The first method is used in Nessler's test, in Eggertz' method of estimating carbon in steel, and in the simple colorimeter of the U.S. Geological Survey (Bulletin 422). It is applicable to all colorimetric measurements. The second principle is adopted in most cases because it allows the repeated use of the standard solution and facilitates rapid work. In certain cases, however, e.g. in comparing manganese solutions, this method fails, as varying the length of column changes the hue as well as the intensity of the colour.

The standard used may be of the same composition as the liquid under examination, or may be made of any suitable materials, but its colour must be identical in quality with that of the liquid tested, and its value per unit volume in terms of the substance estimated must be accurately known. Thus the permanent standards used in the estimation of combined carbon in steel are generally made of mixed solutions of metallic salts, and in the estimation of ammonia in water a solution coloured with caramel and a little aniline red has been used (Leeds, Chem. News, 37, 229).

Equality of tint having been obtained, the lengths of the columns are noted, and the com-

parison is repeated, using, preferably, a different length of column of the standard.

The relative strength of the solutions varies inversely as the lengths of the columns, so that if 1 c.c. of the standard solution correspond with x parts by weight of the substance estimated, the weight of that substance in 1 c.c. of the test solution will be

$$\frac{\text{length of column of standard solution} \times x}{\text{length of column of test solution}}$$

If the strength of the standard differ by more than 10 p.c. from that of the test liquid, it is advisable to dilute one or other before comparison.

For the examination of precipitates, a solution of considerable suspensory power is prepared by dissolving 100 grams of gelatine, 100 grams glacial acetic acid, and 1 gram of salicylic acid (to prevent decomposition of the gelatine by keeping) in 1 litre of distilled water.

The solution is clarified with white of egg and filtered hot. For estimation of sulphuric acid, this solution is charged with barium chloride, and is added to a weak standard solution of sulphuric acid or a sulphate and to the solution to be tested, the two turbid liquids being then compared as above. By the use of other reagents, lime, zinc, and a large number of other substances may be estimated.

A useful colorimeter for general purposes, devised by Mills, is shown in Fig. 1. It consists of a glass jar closed above by a cap of which the length is sufficient to cover the top of the liquid. The cap is perforated in the middle and carries a short tube in which slides a glass rod bent as shown, and supporting, exactly at right angles to the axis of the jar, a flat circular opaque white disc. In the bottom of the jar are laid, one above another, a red and a green glass disc which form a black background to the white disc. When examining solutions of certain colours, a background of a colour other than black may be advantageous, and the white disc itself may be covered by a coloured plate. The white disc is lowered to the bottom of the jar by moving its rod, and the jar is filled to exactly 100 divisions with a standard liquid.

The white disc is raised until, on looking vertically down through the liquid at the disc, the depth of tint appears suitable. A second apparatus is then filled to 100 divisions with the liquid to be tested, and its disc is adjusted until the colours of the columns of liquid in the two jars appear of equal intensity.

By placing on the white disc a small, black, hemispherical button, this instrument may be used for determining the strength of turbid solutions, such as milk, or for ascertaining the

FIG. 1.

amount of a precipitate suspended in a liquid. Milk is diluted before examination with 99 parts of water, and is compared with a similarly diluted milk of known quality, the disc with the button being adjusted in each tube as above until just invisible.

The slight alteration in the level of the liquid caused by the varying length of the sliding tube contained in the liquid when adjusting the height of the white disc is found by experiment, and a correction must be introduced into the calculation for variations of more than two or three divisions.

A very useful colorimeter, especially designed for the estimation of carbon in steel, but of course available for other purposes, has been introduced by Stead (Proc. Iron and Steel Inst. 1883, No. 1, 213). A similar, but more convenient apparatus, devised by Ridsdale (J. Soc. Chem. Ind. 1886, 586) is shown in Fig. 2. Three glass tubes, each fitted below with a small,

the outer tubes are drawn out and pass through indiarubber corks into ruby glass bottles, containing standard solutions of different strengths. Each bottle has a tube with a stopcock through which the liquid may be introduced or removed, and each is connected by a flexible tube with a syringe.

The liquid under examination is introduced into the central tube, and by working the syringes the standard solutions are raised in their tubes until the intensity of colour in each tube, as seen by looking into the mirror which is adjusted to reflect the light passing upwards through the tubes, is identical. Two distinct comparisons are thus simultaneously made, and, by noting the height of each column by means of the sliding pointer, the strength of the tested liquid may be ascertained from the formula already given. A very important advantage of this apparatus is that every part except the central tube is cleaned and recharged without disconnection.

Ridsdale (J. Soc. Chem. Ind. 1888, 70) has devised an apparatus for the examination of liquids of deeper tint than can be used in the foregoing apparatus. The central upper tube (Fig. 3) is sealed below, the upper side tubes are perforated at the bottom. Each tube contains a loose white opaque plug, and each is held at

FIG. 2.

opaque, white cylinder, are placed beneath a movable mirror, in a stand which may be turned to any position upon its weighted base. The central tube is removable and is closed below;

FIG. 3.

any height by a movable jaw pressed against it by an indiarubber band.

The centre tube is charged with, say, 10 divisions of the standard solution, and the test

liquid is run into one of the side tubes, whence it passes at once into the lower tube. When this is nearly filled, it is gradually raised to bring a portion of its contents into the upper tube, until, on looking down vertically, the colours in the upper side tube and in the standard tube are of equal intensity. The calculation is made as already described. The lower tube beneath the standard tube must be raised with that of the side tube in order to equalise the effect of the double thickness of glass. When the solutions to be tested differ widely in tint, the standard tube may be perforated so that the length of its column may be readily adjusted.

Stokes' apparatus (Chem. Soc. Proc. 1887, 135) has two tubes placed vertically in a stand with a reflector below. One tube is connected with a reservoir of the standard solution, by raising or lowering which the level of liquid in the tube can be altered.

A similar arrangement is used in Le Docte's colorimeter (Eng. Pat. 20667, 1898).

The Kennicott-Sargent colorimeter (Chem. Engineer, 1907, 213) differs from the above only in altering the level of the standard liquid by moving a glass plunger in a fixed cylindrical reservoir.

Another arrangement, in which the standard liquid is forced into a graduated tube from a reservoir, is described by Günsberg (Dingl. poly. J. 228, 457).

The Nesslerising tubes adopted by Hehner (Chem. News, 33, 185) and recommended by Milne (J. Soc. Chem. Ind. 1887, 33) are two cylinders of equal and perfectly uniform diameter, holding about 100 c.c. Each is graduated from below, and at about the 30 c.c. division has a glass stopcock.

The two cylinders are placed side by side on white paper, and to one of them is added 100 c.c. of the liquid to be tested, followed by 2 c.c. of Nessler's solution. To the other tube a suitable and known amount of standard solution of ammonium chloride is added, and the volume is made up to 100 c.c. with distilled water, after which 2 c.c. of Nessler's solution is added. The two liquids are looked at *vertically*, and the darker is allowed to slowly run off into a clean beaker, until their colours are equal. The comparison may be repeated after filling up from the beaker. The mode of calculation is the same as in former cases.

A modified form of Eggertz tube has been described by Hogg (J. Soc. Chem. Ind. 1895, 1022).

In a colorimeter devised by Leeds (Chem. News, 37, 229) comparison tubes are arranged in a rack, light being reflected through them by an inclined upper mirror, and again reflected to the eye of the observer from a mirror similarly placed beneath them. The standard liquid is contained in a bottle prism which is moved beneath one of the comparison tubes containing distilled water only until the colour observed is identical with that in the tube containing the test liquid. The strength of the test liquid is calculated from the thickness of liquid in that section of the prism which is interposed.

Gallenkamp's colorimeter (Chem. Zeit. Rep. 1891, 324) consists of two vertical troughs enclosed in a metal frame. That which contains

the standard solution is wedge-shaped, while that for the test liquid is rectangular. An observation apparatus, moving vertically over a scale of 100 parts, has two slits at the same level, one opposite each trough, the light from which is reflected and brought into one eyepiece. The observation consists in finding the thickness of the stratum of standard solution in the prism, which shows the same depth of colour as the test liquid.

White's apparatus differs from the above in having two wedge-shaped tanks, both movable with reference to two fixed slits through which the depth of colour is observed.

A colorimeter, described by Autenrieth and Koenigsberger (Chem. Zentr. 1910, i. 2032) and recommended especially for the determination of hæmatine in blood, depends on comparison of the test liquid with a stable solution of similar hue contained in a wedge-shaped reservoir which is movable vertically beside the trough containing the test liquid. The movement of the wedge is measured on a millimetre scale, and the reading translated directly into percentages by reference to a plotted curve. The two colours are observed through a Helmholtz 'Doppelplatte,' which obviates a dividing space in the field of view. By substituting a suitable wedge, the instrument can also be used for the estimation of titanium, iron, chromium, iodine, ammonia, nitric acid, &c.

Schreiner's colorimeter (J. Amer. Chem. Soc. 1905, 1192) consists essentially of two parts: a

FIG. 4.

wide flat-ended immersion tube A, about 26 cm. \times 3 cm., graduated in millimetres, and the flat-ended immersion tube B, about 26 cm. \times 2 cm., which slides inside the wider tube. Two such pairs of tubes are mounted on a stand (Fig. 4), the inner tubes being fixed to the top of the camera while the outer tubes are held in brass clips which keep them in position, but permit their being moved up and down. The length of the column of liquid enclosed between the ends of the outer and inner tubes can thus be adjusted at will. Light, reflected from a white surface D, passes through the two columns of liquid, and is then reflected at a mirror E to the observer's eyes at F. The axes of the tubes are inclined to one another so as to bring the images close together. Standard glass slides may be inserted at G

in place of one of the wide tubes, the immersion tube being left in position.

Patterson has described (J. Soc. Chem. Ind. 1890, 36) a more complex apparatus employing the same principle. In this case the adjustment of the concentric tubes is made by rack and pinion, and total reflection prisms are employed to bring the two images into one eyepiece. By substituting a direct-vision spectroscope for the eyepiece, the apparatus becomes a *spectrum absorptimeter*.

The simple and effective colorimeter devised by Steiger (J. Amer. Chem. Soc. 1908, 215) consists of two wooden boxes painted dead-black inside, one of which (Fig. 5A) is mounted on a

FIG. 5A.

stand and has a rectangular opening *c* in the base, while the second box (Fig. 5B) fits into the

FIG. 5B.

stand, and has a rectangular opening, *E*, which coincides with *c*.

In the base of this box are two grooves in which slide two rectangular glass cells *K, K*, about 15 cm. long \times 2.5 cm. wide \times 5 cm. deep.

Fixed vertically over the opening *E* are two glass rods *F, F*, held in place by the springs *R, R*, each carrying at the lower end a small plane mirror, *G*, fixed at angle of 45°. Light coming through the ground-glass *A* is reflected by a mirror, *B*, through the aperture *E* into the tank, where it is again reflected at the mirror *G* and passes through a column of liquid, the length of

which can be altered by moving the tank backwards and forwards. When equality of colour is obtained, the lengths of the columns are read off on millimetre scales engraved on the base of each tank. The reading is taken where the lower edge of the mirror touches the bottom of the tank.

Otto's *ozonometer* has two parallel tubes for gases or liquids, and employs wedges of coloured glass moving over a graduated scale as a means of measuring the depth of tint (Eng. Pat. 17524, 1898).

H. Krüss suggests (Zeitsch. anorg. Chem. 5, 325) the application to colorimeters of the Lummer-Brodhun double prism, which gives a field of view in which there is no visible line of separation between the two colours under observation. This condition gives maximum accuracy in matching the colours (see also Chem. Soc. Abstr. 1894, ii. 158).

Andrieux (Compt. rend. 103, 281) describes an apparatus in which the *quality* and *intensity* of a colour are determined by comparison with a ray of polarised light.

An apparatus has been described by Meising (Zeitsch. anal. Chem. 1904, 137), in which the hue is matched by the colour of a quartz plate in polarised light, and the intensity is measured by varying the length of the column of liquid.

An ingenious instrument, introduced by Mr. J. W. Lovibond, for the examination of liquids, powders, fabrics, &c., and known as the *tintometer*, is shown, partly in section, in Fig. 6. It consists of a box, closed at one end by a ground-

FIG. 6.

glass plate, *e*, and separated into two divisions *b, c*. The box is carried by a stand, adjustable to any angle. A square glass cell, of known width, along the line *g'g'*, containing the solution to be examined, is placed in one division, and glass plates *h* of similar colour (or, if necessary, of different colours, producing the proper tint in combination), and of known intensity, are placed in grooves in the other division, until, on looking through both tubes simultaneously through a single eyepiece, *d*, shaded to prevent access of side light to the eye, the appearance through the glass plates is identical with that through the solution.

The standard plates are specially prepared of various colours, and each is distinguished by a number indicating its *colour*, and another number showing the *intensity* of colour, *i.e.* the number of plates of that colour of unit intensity required to produce an intensity equal to that of the plate. The unit chosen by the inventor for each colour is an arbitrary one, but its actual value can be ascertained at any time by comparison with a standard solution of similar colour.

In some cases the glass plate *e* is wanting, and an adjustable plane glass mirror is used to reflect the light to the apparatus (Eng. Pat. 12867, 1886).

When the colour of a fabric is to be estimated, the fabric is stretched on a block placed in the

division *c*, and a white fabric of *similar texture*, previously compared with a plate of pure *plaster of Paris*, is placed in the division *b*. The standard plates are then inserted as above until the appearances through the eyepiece are identical. *Powders, sugars, &c.*, pressed in a small tray placed in the division *c*, may be similarly examined, a tray containing pure plaster of Paris being placed in the division *b* (J. Soc. Chem. Ind. 1888, 234).

For very delicate observations, the intensity of the light used may be found and noted, before commencing, by closing the division *c* and placing in the divisions *b* as many standard plates of *neutral tint* as serve to obstruct all the light.

The substitution of a movable wedge of coloured glass for the standard plates makes the apparatus available for ordinary colorimetric determinations (J. Soc. Chem. Ind. 1888, 234). An improved form of Lovibond's apparatus is binocular, and has a movable diaphragm. This makes it applicable to tests of colour vision (*ibid.* 1891, 489) (*see also* Lovibond, *ibid.* 1909, 500).

Procter has described (*ibid.* 1895, 123) a modified form of tintometer in which, by a system of mirrors, the colours to be compared are brought close together in the field of view, thus giving greater accuracy.

Szczepanik (Eng. Pat. 22995, 1907) has patented an ingenious apparatus with which a numerical record of any colour can be obtained. Three strata of liquid of the three primary colours are superimposed. The thickness of each stratum can be measured and altered independently of the others, and thus any hue or intensity of colour can be matched.

Gardner and Dufon have introduced the 'Dalite' lamp, which gives a light of the quality of daylight, and may be used for tintometric work (J. Soc. Chem. Ind. 1904, 598). This lamp is also of use in performing titrations by artificial light.

A useful device, introduced by Dupré (Analyst, 5, 123), may be mentioned under this heading. In the volumetric estimation of silver with potassium chromate as an indicator, especially when the solution is weak, it is somewhat difficult, on account of the original yellow colour of the solution, to observe the first tinge of red produced by the formation of the silver chromate. Dupré interposes, between the eye and the test liquid, a flat glass cell (of which the faces are about half an inch apart) containing a solution of potassium chromate of such strength as will neutralise the colour of the test liquid, which thus appears perfectly colourless, and in which the faintest appearance of red is readily visible. The cell filled with other liquid may be similarly adopted in many other titrations.

König (Proc. Amer. Phil. Soc. [18] 7, 29, 184, 208, 211) has devised a method for estimating metals by the intensity of the colour imparted by them to the borax bead. He dissolves a known weight of the oxide in a known weight of borax, grinds the bead until its faces are flat, coats it with Canada balsam to render its rough faces transparent, and places it in an apparatus where it is viewed by a lens of small power, while, by means of a rack, a glass prism whose colour is complementary to that under examination, is

moved before it until such a thickness is interposed that the colour of the bead is extinguished.

A photochemical process for estimating differences in the intensity of a colour has been described by E. J. Mills and Buchanan (J. Soc. Chem. Ind. 1888, 309). It has been applied to the comparison of dyed goods. A number of discs of the tissues are photographed on one negative from which a number of positives on paper sensitised with silver, are copied. These are treated as usual, soaked for a considerable time in sodium thiosulphate to remove the whole of the unaltered silver salt, well washed, and dried. The disc photographs of each tissue are cut from a number of positives and each set is burned separately. The silver in the residue is dissolved and estimated volumetrically. The relative amount of silver found in the different sets of discs directly represents the relative intensity of the colours.

The following colorimetric process for the estimation of minute quantities of sulphur in iron, mineral waters, black ash, slag, &c., is due to Wiborgh (Chem. Zeit. 10, 92; Chem. News, 1886, 54, 158).

The divided metal, ore, &c., or the concentrated solution, is introduced into a small flask provided with an indiarubber cork, through which passes a stoppered funnel for introduction of acid, and a narrow-mouthed funnel ground at the top. A disc of white calico, which has been previously saturated with a solution of 5 grams crystallised *cadmium nitrate* (or, preferably, *cadmium acetate*) in 100 c.c. of water and dried in a horizontal position on a cloth, is fixed between two indiarubber rings of the same interior diameters as the standard discs hereafter described, and the rings are firmly clamped over the funnel mouth. Dilute sulphuric acid is poured into the flask and heat is applied. In from 30 to 45 minutes the whole of the sulphur which is capable of conversion into sulphuretted hydrogen has passed off in that form and has been *wholly* absorbed by the cadmium salt on the calico. The disc is removed and compared with a set of standard discs, similarly prepared from iron containing a known amount of sulphur. The standard discs should not be exposed too freely to light. Arsenic, carbon silicon, and copper do not appear to affect the determination. This method is so delicate that a disc will show a tinge of the yellow colour due to the cadmium sulphide when so small a quantity as the 1000th of a milligram of sulphur is present per square centimetre.

COLUMBA or **COLUMBO**; **COLUMBIC ACID** and **COLUMBIN** *v.* **CALUMBA**.

COLUMBIA BLACK, **-BLUE**, **-GREEN** *v.* **AZO-COLOURING MATTERS**.

COLUMBIA YELLOW *v.* **PRIMULINE** AND ITS DERIVATIVES.

COLUMBITE. A columbate (niobate) of iron, usually containing some manganese and tantalum, the general formula being

With an increase in the amount of tantalum, there is a transition to the isomorphous species, *tantalite* (*q.v.*). The orthorhombic crystals are dark brown or black and opaque, and range in sp.gr. from 5.3 (columbite) to 7.3 (tantalite). It was in this mineral that C. Hatchett discovered, in 1802, the element columbium, so

named because the specimen he examined came from America. Columbium is found as single crystals embedded in pegmatite at Haddam in Connecticut, Chesterfield in Massachusetts, Moss in Norway, &c.

L. J. S.

COLUMBIUM (*Niobium*). Sym. Cb. At. wt. 93.5 (Balke and Smith). Although this metal is still commonly termed niobium by the mineralogist and the metallurgist, the name columbium, which was given to it in 1802 by Hatchett, who first isolated it in the form of a new 'earth' (Cb_2O_5) from a mineral found in Connecticut, has been officially adopted by the chemist in English-speaking countries, and generally throughout the world, except, perhaps, in Germany.

Columbium is a member of a group of comparatively rare metals, including tantalum, tungsten, molybdenum, titanium, and uranium, commonly occurring together in minerals found in the oldest Plutonic rocks and especially in and around intrusions which traverse pegmatites and other extremely coarse-grained granite rocks. Monazite, and other minerals containing metals of the cerium group, zircon, cryolite, and fluorspar, and minerals containing lithium, caesium, and rubidium, are often associated with these minerals, and are probably intimately connected with their genesis.

Although an extremely rare metal, columbium exists as the pentoxide in a considerable number of minerals, in some of which—such as pyrochlore and columbite—it may be regarded as the essential constituent, while, in others, although practically always present, its proportion varies from a mere trace up to an amount which justifies its being considered as the principal oxide.

Columbium occurs in minerals only as the pentoxide Cb_2O_5 , in combination with a base, the columbium in the few minerals (such as wöhlerite) which contain silica, being present as a silico-columbate, and never as a silicate of columbium.

A list of thirty or forty minerals in which columbium is commonly found in association with tantalum might be given, but the principal will be given in the article TANTALUM, with which metal columbium invariably occurs in nature. From the technical point of view, the principal columbium minerals are those which consist essentially of columbates of iron, manganese, and lime, zirconia and metals of the cerium group being also usually present in, or at any rate intimately associated with, such minerals as contain lime.

The mineral richest in columbium is *pyrochlore*, a columbate of lime containing titanium, cerium, and thorium, together with other alkaline earths and alkali bases and some fluorine. The most important mineral, however, is the columbate of iron and manganese known as *columbite* or *niobite*, in which the Cb_2O_5 may even exceed 78 p.c., a condition nearly reached by certain specimens occurring in the cryolite of Arsukfiord (Greenland).

The columbium is always partly replaced by tantalum, the proportion of which may vary from a trace through all gradations, until the mineral merges into tantalite which is isomorphous with columbite, and which occurs in much larger quantity and furnishes the bulk of the tantalum

of commerce and, as a by-product, of the columbium. These two minerals are found in alluvial deposits with cassiterite and wolfram, and in isolated masses left by the denudation of intrusions in pegmatites, &c., at Greenbushes and elsewhere in Western Australia, in Colorado (Cañon City), Dakota (Black Hills), North Carolina and other districts of the United States, and in Sweden, Norway, Greenland, and many other districts. They may be considered to possess the general formula $(FeMn)O(CbTa)_2O_5$, the relative proportions of ferrous and manganese oxides varying within extremely wide limits.

New deposits are constantly being discovered, and columbium, like many others of the rare metals for which a demand now exists, will doubtless be found to occur in much larger quantities than is generally believed.

Amounts, far in excess of present requirements, are obtainable as by-products from the preparation of the rare earths employed for incandescent mantles, from tin and wolfram ores, and from the heavy waste material obtained in the dressing of cryolite.

Metallic columbium may be prepared by passing a mixture of the vapour of the pentachloride and hydrogen through a red-hot tube (Roscoe); in a less pure condition, by heating the pentoxide with carbon in the electric furnace (Moissan); by the aluminothermic process, and by the method of von Bolton, introduced with a view to the manufacture of metal filament lamps, before tantalum came into use. In this process, the pentoxide is mixed with paraffin and formed into threads which are heated *in vacuo* to a temperature of over 1900° by passage of an electric current.

By the aluminothermic reaction, von Bolton has obtained columbium containing about 3 p.c. of aluminium which can be driven off with other impurities by prolonged heating *in vacuo* in the electric furnace. The purest columbium hitherto prepared in bulk is said to have been thus obtained. Like tantalum, it can also be obtained by reduction of the fluoride K_2CbF_6 with potassium, as a black powder from which the residual hydrogen may be expelled by shaping it into small cylinders and melting *in vacuo* in an electric furnace.

Although the most important use of tantalum is for manufacture of electric lamps, in which case it requires to be separated from columbium, the amount actually consumed for the purpose is extremely small. The standard tantalum lamp, introduced in 1904, contained only one twenty-thousandth of a pound of tantalum, and those now manufactured contain much less.

The method employed for the separation of columbium from tantalum in the preparation of the latter element for electric lamp filaments probably depends essentially upon a fractional crystallisation of the mixed double fluorides of potassium with tantalum, columbium, and titanium.

There is reason to think that the peculiar virtues imparted to steel by tantalum, in common with tungsten, molybdenum, vanadium, uranium, and zirconium, will result in a larger demand for tantalum, and this property is shared by columbium. The ferro-tantalum at present

manufactured for this purpose is prepared from tantalite containing columbium by direct smelting in the electric furnace, and contains much of the latter metal, no attempt being made to separate it.

Similarly, should the suggested use of tantalum in place of steel for surgical, dental, and other purposes, or in the manufacture of acid- and alkali-resisting utensils, be found practicable, it is possible that the alloy prepared from the mixed tantalum and columbic acids obtained from minerals containing both, may be as suitable as either metal alone.

Metallic columbium melts at 1950°, and has a sp.gr. of 12.7, and an electrical resistance of 0.1870 ohm for a wire 1 metre long by 1 mm. diameter. It is less malleable or ductile than tantalum, but the rolled metal has a hardness greater than that of wrought iron, and may be welded at a red heat.

Although the powdered metal oxidises rapidly when heated in air, the rolled or cast metal is but little affected, as a protective coating of oxide rapidly forms. It is practically unaffected by any acid except hydrofluoric acid, or by solution of the alkalis, but is rapidly attacked by fused alkalis or alkaline nitrates.

It combines with carbon when heated, and at dull redness rapidly absorbs hydrogen or nitrogen and becomes brittle, the hydride and nitride respectively being apparently formed.

It reacts violently when heated with sulphur or selenium, and forms the volatile pentachloride when heated to redness in chlorine.

It does not form an amalgam with mercury, but alloys with many other metals and in all proportions with iron.

The compounds of columbium have not yet been applied commercially, but the pentoxide, generally known as columbic acid, and the fluorides, especially the double fluoride with potassium $2KF \cdot CbF_6$, are of interest in connection with the preparation of the pure compounds or metal from minerals. G. T. H.

CONDENSERS. A condenser is an apparatus in which the vapour of a liquid may be cooled down to a temperature below that at which it is converted into the liquid state under the prevailing pressure. The condensation of the vapour is usually effected by bringing it into contact with a cold surface, to which it imparts its heat, suitable arrangement being made for conveying away this heat from the cooling surface. Although air cooling is sometimes depended upon for this latter purpose, the arrangement usually adopted consists in causing a stream of cold liquid (water in the majority of cases) to circulate over the exterior of the condensing chamber. The following points should be considered in the designing of an efficient condenser:—

(a) The cooling surface must be made of material upon which the vapour has no chemical action, and should be capable of withstanding repeated variations of temperature without fracture.

(b) The area of cooling surface should be as

great as possible, without making the apparatus unduly large and heavy.

(c) The material should preferably have a high specific heat, so that its rise in temperature may be kept within reasonable limits; and it should have a high thermal conductivity, in order that the heat it absorbs may be rapidly carried away.

(d) The design should be such as to admit of the condenser being readily cleansed.

It is not possible to obtain materials entirely satisfactory in each of the above respects, and so in practice the materials employed are those which combine cheapness with reasonable satisfaction in the foregoing particulars. For laboratory apparatus, the material commonly used is glass; metals (block tin, copper, &c.) are less often employed, except for constructing fairly large pieces of apparatus; of recent years, silica has found a limited use.

Condensers are used in two different kinds of operations: (1) for condensing vapours in distillation processes, in which case a still is attached to the upper end and a suitable receiver to the lower end; and (2) as 'reflux' apparatus in cases where it is necessary to boil a liquid for some time without sensible loss through evaporation; the vessel containing the boiling liquid is then attached to the lower end of the condenser and the condensed vapours flow back into the vessel. A number of condensers described below are specially designed for this purpose.

The simplest type of condenser is the familiar form devised by Weigel in 1771, but usually known as Liebig's condenser. It consists simply of a straight cylindrical glass tube, in which the vapour is condensed. The upper end is widened out slightly to facilitate connection with the still, and its lower end is cut off obliquely: a cylindrical glass jacket is slipped over the greater portion of the length of the tube, and through it, by appropriate entrance and exit tubes, cold water is circulated in an upward direction, so that the vapours passing down the inner condenser tube encounter a surface the temperature of which continuously falls in the direction of the receiver. This type of condenser admits of considerable variation and modification in the precise details of construction; thus, with a view to exposing a large cooling surface, the portion of the condenser within the jacket is sometimes made of approximately rectangular section, thus

 being broadened considerably

in one direction; in other condensers the central portion carries a series of bulbs blown on it. Cooling surface is obtained in some condensers by replacing the central portion by a closely wound glass spiral, as in Fig. 1, the water-jacket being sealed on to the condenser proper. The modified Liebig condenser, shown in Fig. 2 (Chem. Zeit. 1902, 26, 633) is arranged for use with the two limbs *a* and *c* of the inner U-tube

FIG. 1.

on the same level to prevent accumulation of liquid at *b*. The inner tube is fused into the outer tube at *d*,

Glass condensers with water-jackets sealed on are restricted in their use to the condensation of the vapours of liquids of fairly low boiling-point (below 100°), since otherwise the glass

FIG. 2.

joints are liable to crack. For liquids of moderately high boiling-point (140° - 200°), it usually suffices to employ merely the inner tube of a Liebig condenser (air condenser).

In the reflux condensers illustrated in Figs. 3 and 4 (J. Soc. Chem. Ind. 1897, 16, 979) the relative positions of the vapour and cooling stream of water are reversed, the water entering as shown by the arrows (at *a* in Fig. 3). A large area of exposed surface is obtained in these condensers, which, it will be observed, are of the 'double-surface' type, since, in addition to the inner water-cooled surface, condensation also occurs on the outer surface, which exposes an even larger area to the cooling action of the air.

Several vertical condensers have been devised by Friedrichs in which one of the two surfaces between which the vapours condense is constructed spirally (Zeitsch. angew. Chem. 1910, 23, 2425).

A number of extremely useful, compact condensers of the 'double-surface' type have been

FIG. 3.

FIG. 4.

FIG. 5.

described. The vapours are condensed in the annular space between two surfaces, both of which are water-cooled, the design being such that one stream of water flows in succession over each. The efficiency of this cooling process is so great that these condensers can be made quite short; they are readily fixed in a vertical position and occupy little bench space.

In the Burgess condenser (J. Soc. Chem. Ind. 1905, 24, 1190), the tubes *a* and *c* (Fig. 5) are the cooling jackets, and *b* is the condensing tube

proper. Cribb's condenser (Fig. 6) consists of two concentric tubes joined together at the top; condensation is effected in the interior chamber thus formed. Water is conveyed into the inner tube by the tube *a*; overflowing, it passes round the exterior of the outer tube and flows away by the side tube *b*. The vapour is led in through the inlet tube *c*.

Another double-surface condenser of simple construction is illustrated in ANALYSIS (Vol. I. p. 209).

The condensers illustrated in Figs. 7 and 8

FIG. 6.

FIG. 7.

FIG. 8.

have the advantage of exposing four cooling surfaces to the vapour, and may be readily cleansed when necessary by removing the inner portions with the stopper (Chem. Zentr. 1908, ii. 277).

The condensers so far described are usually constructed of glass, but occasionally metals are employed. The use of *aluminium* for the inner tube of a Liebig condenser has been advocated by Norton (J. Amer. Chem. Soc. 1897, 19, 153). Many agricultural chemists, who have to deal with numerous ammonia distillations, prefer block-tin condensers; they are constructed like inverted U-tubes, one arm (the condenser arm) being much longer than the other and carrying a water-jacket if required, while the short arm is attached to the distilling flask. A convenient method of constructing a number of such condensers in series to be cooled by one stream of water is described in J. Amer. Chem. Soc. 1906, 28, 999.

A useful metallic condenser is the 'ball' type, used on the reflux principle in numerous experiments involving extractions with volatile solvents. Soxhlet's pattern is shown in Fig. 10, while the construction of a double-surface condenser of this pattern is sufficiently indicated in Fig. 9. Storch's metallic reflux condenser is depicted and described in J. Soc. Chem. Ind. 1897, 16, 979.

The spiral (worm) type of condenser is frequently constructed of metal (copper) and enclosed in a metal tank which can be filled with cold water; these condensers find considerable use in small plants for preparing distilled water. For this latter purpose, a novel

form of condenser is described in Eng. Pat. 6916, 1905, which combines efficiency with extreme simplicity of construction. The condenser, which is placed vertically above the evaporating chamber, consists of two metallic truncated cones, the lower being open at the top, while the upper is closed by a dome-shaped

FIG. 9.

FIG. 10.

lid. The outer surface of the upper cone is cooled by a continuous stream of cold water, and condensation is effected upon its inner surface. The condensed vapour collects in the annular space between the two cones, and the water is continuously run off into large earthenware jars. Special apparatus, devised for preparing pure distilled water (so-called 'conductivity water') on a laboratory scale are described by Bousfield (Chem. Soc. Trans. 1905, 87, 740); Golding (J. Soc. Chem. Ind. 1906, 25, 678), and by Hartley, Campbell, and Poole (Chem. Soc. Trans. 1908, 93, 428).

Condensers of various designs are described in J. pr. Chem. [2] 34, 427; [2] 49, 44; Compt. rend. 118, 478; Ber. 1892, 24, 3950; 1895, 28, 2388; J. Soc. Chem. Ind. 1899, 18, 707; Chem. Zeit. 1902, 26, 325; 1904, 28, 598, 686; 1905, 29, 809; 1910, 34, 116; Bull. Soc. chim. 1904, 31, 1116; Chem. Zentr. 1906, ii, 993; and reflux condensers in Chem. Zeit. 1896, 20, 462; 1904, 28, 598; Bull. Soc. chim. 1901, 25, 476; 1908, 3, 855; Zeitsch. anal. Chem. 1901, 40, 769; Chem. Zentr. 1906, ii, 993; Chem. News, 1907, 95, 52; and J. Soc. Chem. Ind. 1908, 27, 962.

CONDURANGO. The dried bark of *Marsdenia condurango* (Nichols) (*Gonolobus condurango triana*, Reichenbach; family *Asclepiadaceae*). It is obtained from a half-climbing or prostrate shrub of Ecuador. The bark comes into commerce in quills or quilled pieces, about 10 cm. long, and rarely exceeding 2 cm. in diameter; externally brown grey, roughened, with scale like warts; internally, greyish or pale brownish-white, striate; fracture short, granular or slightly fibrous in inner layer. Taste, somewhat bitter; odour of fresh bark, aromatic.

Kubler (Arch. Pharm. 1908, 246, 620) states that the principal constituents of the bark are dextrose, other usual components of plants, the glucoside *condurangin* and a polyhydric alcohol *conduritol*. *Condurangin* $C_{40}H_{60}O_{16}$ contains two methoxyl groups, is soluble in water, alcohol, and chloroform, insoluble in ether. Dilute sulphuric acid hydrolyses it to dextrose and an amorphous powder, containing several substances; alcoholic potash yields some cinnamic acid. *Conduritol* $C_6H_{16}O_4$ crystallises from hot alcohol in colourless prisms, and yields a tribenzoyl derivative, m.p. 142°-143°. According

to Carrara (Gazz. chim. ital. 21, i, 204; 22, i, 236), commercial *condurangin* can be separated into two parts, one insoluble and the other soluble in water. The former is a white powder, $C_{20}H_{32}O_6$, m.p. 60°-61°; and the latter a yellow substance, $C_{18}H_{28}O_5$, m.p. 134°. Hager (Handbook, 1900) has further investigated these substances and named them *a*- and *b*-*condurangin*; *a*-*condurangin* gives a green colour with Froehde's reagent (conc. sulphuric acid and molybdic acid), *b*-*condurangin* does not. Carrara (l.c.) also isolated a yellow powder, $C_{30}H_{50}O_8$, which he named *conduransterin*, m.p. 52°. Flückiger has isolated a small quantity of an alkaloid having a strychnine-like action. Firbas (Pharm. J. 70, 417) treats the chloroform extract of the crude glucoside with a mixture of equal volumes of sulphuric acid, hydrochloric acid, and alcohol (Lafon's reaction). On warming, a green colour is produced, changing to bluish-green on the addition of a trace of ferric chloride. Certain other glucosides give this reaction, but they are not likely to be present in the bark.

Condurango has been employed for many years in South America as an alterative in the treatment of syphilis. It is used as a stomachic, and lessens gastric catarrh and relieves the vomiting and nausea which are usually associated with carcinoma of the stomach; it is also used to lessen the pain consequent upon gastric ailments. *Condurango* produces in large amounts incoördination of the muscles and convulsions, which may be followed by paralysis. Dose, 1 fluid drachm of the fluid extract of *condurango*, or 4 fluid drachms of the wine of *condurango*.

There are many other varieties of *condurango* and *marodenias*. The *Guayaquil condurango* has several peculiarities in the wood of the bark, and has not so many medullary rays. Mexican *condurangos* contain a strong collenchyma next to the bark, while nearer the pith is a layer of bast fibres containing large crystals of calcium oxalate (Chem. Zeit. 11, 1601; 12, 26).

- COPPER.** Sym. Cu. At. wt. 63.57. Melting-point in air, 1062°; in reducing atmosphere, 1084°. Specific gravity: Roberts Austen (Int. Study of Mct. 1902, 16) gives 8.217 as the sp. gr. of the molten metal. Copper, deposited by electrolysis from an acid solution of copper

sulphate and not subjected to any mechanical treatment. was found to have sp.gr. of 8.9544 at 15.5° in air (Watson, J. Soc. Chem. Ind. 2, 153).

Commercial copper, prepared in the usual way, is never pure, and the examination of the fractured surface of a cast ingot of copper shows a minutely vesicular structure. On this account the density of such metal is less than the same sample of metal after it has been subjected to a compressing mechanical treatment.

Colour.—Copper has a characteristic red colour which, in a fractured surface of worked metal, may be described as salmon-red. The only other metallic substance which at all resembles copper in colour is the titanium cyanonitride, which is sometimes formed in blast furnaces working on iron ores containing titanium.

Lustre.—A smooth cut or polished surface shows a bright metallic lustre which, however, soon tarnishes.

Crystalline system.—Copper crystallises in the cubical system.

Ores of copper. The following minerals are those from which copper is extracted on a commercial scale: native copper, cuprite, melanconite, malachite, azurite, chrysocolla, atacamite, chalcocite, bornite, chalcopyrite, fahl ore.

The importance of the several species in the above list as ores of copper varies very much with the locality. Thus, while native copper is the chief ore in the Lake Superior district of North America, and atacamite in one or two localities in Chile, they would in other localities, and generally, be looked upon as rather rare, especially so in the case of the last species mentioned. So also in the case of malachite; this species, as an ore of copper, is seldom met with except in small quantities in the upper and oxidised portions of some copper lodes; yet in the case of the once celebrated Burra Burra mine in Australia, and at Nischne-Tagilsk in Russia, it formed the bulk of the ore produced.

Generally, in a copper-mining district, all the oxidised species mentioned above occur in varying proportions, but as depth is attained, and almost invariably at or about the level at which water is reached, the copper-bearing minerals change and the oxidised species give place to the richer sulphide species, and these finally to chalcopyrite intimately mixed with varying proportions of pyrite. The intermingling of the two species last mentioned is frequently so intimate that it is not easy to distinguish the component minerals or to separate them. Chalcopyrite thus diluted down, as it were, with one or more of the minerals—pyrite, pyrotite, &c.—forms the ore from which the greater proportion of the world's copper supply is derived and the bulk of the material treated at the smelting works generally. Such ore frequently contains appreciable quantities of gold and silver and, almost universally, nickel, in quantities varying from traces upwards. The silver is frequently carried by intermixed fahl ore, but also, in many instances, by the pyritic mixture in which distinct silver-bearing minerals are not observable.

As by far the larger proportion of ore presented for metallurgical treatment is of the nature indicated above, viz. chalcopyrite mixed with varying quantities of the pyrite

family of minerals, it will best serve the purpose of this article if the methods adopted for the extraction of copper from this material are considered, and in the following description of processes it is to be understood that ore of this character is referred to.

The elimination of the several elements in the ore and the final production of the copper in the metallic state, are effected by two distinct series of chemical operations. One of these—the most important, because of its very general application—treats the ore by smelting, and causes the necessary reactions to take place while the material is in a molten condition. The other—of very limited application—treats the material in the wet condition, and causes the necessary reactions to take place in solutions of the material.

These two distinctly different methods of procedure may be distinguished as (a) dry methods, and (b) wet methods.

Dry method. The object which the smelter keeps in view in the first stages of the process is to concentrate the copper contained in the ore in as small a quantity of material as may be economical. For this purpose, the product known as 'matte' or 'regulus' is universally selected. This is a combination of cuprous sulphide Cu_2S and iron sulphide FeS in varying proportions, together with sulphides of such other metallic elements as are capable of entering into the molten matte. The whole of the copper contained in the ore thus passes into the matte, while the silica combines with iron oxide and earthy bases, if present, and forms the slag. The slag, free from copper, separates easily from the matte, owing to its lower specific gravity, and is thrown away. Having thus concentrated the copper into regulus, or matte, the next stage of the process concerns itself with the decomposition of this matte in such manner as to eliminate the iron and sulphur and, as far as possible, other metallic elements which may be present and to yield the copper in the metallic state.

The final process consists in refining the copper produced as above; or, in other words, removing, as far as practicable, the small quantities of such elements as may still be present in the product of the preceding operation which would injuriously affect the copper for manufacturing purposes.

The treatment of the ore involves, therefore, three distinct operations:—

I. Smelting the ore with the production of matte and slag.

II. Treatment of the matte for the production of crude copper.

III. Refining.

The methods and the plant used for carrying out each of the three operations vary considerably, and the choice of any one depends upon local conditions, the nature of the ore as regards physical character, and the nature and quantity of the foreign elements present. It will not be possible within the limits of this article to study these considerations and the bearing they may have on the methods to be adopted; all that the space will allow of is a description of the methods as actually carried out under the most generally prevailing conditions.

I. *Smelting the ore with the production of matte and slag.*—The object of this process being the concentration of the copper in the matte, the chief considerations kept in view are the production of a matte as rich in copper, and a slag as poor in copper, as is practically and economically possible.

The grade of the matte to be produced having been decided upon, the smelter regulates this by suitably proportioning the sulphur in the ore to be treated so that there shall be sufficient to form Cu_2S with all the copper, and a further proportion to form FeS with the iron present in such quantity as will cause the matte to contain the desired percentage of copper. From these considerations it will be seen that the factor which regulates the grade of the matte is the quantity of sulphur present in the ore mixture smelted. With the class of ore under consideration, it invariably happens that the quantity of sulphur present is considerably in excess of requirements, and the production of the most suitable grade of matte necessitates the removal of this excess, which may be, and generally is, effected before the actual smelting of the ore is commenced. Under certain favourable conditions, however, it may be removed during the smelting process (see *Pyritic smelting*). This preliminary operation is designated 'calcining' or 'roasting,' the former term being more often used by English smelters and the latter by Americans. It is obvious that, as it is the total sulphur in the charge to be smelted which is concerned, either the whole of the ore may be taken and a small proportion of this element removed, or a small proportion of the ore may be taken and a large quantity of the sulphur removed. A suitable mixture of this latter with raw ore, so as to give the necessary total quantity of sulphur in the mixed charge, can then be used.

Whichever course is adopted, the mode of carrying out the operation is practically the same. The process consists in subjecting the ore to a dull-red heat under oxidising conditions, so that the sulphur is caused to combine with oxygen derived from air admitted into contact with the ore with the production of sulphur dioxide, while the iron is also oxidised at the same time.

The method of carrying out this calcining process depends upon whether the ore is to be treated:

(a) In the rough—say in pieces from $\frac{3}{4}$ inch cube upwards; or

(b) Whether it is to be treated as fines or 'concentrates,' i.e. in which the particles are less than $\frac{3}{4}$ inch cube.

Under (a): *The ore may be calcined by forming heaps of it in the open air and starting the combustion by means of a small proportion of wood, the combustion being maintained by the sulphur present in the ore.*

The ore may also be calcined in stalls more or less open. These consist of series of chambers in rows built back to back. The chambers are each bounded by three walls, viz. back and two side walls, but are open in front and have no roofs. Small flues, opening out into the chambers, are built in the walls separating them, and these flues connect with a larger flue in the central division wall between the two

rows, and these again connect with a chimney stack.

The ore is charged into these open chambers on to a layer of wood; when filled up, the wood is fired and combustion extends to the ore itself in the same way as in the case of the heaps. The gases produced in the operation are to a large extent led away by the flues in the walls above referred to. The annoyance caused by the escape of these gases at or near the ground level of the works—as is the case in open-heap roasting—is in this way to a large extent avoided.

The ore may be calcined in kilns.—These are similar to the stalls, but are generally built of much larger size, are closed in on all four sides, and are roofed over. They are provided with suitable openings in the roof through which the ore is introduced, and a doorway in the front wall (bricked up when the kiln is in operation) through which the calcined ore is removed. An outlet flue, connected to the roof or back wall, allows the gases to be conveyed to a chimney.

The ore may be calcined in 'burners.'—These are constructed and worked on very much the same lines as the 'burners' used for burning 'pyrites' at sulphuric acid works, and—in the case of copper ore—are the most suitable form of plant, if the gases evolved in the operation are to be used in the chamber process of making sulphuric acid. In this plant, a number of closed cells or 'burners' are built in rows, back to back. Each cell is roofed in and connects at the back with a central flue common to all the cells, by which the gases are led to the acid chambers. In the roof of each cell is an opening through which the ore can be charged from a hopper placed above. This opening is capable of being closed and is only open during charging. In this class of plant, the ore does not rest on the floor as it does in each of the cases previously considered, but upon a series of square bars suitably spaced. These bars are formed with circular necks where they are carried by the bearers, and can be rotated by applying a box key to their square ends. Below these bars is an enclosed space with suitable door through which the calcined ore is removed and by means of which the air supply is regulated.

In operating this plant, the cell having been brought up to a good red heat by the combustion of wood or other suitable fuel, ore in small quantities is gradually added as combustion proceeds, until the burner is full. At suitable intervals, a small quantity of the calcined ore is removed from the bottom of the burner and a corresponding fresh supply of ore is added through the opening in the roof. In this way, the operation of the burner is rendered continuous, and no fresh extraneous fuel is required after the first starting of the fire. The removal of the ore at the bottom of the burner is effected by rotating, or rocking, the square bars upon which the ore rests. As the space between the bars can in this way be made to vary from the distance between the bars when

in this position , to the distance when in this position , the ore is caused to fall through in any quantity desired, and by this means, and by occasional working with long bars

through suitable holes provided for the purpose in the upper portion of the burner, the passage of the ore from top to bottom is facilitated.

In all the methods of treatment described under (a), it is essential that proper care be taken to prevent the temperature reaching anything like melting-point. If the ore melts or sinters together, calcination is delayed owing to the reduced surface on which oxidation can take place. Further, in the case of such sintered or melted material, difficulties are created in working the process. In the case of heap roasting and also in the stalls and kilns, the formation of large masses of sintered or melted ore introduces undesirable irregularities in the air current through the mass of ore under treatment, and

causes trouble when the ore is removed. In the burners, the formation of sintered masses of ore must be avoided, as such masses would have to be broken up in the burner with suitable tools before it could be made to pass out between the grate bars.

Under (b): *The ore may be calcined in hand calciners or mechanical calciners.*—The former are not much used at the present time, as the necessary labour is effectually replaced by mechanical appliances. The hand calciner, which was universally used some years ago, consisted of a long flat bedded reverberatory furnace, with the usual fire box at one end and the outlet flue for the exit of the gases at the opposite end (Figs. 1, 2, and 3). The ore was

FIGS. 1, 2, AND 3.

dropped from a hopper through an opening in the roof on to the bed at the flue end of the furnace, where it was spread out by means of suitable tools worked by men at both sides of the furnace, operating through doors in the side walls.

The conditions in the furnace were intensely oxidising, and it was necessary to stir the ore frequently to prevent it sintering. In the process of stirring, the ore was turned over and moved towards the fire end, thus making room for a fresh charge from the feed hopper. This process of stirring and moving the ore forward towards the fire end was continued until the ore reached close up to the fire box, at which point it was discharged through openings in the bed of the furnace into vaults, or chambers, constructed below, from which—when sufficiently cool—it was removed. The labour required on these furnaces was very heavy and the output small, and, except in unimportant installations,

they have given way to furnaces in which the ore is stirred, moved forward, and discharged by mechanical means operated by power. It will be impossible within the limits of this article to describe the many furnaces of this type which have been introduced, and it will suffice to describe one or two which will serve as examples of the class of plant employed.

The McDougall furnace (Fig. 4).—This is very largely used, and consists of a series of flat circular superimposed firebrick hearths, enclosed in a brick-lined cylinder of steel plate. An iron shaft passes centrally up the cylinder through openings in the several hearths, and is caused to revolve by suitable gearing attached either to its upper or lower end. This shaft may be made hollow and cooled by air or water circulation.

One or more iron arms are attached to this shaft above each bed. The arms extend from the shaft to the periphery of the circular beds,

and have attached to them a series of iron plates or ploughs set at a slight angle to the arm. The ore is fed from a hopper on to the top bed near the centre, and the angle of the ploughs is such that, as the arms revolve, they not only turn the ore over, but gradually move it from the centre to the edge of the bed. At one point in the edge of the bed is an opening through which the ore falls on to the second bed. On this bed the ploughs are so set on the arms that the ore travels in the reverse direction and is drawn to the centre of the bed. Here it discharges on to

FIG. 4.

the third bed; and so on until it escapes at the bottom of the furnace. The openings through which the ore falls from one bed to the other also serve as flues through which the gases pass upwards through the furnace, finally escaping through a flue above the top bed.

In one modification of this furnace, the flues from the fire box are built in the walls, and are so controlled by dampers that the heat can be conveyed to any one or two of the beds required.

Attached to the lowest bed is a fire box by which the furnace is heated up in order to start it; but, after being once started, little or no fuel is required, as the oxidation of the ore provides sufficient heat throughout the apparatus.

The straight-hearth mechanical furnace.—This type of furnace passes under various distinctive names, according to the several methods adopted for operating the ploughs, and slight modifications in the construction. One such furnace consists of a flat bed about 100 feet long covered with an arch. At one end is the inlet for the ore, and at the opposite end is the outlet. At the ore inlet end is the flue for carrying off the gases, and at the opposite end, but to one

side, is a fire box with the inlet to the furnace constructed in the roof of the latter. Other similar fire boxes—one or two in number—are placed at intervals along the length of the furnace. A channel is constructed in the side walls of the furnace and in these a rail is laid. A suitable carriage with wheels resting on the rails stretches from one side of the furnace to the other, and the bearings pass through slots in the two side walls and are carried by the wheels above referred to. To this carriage, suitable ploughs are attached in such manner that, in the course of its travel from one end of the furnace to the other, the ploughs turn the ore over and also move it forward. The carriage is moved by a pair of chains or ropes travelling in the channels formed in the side walls, and at the two ends of the furnace these chains or ropes are carried round wheels sufficiently large in diameter to lead them back under the furnace, thus making them continuous. One pair of these wheels is driven by suitable gearing, thus causing the pair of ropes or chains—and with them the carriage—to travel the whole length of the bed of the furnace, returning through the tunnel under the bed, where rails are laid for supporting the carriage. Two or more such carriages are attached to the ropes, or chains, at equal distances apart. The ore is fed mechanically on to the bed at intervals just as a carriage is about to enter, and the ore is spread, turned over, and moved forward gradually from one end of the furnace to the other. Each time a carriage emerges from the furnace, it draws with it a quantity of calcined ore. The carriage and its attached ploughs are cooled during the passage through the tunnel. The ends of the furnace are closed by light iron doors which hang down vertically and are automatically opened by the passage of the carriage and close themselves as soon as the carriage has passed.

There is yet another method of removing the excess sulphur which has lately been introduced, known as 'pot roasting,' or 'blast roasting.' This method of calcining is advantageously applied to concentrates and fines, and, while it eliminates the sulphur, the heat attained is at the same time sufficiently intense towards the end of the process to cause the ore to partially smelt or sinter together. In this respect it differs entirely from the methods of treatment described above. It has already been pointed out that, in the processes of calcining previously considered, the aim of the smelter is to prevent the ore particles from becoming soft and sintering together, because, under those conditions, oxidation is retarded. In the process now to be considered, however, the final result is a completely sintered mass which requires to be broken up before it can be treated in the smelting furnace. Although one or two modifications of the process have been introduced, the general method of conducting it is as follows:—A cast-iron vessel, capable of holding from 5 to 10 tons of ore mixture, is so supported that at the end of the operation it can be inverted. The usual shape of the vessel is hemispherical, and it is supported by trunnions on a framework at some few feet above the floor. Near the bottom a perforated iron plate is fitted, which is kept in place by an iron bolt passing through it and the bottom of the pot. Under the plate, air—at a

few ounces pressure—can be introduced through a pipe cast on to the pot. The top of the pot is fitted with a light iron hood, connected to the flue system for taking away the gases produced in the operation. This hood is supported in such manner as to allow of its easy removal and replacement. The pot being in the upright position, a thin layer of already calcined ore, in small lumps, is spread on the perforated plate, and upon this a light fire is started and a gentle current of air turned on.

The ore mixture, which must be quite damp, is then charged, a few shovels full at a time, and, as the fire burns up through the combustion of the sulphur, the ore is put in in gradually increasing quantities until the pot is full, the supply of air being increased as the filling up is proceeded with. When the pot is full, the hood is lowered into place, and the operation then proceeds by itself. The air current causes a rapid oxidation, and the fire gradually rises from the bottom upwards; finally, the temperature reaches the point at which slag formation commences, and the whole mass sinters together. When this stage is completed, the hood is lifted or moved away, and the pot is rotated until the sintered mass falls out on to the floor below, where it is broken up into pieces of a suitable size for the smelting operation to follow. In carrying out this process, it is essential that the ore mixture treated should contain all the necessary elements for the production of slag. Thus, for instance, if the silica content of the ore is low and not sufficient to combine with the iron oxide produced in the operation, then silica, in some form, must be added to the ore before it is charged into the pot.

After the sulphur in the ore mixture has been reduced to the requisite amount, the ore is ready to be smelted. For this operation one of two distinctly different types of furnace are used; these are:

(1) Blast furnace. (2) Reverberatory furnace.

The choice between these two methods of carrying on the smelting operation depends on a variety of circumstances, all of which must have proper consideration, but the following are the chief points, viz.: If the ore is to be smelted in the state of fines or concentrates, it is unsuitable for blast-furnace treatment, while it is eminently suitable for the reverberatory furnace. On the other hand, rough ore is unsuitable for reverberatory-furnace smelting.

Blast-furnace smelting.—The furnace used may be built of brick, but is more generally, nowadays, constructed with water-cooled walls of steel plate (Fig. 5), each section of which is termed a jacket. In the smaller furnaces the horizontal section is circular, but in the ordinary sized and larger furnaces the section is always rectangular. As the working of this type of furnace is—as its name implies—dependent upon an air blast projected into the interior, the width of the furnace is limited by the strength of the blast which is required to penetrate the charge from the sides to the centre of the furnace, while the length of the furnace is only limited by the capacity required. The increase in length is obtained by clamping together two or more of the jackets on each

side, thus extending the longer axis of the furnace.

The jackets stand on a thick cast-iron plate carried on iron supports. In some cases these jackets are only used in the lower part of the furnace, all the upper part being constructed of brick, but the brickwork may, in certain cases, be advantageously replaced with a second tier of jackets, reaching up to the feed floor. Above the feed floor the furnace is continued in the form of a covered-in brick chamber with lifting doors at each side and an outlet in the roof of the chamber, connecting, by means of a suitable iron flue, to the general flue system of the works.

FIG. 5.

Through the doors the charge, consisting of a proper mixture of ore—both raw and calcined, or partially calcined ore—is introduced. To this ore mixture there is also added such flux, either limestone or silicious material, and the necessary amount of coke as is required to form a suitable smelting mixture. As previously indicated, the object of this is to produce a matte of the desired grade and a slag which shall be as free from copper as possible and which shall be of such fusibility as to flow readily from the furnace. On the lower or working floor, the furnace is provided, either at the ends or sides, with one or more spouts through which the molten products of the smelting operation flow. Except in very large furnaces, only one such spout is used at a time, and if more than one is fitted, it is with the object of having one in reserve in case of a stoppage to the one in use.

The side jackets of the furnace are provided with circular openings (tuyères) passing from

the outer to the inner surface. When the jackets are set up, these tuyères form a horizontal line of openings on each side of the furnace. The blast is brought down from the air main by light iron piping to the tuyères, and through these it passes to the interior of the furnace.

The blast, at a pressure of 10-50 or 60 oz. per sq. inch, is generated by a suitable blowing machine, which must be of the positive, and not the fan, type. A plentiful supply of water is circulated through all the jackets, and the overflow pipes from these, carrying away the hot water, discharge into sinks or launders.

The products of the smelting operation performed in this furnace flow out through the spout above described into the settler. In the case of small furnaces, this is a square cast-iron vessel open at the top and mounted on wheels to allow of easy replacement. It is furnished with a cast-iron spout at its upper edge through which the slag overflows, and is provided with a tap hole near the bottom from which the matte is tapped from time to time. In the case of larger furnaces for this form of settler, there is substituted a circular tank, formed of steel plates lined with refractory material, placed permanently in position under the spout of the furnace. This form of settler may be 10 or more feet in diameter, and, like the smaller pattern mentioned above, is provided with a

slag spout near the top and a tap hole near the bottom.

In the settler, a thorough separation of the slag and matte takes place: the matte, having the higher specific gravity, falling to the bottom of the vessel and the lighter slag rising to the top, where it overflows through the spout into suitable pots provided for its removal to the slag dump. From time to time the matte is tapped off through the tap hole at the bottom of the settler. The working of this type of furnace proceeds continuously, fresh ore charges being dumped in at the top at intervals, while a constant flow of slag and matte passes out through the spout.

Reverberatory-furnace smelting.—The furnace used is essentially different both in construction and method of working from the one previously described. In the blast furnace, the fuel—coke—is burnt in contact with the materials to be smelted, and the intense heat required for the operation is obtained by urging the combustion of the fuel by means of an air blast. In the reverberatory furnace the material to be smelted occupies one compartment of the furnace, while the fuel—coal or wood—is burnt in another. The draught required for the combustion of the fuel is quite moderate, and is obtained by a chimney of suitable height and area. The work-

FIG. 6.

ing bed of the furnace in plan is a parallelogram (Fig. 6) with rounded corners. At one end, and separated from it by a low partition, is the fire box, in which the fuel is consumed. At the opposite end is the outlet flue connecting with the chimney. A brick arch extends from the back wall of the fire box to the flue. This arches the furnace across from side wall to side wall, and is constructed with a fall from the fire-box end to the flue end of the furnace. The partition, or bridge, as it is termed, to which reference is made above as separating the working bed from the fire box, reaches to such a height above the bed that an opening is left between its top surface and the roof of the furnace. Through this opening above the bridge, the flame from the burning fuel passes over the bed on its way to the outlet flue. The side walls of the furnace are pierced with a number of openings used in working the

furnace for spreading the ore charge, drawing off the slag, &c., and one opening is cut down to the lowest point of the bed for tapping the matte.

The furnace walls and roof are constructed of highly refractory bricks with an outside casing of ordinary bricks, and the whole is bound together with steel girders placed vertically and tied together from one side to the other by iron tie rods. The working bottom is variously constructed. It may be formed of highly refractory bricks, or of silicious sand or crushed quartz. If formed of brick, these are laid on a layer of *brasque* in the form of a slightly curved invert arch, and with as close a joint as possible; when the furnace has been dried by means of a slow fire, it is ready for work.

In the case of the sand or crushed quartz bottom, however, the procedure is different.

After the furnace is completed, but without its refractory working bottom, the brickwork is thoroughly dried by a slow fire, then the heat is very gradually raised and a quantity of sand, or quartz, is thrown in and heated to a dull-red heat. When this stage is reached, the material is formed roughly into the shape required for the bottom by means of suitable tools. The fire is now urged to the highest point possible, so as to slightly frit the particles of sand or quartz, at least on the surface. When this is effected, the furnace is cooled and a small charge of some easily fusible slag is carefully spread over the surface. The heat is again raised so as to smelt this slag, which is absorbed by the bottom; this is repeated once or twice, when the furnace will be ready for a light charge of its ordinary ore mixture, which is gradually increased until the full-weight charge is reached. Charging of this furnace takes place through one or more openings in the roof from hoppers supported above. Assuming that the furnace is heated up to the required temperature, a charge of ore mixture is dropped from the hoppers above through the openings in the roof. This is then spread over the bed by means of suitable tools operated by men working through the side and front doors. When this operation is completed, the doors are closed and the fire attended to so as to raise the temperature of the furnace as rapidly as possible to full heat. The charge is occasionally stirred, if necessary, to remove any agglomerated masses from the bottom of the furnace, and finally, a molten bath is obtained composed of two distinct layers—the matte forming the bottom layer, and the slag floating upon it. When this stage is reached, another charge may be dropped and treated in the same way; and this may be repeated from time to time until the furnace is full of molten slag and matte. A side door and end door are opened and the slag allowed to run off, and towards the end, this is drawn off by means of tools handled by the furnace-men until nearly all the slag has been removed. The tap hole is then carefully opened, and this being at the bottom of the furnace, the matte flows through it and is led by a launder into a ladle or into moulds placed on the floor to receive it. When nearly all the matte has been run off, the tap hole is again closed and made secure, fresh charges are dropped, and the operations repeated.

The slag may be received in ladles mounted on wheels, and in these may be removed to the dump, or it may be received in sand moulds formed on the floor of the furnace house: when cool, it may be broken up and removed to the dump, or it may be run into a stream of water, and thus granulated and removed.

The object attained in this operation in the reverberatory furnace is the same as with the blast furnace, viz. the production of the proper grade matte and a slag of easy fusibility reasonably free from copper.

Pyritic smelting.—This method of working, which has been introduced of late years, secures in one operation what, in the preceding descriptions, is attained in two processes carried on in separate appliances. It has been shown that, in order to produce a proper grade of matte, a certain proportion of sulphur must be oxidised

to sulphur dioxide, and that, accompanying this action, a portion of the iron sulphide must also be oxidised. It has also been shown that, in ordinary working, this preliminary treatment and the actual smelting of the ore are carried out as two distinct operations in two entirely different classes of plant. It has also been indicated that, in the smelting operation proper, the high temperature necessary is obtained by the combustion of carbonaceous fuel. In pyritic smelting, the two processes referred to above are carried out as one operation in one furnace, and the high temperature necessary is derived from the rapid oxidation of the sulphur and iron (chiefly the latter) contained in the ore itself. While this method of working is of the highest importance from an economical point of view, it is of somewhat limited application, owing to the fact that comparatively few mines produce ore which—as regards its physical condition and chemical constitution—is suitable for this method of treatment.

The process is carried out in blast furnaces, and for its successful operation demands a larger volume of air per unit of time than the ordinary smelting process and an ore mixture in which the pyritic material is present in fairly large masses. The silica must be, for the most part, free silica (quartz), and not combined with earthy bases as silicates. Under these circumstances, the ore may be satisfactorily smelted, producing the required matte and slag with the consumption of but 1 to 3 p.c. of coke. A small amount of coke appears at present to be necessary in order to keep the charge open.

II. *Treatment of the matte for the production of crude copper.*—It has already been pointed out that matte consists of cuprous sulphide Cu_2S , with varying proportions of iron sulphide FeS , and the carrying out of the stage which is now to be considered involves the elimination of the sulphur and iron, while the copper is left in the metallic state. The process is carried out by different methods, the chief of which will now be considered. In all of these the operation is performed in two stages, although, in some cases, these follow one immediately after the other and in the same apparatus, while in others the stages are performed as two separate operations and in two or more separate furnaces. The first stage in each case consists in the removal of the FeS with the production of Cu_2S , and the second stage treats the Cu_2S with the production of metallic copper. The carrying out of the first stage depends upon the fact that, when matte is exposed to oxidising conditions, the iron sulphide is the first of its constituents to be decomposed, the sulphur being oxidised to sulphur dioxide. The resulting iron oxide is then caused to combine with silica, forming a slag which can be removed from the residual cuprous sulphide.

The second stage in the process depends upon one or more of the reactions represented by the following equations:—

the first being the most important as representing the change which takes place in the largest proportion of the material. The reactions indicated are effected by bringing the

several chemical compounds together in a molten condition. The oxidised compounds may be added to the molten Cu_2S from outside sources or may be, and generally are, produced by the oxidation of a portion of the cuprous sulphide itself.

The reactions outlined above are, at the present day, almost always brought about by what is termed the 'converter process,' also named 'Bessemerising,' the former name derived from the designation of the vessel in which the operation is performed, viz. converter, and the latter from the name of the distinguished inventor, Sir Henry Bessemer, who had many years previously applied a similar method and plant to the production of wrought iron and steel from cast iron.

The converter consists essentially of a vessel formed of steel or iron plate, with a thick lining, generally of highly silicious rock to which a small quantity of clay has been added, sufficient only to give the necessary coherence. The vessel is provided with a suitable aperture serving the purpose of a charging opening through which the matte to be operated upon is poured in a molten condition, also as an outlet through which the products of the operation are poured, as well as being an escape for the gases produced in the process. The vessel is supported on horizontal trunnions or on friction rollers at some little distance above the working floor of the furnace house, and is capable of being rotated by electric or by hydraulic power (Fig. 7). The form of the vessel is more or less

are continued through the lining to the interior. Air, at a pressure of from 8 to 12 lbs. per square inch, is supplied to the air boxes as required, and the supply is controlled by suitable valves. (Charging of the converter with matte is effected by means of a launder direct from the furnace, or settler, or by tapping these first into a steel ladle handled by an overhead crane which conveys it to the converter and pours it.)

The converter, having been lined and the lining dried by a slow fire, is placed upon the stand and connected up to the air main. A charge of molten matte is then poured in, the converter having been tilted into a suitable position for receiving it. The air being turned on, the converter is then tilted over so that the tuyères are brought beneath the surface of the matte, and the air, being forced through the molten sulphides, causes a rapid oxidation of the constituents of the iron sulphide. The sulphur is oxidised in this way to sulphur dioxide and the iron to oxide, which is immediately converted to silicate by combination with the silica of the lining. As the oxidation proceeds, the temperature of the charge increases and the operation is continued until practically the whole of the iron sulphide has been decomposed, and the contents of the converter consist of cuprous sulphide and slag. The converter is now turned over and the slag run off into pots or moulds, and when this is done, it is again turned into the blowing position, when the second stage of the oxidation is commenced. The passage of the air through the molten cuprous sulphide brings about the oxidation of a part of that material to cuprous oxide, which immediately reacts upon unaltered cuprous sulphide with the production of an equivalent quantity of metallic copper, in accordance with the reactions given on page 133. This action continues until all the cuprous sulphide has been decomposed and the contents of the converter consist of metallic copper; any small quantity of slag which may be on the surface is removed by turning down the vessel and skimming off. The metallic copper is then poured into moulds of the shape required by tilting the converter. As the slags produced in the operation are likely to contain intermixed shots and splashes of cuprous sulphide, they are resmelted in the furnace plant in which the matte was produced in the first place. As soon as the copper has been poured, the converter is ready to receive another charge, and the operations are repeated. When several charges have been put through (the number depending upon the nature of the rock material of which the lining is formed and the care exercised in ramming it into place), the lining becomes too thin for further use; the converter is therefore removed to the relining department by means of the crane, the old lining is taken out and a fresh one put in, when, after drying, it is again ready for use.

Another method for the production of metallic copper from the matte is conducted entirely in reverberatory furnaces, and is sometimes employed where the output does not justify the more expensive converter plant previously described. In this method of working, the first stage, viz. the removal of the iron sulphide of the matte by oxidation of

Fig. 7.

cylindrical with the axis of the cylinder placed sometimes vertically, but more often horizontally. In the case of the former, a shallow circular enclosed space, termed the air box, is attached on the outside at the bottom of the vessel.

In the latter form, this air box takes the shape of a long rectangular box attached horizontally to the outside of the converter. From these boxes holes are led through the plates forming the casing of the converter, and

its constituent elements, is effected by smelting the material with a proper proportion of calcined matte together with silica sufficient to form a silicate of iron slag with the iron oxide; or the matte may be smelted with oxidised copper ore, silica being also present. In either case, the result is that the iron sulphide is decomposed, the sulphur passing from the furnace as sulphur dioxide, and the iron forming, with the added silica, a slag, which is removed. The contents of the furnace at this stage consist chiefly of cuprous sulphide, Cu_2S . Currents of heated air are directed over the surface of the molten bath, with the resulting formation of cuprous oxide and the concurrent reaction between this and the unchanged cuprous sulphide results in the production of metallic copper, in accordance with the equations set out on page 133. When this reaction has extended to the whole contents of the furnace, the heat is raised and the metallic copper is tapped out into moulds.

In one method of working, known as the direct process, the furnace is tapped at the stage when the product is practically cuprous sulphide; when cold, a portion of this is finely crushed and completely oxidised by calcination in furnaces similar to those used for calcining ore fines. The calcined material is then mixed with the crushed uncalcined portion, and the reaction between Cu_2S and Cu_2O is brought about as indicated in the equation on page 133, by smelting the mixture in a reverberatory furnace of the same general construction as that used in the earlier stage of the process.

III. *Refining.*—The method of treatment to be adopted in this operation depends upon whether (a) the copper is practically free from gold and silver and from deleterious elements; (b) the copper contains appreciable quantities of gold and silver, or contains undue quantities of deleterious elements.

If the metallic copper produced by the operations previously described under I. and II. comes under the description (a) above, it can be refined by furnace treatment only; if it comes under (b) it must be refined electrolytically in order to recover the gold and silver or to obtain it free from the impurities.

Under (a), the furnace employed is of the reverberatory type, and the removal of the impurities is effected by slowly melting the pigs of copper under highly oxidising conditions, and maintaining the bath of molten copper under this condition until the impurities are oxidised and removed, either by volatilisation or by passing as oxides into the copper silicate slag formed. The oxidation of the impurities is facilitated by the fact that metallic copper has the property of dissolving a small proportion of cuprous oxide, which compound is brought into contact with the elements to be oxidised under the very favourable condition of fluidity.

The oxidising condition of the bath of molten copper is maintained until the impurities are removed, as far as practicable, and the copper contains a maximum quantity of dissolved cuprous oxide. In this condition the metal is said to be 'dry.' After removal of the slag, the next stage consists in reducing the greater portion of the dissolved cuprous oxide, which is effected by depressing poles of green wood below the surface of the bath of metal, when con-

siderable agitation takes place and the cuprous oxide is subjected to the reducing action of the gases given off by the pole.

The process is continued until only a small quantity of cuprous oxide remains, and the copper attains the physical condition known as 'tough pitch,' when it is ladled out into moulds of any required shape.

Under (b), the copper is refined electrolytically. This process depends for its operation upon the fact that if an electric current is caused to pass through a solution of copper sulphate, the copper in the solution is deposited at the cathode, while the acid is set free at the anode. If the anode is composed of metallic copper, then the acid set free on its surface immediately dissolves an equivalent portion of copper which passes into solution, and is, in turn, deposited at the cathode, and the process thus becomes continuous so long as the current passes and there is copper at the anode to be dissolved. Assuming that the solution of copper sulphate is properly made up and maintained, and the voltage and current are suitably adjusted, then *only* copper will be deposited at the cathode, while the gold and silver and all the impurities contained in the copper anodes will either remain as insoluble slime, collected at the bottom of the vessel in which the operation is conducted, or will pass into the electrolyte. Gold, silver, and lead pass entirely into the insoluble slime; other elements, such as iron and nickel, pass wholly into the solution, and others again are to be found partly in the slime and partly in the electrolyte. The cathode surface is, to start with, a very thin sheet of electro-deposited copper, and when—as the result of the operation—sufficient copper has accumulated upon its surfaces, it is removed from the bath and is ready for melting and casting into any required shape. In practice, a number of anode plates are hung in a lead-lined wooden tank, and are suitably connected to the positive lead. Alternating with these anode plates are hung the cathode sheets, connected in parallel with the negative lead. A large number of tanks are connected in series, and the current is passed through the whole set of tanks. The electrolyte is caused to circulate through the whole series, and, after it has been in use for some time, a certain proportion must be removed regularly for purification. A quantity of anode copper remains undissolved, and when the tank is to be cleaned, this is taken out for remelting into anodes, the solution is run off, and the slime is removed. This latter is washed and dried, any large particles of copper removed by sieving, and the fine slime is then treated for the recovery of any silver or gold which it may contain.

Wet methods. These are of very limited application, and only adapted to very poor ores. They depend upon the fact that some copper minerals are decomposed and rendered soluble by certain acids and ferruginous salts, as, for instance, oxidised ore in sulphuric acid, and some copper and iron sulphides by solutions of ferric sulphate and chloride. When such solutions, separated from the gangue material of the ore by filtration, are brought into contact with metallic iron, the copper contained in the solution is precipitated on the iron and is removed from time to time. After removal, it is washed

and melted and then refined as previously described.

Another method of rendering the copper mineral soluble, which is sometimes employed, is to calcine the finely crushed ore with salt at a low temperature. On treating this afterwards with water, the soluble copper salts resulting from the operation are removed and the solution, on being treated with metallic iron, yields the copper in the metallic state, as in the methods previously mentioned. T. C. C.

COMPOUNDS OF COPPER.

Oxides. Five oxides of copper are said to be known: the quadrantoxide Cu_4O , the trientoxide Cu_3O , the sub- or hemi-oxide Cu_2O , the monoxide CuO , and the peroxide CuO_2 . Other oxides have been described, but their existence is not proved.

Copper quadrantoxide is stated to be formed by adding a solution of copper sulphate to a cooled dilute solution of stannous chloride in caustic potash (Rose, Pogg. Ann. 1861, 120, 1). It is an olive-green powder, which rapidly absorbs oxygen from the air. According to Moser (Zeitsch. anorg. Chem. 1909, 64, 200), this product is really a mixture of cuprous oxide and copper.

Copper trientoxide is obtained by heating cupric oxide at 1500° - 2000° as a hard yellowish mass. It is unaffected by any acid except hydrofluoric (Bailey and Hopkins, Chem. Soc. Trans. 1890, 269).

Copper suboxide, or hemioxide, red oxide of copper, cuprous oxide Cu_2O , occurs native as *cuprite* or red copper ore, and as *chalcotrichite*.

It may be prepared (1) by heating finely divided copper in air below a red heat; (2) by gently heating a mixture of 5 parts cuprous chloride and 3 parts sodium carbonate in a covered crucible, and separating the oxide by lixiviation; (3) by reduction of an alkaline solution of a copper salt by sugar or certain other organic bodies, as in Fehling's solution; (4) by heating in a covered crucible a mixture of 5 parts copper monoxide and 4 parts copper filings; (5) by the electrolysis of copper sulphate solutions under certain conditions (Miller, J. Phys. Chem. 1909, 256; Gillett, *ibid.* 1909, 332).

This oxide is decomposed by most acids into a cupric salt and copper; hydrochloric acid, however, converts it into cuprous chloride.

Cuprous oxide fuses at a bright-red heat. It dissolves in metallic copper and renders it brittle or 'dry' when present in quantity. As much as 4.6 p.c. has been found by Abel in very dry copper, and, according to Watson (J. Soc. Chem. Ind. 1883, 154), from 1 to $2\frac{1}{2}$ p.c. is present in ordinarily good copper.

It is largely used in the manufacture of *ruby glass*, and for the production of a red glaze on pottery (Louth and Dutailly, Mon. Ceram. et Verr. 19, 237), and, together with the black oxide, forms one of the so-called *copper paints* used for painting ships' bottoms.

The hydrated oxide is produced by the action of alkali on cuprous chloride. The yellow precipitate thus formed is not a definite hydrate, but is a colloidal form of the oxide with an indefinite amount of water (Gröger, Chem. Zeit. Rep. 1902, 197). It is a powerful reducing agent, especi-

ally in ammoniacal solution. This solution, which is colourless, immediately becomes blue from the formation of the monoxide on exposure to the atmosphere, and thus forms a delicate test for oxygen. The hydrated oxide dissolves in a concentrated solution of magnesium chloride.

This oxide is produced in Hoepfner's process for extracting copper from ores, &c., with cupric chloride solution. Cuprous chloride is formed and treated with alkali to obtain cuprous oxide (J. Soc. Chem. Ind. 1893, 932; Eng. Pat. 18900, 1892).

Copper monoxide, cupric oxide, black oxide of copper, 'copper oxide' CuO , occurs as *melanconite* or *black copper*, especially at Lake Superior.

It may be prepared by heating the nitrate or carbonate to dull redness or the sulphate to intense redness. The decomposition of the sulphate is the basis of Adcock's process for the preparation of the oxide direct from the natural carbonate or sulphate (Eng. Pat. 11678, 1900). The copper oxide used for organic analysis, &c., may be prepared by moistening copper scale (the mixture of suboxide and black oxide obtained while working copper sheet, &c.) with nitric acid, and igniting.

An electrolytic method of preparing the oxide has been described by Miller (J. physikal. Chem. 1909, 256); and by Luckow (Zeitsch. Elektrochem. 1897, 482).

Copper oxide is a black powder which agglomerates when heated, and fuses at the melting-point of copper, forming cuprous oxide, or Cu_2O , according to the temperature. It can be made to crystallise in regular tetrahedra. It is slightly hygroscopic, especially when in powder. When heated with organic substances or certain gases, it is reduced to metal. The metal produced by reduction in hydrogen always contains that gas, but if the oxide be reduced in formic acid vapour, the metal is quite free from hydrogen and is suitable for organic analysis (Weyl, Ber. 15, 1139).

It dissolves in acids with formation of cupric salts. In oils, &c., it is soluble to some extent; it is for this reason that copper cooking vessels require such constant cleansing.

Copper oxide is used for ultimate organic analysis; to make green and blue glass and glazes, and to some extent as a pigment. It has also been used as one electrode of a galvanic cell (*v. Lelande* and *Chaperon*, Bull. Soc. chim. [2] 49, 173).

Hydrated copper oxide $\text{CuO}\cdot\text{H}_2\text{O}$ may be prepared by precipitating a solution of a copper salt by addition of alkali and washing rapidly. When heated with water, it becomes black and amorphous.

A colloidal form of the oxide has been obtained by Paal and Leuze (Ber. 1906, 1545), which gives blue-violet solutions, and when dry retains its solubility indefinitely.

The hydrated oxide is used as a blue pigment by paper stainers, but becomes green on exposure. It corresponds closely with certain of the highly basic carbonates sold as *verdriers*. According to Dumas, it is best prepared as follows: 6 parts of copper sulphate are dissolved in water and mixed with a solution of 3 parts of calcium chloride. The clear liquid is decanted

from the precipitated calcium sulphate and is mixed with $1\frac{1}{2}$ parts of lime made into a cream with water. The greenish precipitate is collected, washed, and mixed with one-fourth its weight of slaked lime and as much pearl ash, and to render the colour more permanent, one-fourth its weight of ammonium chloride and one-half its weight of copper sulphate are usually added.

The hydrated oxide dissolves in ammonia, the saturated solution in strong ammonia being known as 'Schweitzer's reagent,' or *cuprammonium*. This solution has the property of gradually dissolving cellulose with formation of a viscid solution which is used for the preparation of the 'Willesden papers,' and for the production of 'artificial silk' on the large scale. This process consists in injecting the copper-cellulose solution into strong solutions of alkali or acid. In either case, coagulation takes place with formation of a fibre of cellulose corresponding in thickness to the diameter of the jet.

Cuprammonium solutions are prepared on the large scale by the joint action of oxygen and ammonia on metallic copper at temperatures near 0° (Schaefer, U.S. Pat. 884298, 1908; Bronnert, Frémery, and Urban, Eng. Pat. 1763, 1900; Lecœur, Fr. Pat. 374277, 1906).

Bellet has patented a continuous process of manufacture, using a series of closed vessels (Fr. Pat. 335207, 1903).

The solution should be purified by dialysis, as the presence of crystalline salt favours its decomposition (Lecœur, Fr. Pat. 362986, 1906). Addition of 1-2 p.c. of polyhydric alcohols, carbohydrates, gum, &c., to cuprammonium solutions increases their stability and prevents the deposition of cupric hydroxide (Friedrich, Eng. Pat. 4104, 1909), and the presence of such substances facilitates manufacture of the solution, making it possible to employ copper concentrations up to 5 p.c. without cooling (Fr. Pat. 399911, 1909).

Chattaway has shown (Proc. Roy. Soc. 1908, 80, A, 88) that by the reduction of a cuprammonium solution with aromatic hydrazines, copper mirrors can be deposited on glass.

Dawson states that a solution of cupric hydroxide in ammonia contains copper as the base $\text{Cu}(\text{NH}_3)_2(\text{OH})_2$ (Zeitsch. physikal. Chem. 69, 110). (For a general discussion of the constitution of cuprammonium salts, see Horn and Taylor (Amer. Chem. J. 1904, 253); and Horn (*ibid.* 1907, 475).)

Copper dioxide, copper peroxide CuO_2 , is obtained by the action of hydrogen peroxide on cupric hydroxide in neutral solution at 0° (Krüss, Ber. 1884, 17, 2593; Moser, Zeitsch. anorg. Chem. 1907, 54, 121). The crystalline precipitate is washed with water, alcohol, and ether at 0° , and dried *in vacuo*. It has a yellowish-brown colour, and decomposes at 180° , forming cupric oxide.

SALTS. Two series of copper salts are known, *cuprous* and *cupric*. The former are mostly insoluble in water, and are of but little commercial importance. They act as powerful reducing agents and readily pass into the cupric condition. Cupric salts are mostly soluble, and are of wide application.

Cuprous chloride Cu_2Cl_2 may be prepared, amongst other methods, by boiling cupric chlor-

ide with hydrochloric acid and copper turnings. On addition of water it is precipitated in white crystals.

Zuloaga has suggested (Rev. Chim. Ind. 1900, 107) that the cuprous chloride solution used in the extraction of silver from its ores should be prepared by mixing solutions of cupric sulphite and of cupric sulphate and sodium chloride.

Cuprous chloride melts below a red heat into a yellow transparent mass. The dry crystals become yellowish on exposure to light; if moist, they acquire a dirty-violet tinge. Plates of copper coated with this chloride by the action of chlorine will take photographic impressions, but cannot be made to withstand exposure to light (*v.* Carlemann, J. pr. Chem. 63, 475; and Priwoznik, Dingl. poly. J. 221, 38).

Cuprous chloride combines with ammonia to form three compounds

Cuprous bromide and iodide form compounds analogous to the last two (Lloyd, J. Phys. Chem. 1908, 398).

The hydrochloric acid solution, when exposed to air, absorbs oxygen and acquires a brown colour, subsequently depositing a pale bluish-green insoluble copper oxychloride

An identical substance used as a pigment, and known as *Brunswick green*, is prepared by boiling a solution of copper sulphate with a small quantity of bleaching powder solution; or by moistening copper turnings with hydrochloric acid or ammonium chloride with free exposure to air. It occurs in nature as *atacamite*.

The use of the oxychloride in preference to the sulphate for destroying mould on vines, &c., is recommended. 200-250 grams per litre of water are taken (Deletrez, J. Soc. Chem. Ind. 1909, 438).

When a solution of cuprous chloride in potassium chloride, acidified with hydrochloric acid, is treated with acetylene, a yellow precipitate of $\text{Cu}_2\text{Cl}_2 \cdot \text{C}_2\text{H}_2$ is formed. Other compounds containing copper oxide or potassium chloride can be obtained by varying the conditions (Chavastelon, Compt. rend. 132, 1489).

Acetylene reacts with solutions of cuprous chloride in ammonia to form a blood-red precipitate of *cuprous acetylde*, which, on dehydration, has the formula Cu_2C_2 , and is highly explosive (Scheiber, Ber. 1908, 3816). Its decomposition by acids has been used as a means of preparing pure acetylene. A colloidal solution of copper acetylde has been prepared by Küssert (Zeitsch. anorg. Chem. 34, 453) (*v.* ACETYLENE).

Cuprous bromide Cu_2Br_2 is obtained by the union of its elements or by boiling a solution of cupric bromide with copper, and forms a brown crystalline mass.

Cuprous iodide is the only known iodide of copper, and is obtained as a white precipitate by adding potassium iodide to a solution of copper sulphate containing ferrous sulphate or sulphurous acid. It has a sp.gr. 5.653 at 15° (Spring, Rec. trav. chim. 1901, 79), melts without decomposition at 628° , and is practically insoluble in water.

Cuprous sulphate Cu_2SO_4 can be prepared

by the action of dry dimethyl sulphate on dry powdered cuprous oxide (Reccura, Compt. rend. 148, 1909, 1105). A compound of cuprous sulphate and carbon monoxide $\text{Cu}_2\text{SO}_4 \cdot 2\text{CO} \cdot \text{H}_2\text{O}$ has been obtained by Joannis (*ibid.* 1903, 615), by reducing cuprammonium sulphate with hydroxylamine. Pechard has made ammonio-cuprous sulphate $\text{Cu}_2\text{SO}_4 \cdot 4\text{NH}_3$ (*ibid.* 1903, 504).

Cuprous sulphide Cu_2S occurs as *chalcite* or *copper glance*. It may be prepared by heating copper to redness in sulphur vapour, or by heating a mixture of copper and sulphur. It has no commercial application.

Cupric chloride CuCl_2 may be prepared as a fused, liver-coloured, anhydrous mass by heating copper in excess of chlorine. In solution it may be prepared by dissolving the oxide in hydrochloric acid. It crystallises in grass-green prisms or needles containing 2 molecules of water. They become pale-blue when dried *in vacuo*. The anhydrous salt is obtained on gradual addition of a large excess of conc. sulphuric acid to a solution of the chloride (Viard, Compt. rend. 1902, 135, 168).

Cupric chloride is very deliquescent, and is soluble in alcohol. When a small quantity of potash is added to the aqueous solution, a pale-blue basic oxychloride $2\text{CuO} \cdot \text{CuCl}_2 \cdot 4\text{H}_2\text{O}$ is precipitated. It turns to a black anhydrous powder when heated, but again becomes green with absorption of 3 molecules of water when moistened. It is an intermediate product in the manufacture of *verditer* (*v. Copper carbonates*).

Cupric chloride is used in calico printing, in the manufacture of *methyl violet*, and for the oxidation of *Cutch colours*.

Green has shown that the chloride is a very effective disinfectant (*Zeitsch. für Hygiene*, 1893, 495).

Cupric bromide CuBr_2 is obtained by dissolving cupric oxide in hydrobromic acid and evaporating *in vacuo*. It is dark-coloured, very deliquescent, and, when heated, decomposes into cuprous bromide and bromine. It is used as an intensifier in photography, and for that purpose is made by dissolving in water a mixture of anhydrous copper sulphate and potassium bromide (Akt. Ges. f. Anilinfabr. D. R. P. 201168, 1907).

Cupric sulphate, *Blue vitriol* $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, occurs naturally at Copaqueire, Chile, the rock containing over 12 p.c. of the hydrated salt (Walker, Eng. and Min. J. 1903, 710). This salt may be prepared by dissolving copper or its oxide in sulphuric acid.

It is prepared on the large scale from metallic copper in the following way: Old copper plates from the sheathing of ships, &c. are heated to strong redness in a reverberatory furnace, and an excess of sulphur is thrown in and the doors are closed. When combination is complete, the doors are reopened and the heat is raised to dull redness to oxidise the sulphide into sulphate. The mass, while hot, is thrown into dilute sulphuric acid, allowed to settle, decanted, concentrated, and crystallised. The sulphate so produced is of considerable purity. *Coarse copper* and *copper glance* or other sulphurous copper ores are similarly treated. Pauffin and Couvert have patented a process for the direct manufacture of the sulphate from the metal

(Fr. Pat. 399413, 1909). (See also Walker, U.S. Pat. 788862, 1905.)

When much iron is present, as in most copper ores and especially in copper pyrites, it would be impossible to separate the copper and ferrous sulphates by crystallisation, because, although copper sulphate crystallises normally with 5 molecules of water, it forms, in presence of ferrous sulphate, crystals isomorphous with that salt and containing 7 molecules of water. By carefully adjusting the temperature at which the sulphide is roasted, however, the iron salt may be converted into the oxide while the copper sulphate remains almost unaffected. The iron may be removed by heating the solution of the sulphates to 180° in a copper boiler under pressure. Ferrous sulphate crystallises out and is filtered off (Gin, Fr. Pat. 328800, 1903). The iron may be oxidised and thus separated from the copper by boiling the solution with a little nitric acid. It may also be precipitated as oxide by boiling with copper oxide, or by boiling with lead peroxide with subsequent addition of a little barium carbonate.

Crude copper or the ore may be roasted in air, and then treated with sulphur dioxide to form the sulphate (Gin, *Zeitsch. angew. Chem.* 1903, 566; Eng. Pat. 5230, 1903).

Darier has patented a process in which cupric chloride is formed by the action of chlorine and water on the metal, and is then decomposed by sulphuric acid, with formation of the sulphate and regeneration of hydrochloric acid (Fr. Pat. 350421, 1904).

When the sulphate is required for purposes where the presence of iron is not injurious, such liquors, or the mother liquors from which the purer salt has been separated, may be at once crystallised out, with the formation of crystals containing both iron and copper. Much of the 'agricultural copper sulphate' is of this class. The '*Salzburg vitriol*,' prepared at Buxweiler, also contains both iron and copper. According to Lefort (Compt. rend. 26, 185), it consists of $\text{CuSO}_4 \cdot 3\text{FeSO}_4 \cdot 28\text{H}_2\text{O}$. '*Cyprian vitriol*,' prepared at Chessy from zinciferous copper ores, forms blue rhombic prisms, which contain, according to Lefort, $\text{CuSO}_4 \cdot 3\text{ZnSO}_4 \cdot 28\text{H}_2\text{O}$.

The copper may be separated from the ferrous mother liquors by placing them in vats containing iron plates upon which the copper is slowly deposited.

Apparatus for the solution of copper oxide in sulphuric acid upon a large scale has been described by Coste (Fr. Pat. 392617, 1908). If copper be known to contain silver or gold, as is the case with that from the Harz, it is treated with sulphuric acid diluted with its own volume of water, the copper being thus dissolved while the silver and gold are unattacked.

Argentiferous copper ores are roasted in a reverberatory furnace, and added in small charges to sulphuric acid and digested until the solution contains but little free acid. The solution is then decanted from the precipitated lead and gold, and is concentrated and run into lead-lined tanks containing plates of copper, upon which all the *silver* and part of the *antimony* and *arsenic* are deposited, while the greater proportion of the *bismuth* is precipitated as a basic sulphate, and the iron is reduced to the ferrous

condition. The liquor is then crystallised, the mother liquors being used for treating a fresh quantity of ore. Copper sulphate is obtained of great purity and in considerable quantity in the refining of silver by precipitating it upon plates of copper from its solution as sulphate (*v. SILVER*).

An electrolytic process for the production of the sulphate consists in using a solution of sodium sulphate and copper electrodes, a current of carbon dioxide being passed through the liquid. Copper is dissolved from the anode as sulphate, while sodium carbonate is produced at the cathode. These react, regenerating sodium sulphate and precipitating copper carbonate, which is collected and dissolved in sulphuric acid (Kroupa, *J. Soc. Chem. Ind.* 1906, 78).

Palas and Cotta have also described electrolytic processes for the production of the salt (*Eng. Pat.* 9806, 1899, and 17485, 1900).

The electrolytic production of the sulphate from 'cement copper waters' has been described by Rambaldini (*Chem. Zentr.* 1909, i. 1675).

It is stated that copper sulphate is sometimes adulterated with ferrous sulphate and Prussian blue to the extent of 90 p.c. (*J. Soc. Chem. Ind.* 1900, 84).

Copper sulphate crystallises in large transparent blue, doubly oblique rhombic prisms of sp.gr. 2.28, of the formula $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$. According to Poggiale, their solubility in 100 parts of water is:

10°C.	20°	30°	40°	50°
36.59	42.31	48.81	56.9	65.83
70°	80°	90°	100°	
94.60	118.0	156.44	203.32	

When heated, it loses 2 molecules of water at 30°, 2 more at 93°–98°, and at 232° becomes anhydrous, white, and hygroscopic, and combines with water with considerable evolution of heat. At 341° the anhydrous salt begins to decompose (Wanjukow, *Chem. Zentr.* 1909, ii. 1124). The sp.gr. of the anhydrous salt is 3.606 (Thorpe and Watts). It combines with water in alcohol and other organic liquids with production of a blue colour, and may be used for ascertaining the presence of water in those substances, but the test is not delicate. The anhydrous salt is also soluble in *anhydrous* methyl alcohol, and produces a bluish-green solution (Klepl, *J. pr. Chem.* 1882, 25, 526).

Copper sulphate absorbs hydrogen chloride with evolution of heat, forming cupric chloride and liberating sulphuric acid. It is therefore used to remove hydrogen chloride from such gases as chlorine or carbon monoxide. A similar reaction occurs in solution.

When mixed in solution with molecular proportions of potassium and other sulphates, it produces well-defined, crystalline double sulphates. Several basic sulphates are known.

The sulphate is the most important of the copper salts. It is largely used in calico printing, principally in connection with potassium dichromate or iron mordants; in black dyeing with logwood; directly or indirectly for the preparation of most pigments containing copper; and to prevent rot in timber. In agriculture the crude sulphate containing ferrous sulphate is used to a considerable extent to prevent smut in seeds. The seeds are soaked for some hours in a

weak solution of the sulphate, and are sown within 24 hours.

A 10–20 p.c. solution of copper sulphate, preferably mixed with lime, is applied to vines with great benefit. A small quantity is found in the vines and must, but the tannin and sulphur introduced before fermentation appear to remove it in most cases.

Karsten has stated (*v. J. Soc. Chem. Ind.* 1896, 367) that attacks of illness resembling dysentery have been caused by a wine which contained copper in such quantity as to give a visible deposit on steel in 12 hours. Its presence was due to spraying the vines with a copper salt.

An effective wash for vines is prepared by boiling 25 parts of sodium carbonate and 25 parts of resin in 100 parts of water, and then diluting and adding copper sulphate (*J. Soc. Chem. Ind.* 1899, 155).

Copper sulphate is used in preparing *copper ferrocyanide*, a solution of which, in potassium citrate solution, is used as a toning-bath for photographs (Ferguson's Copper Toning, *ibid.* 1900, 465).

Copper sulphate is also used in dyeing to make diazo-colours permanent to light. The dyed fabric may be treated with the salt (Graebing, *ibid.* 1905, 797), or it may be added to the diazotising bath (Grossmann, *Färber-Zeit.* 9, 328).

Cupric nitrate $\text{Cu}(\text{NO}_3)_2$ may be prepared by dissolving copper or the oxide or carbonate in nitric acid. The solution at temperatures above 20° deposits dark-blue crystals containing 3 molecules of water, which melt at 114.5° and boil at 170° with evolution of nitric acid and formation of a green basic salt. This basic salt may also be prepared by boiling the solution of the nitrate with copper or copper hydrate, or with a little alkali (*v. also Copper carbonates* for an application of the basic nitrate).

The anhydrous salt may be obtained by the action of nitric anhydride on the hydrated salt. It is a white, deliquescent powder, decomposing at 155°–160° (Guntz and Martin, *Bull. Soc. chim.* 1909, 5, 1004).

Copper nitrate is used to a slight extent in dyeing and calico printing, and a solution, prepared by mixing solutions of copper sulphate and calcium nitrate, is used in viticulture (Gouthière et Cie and P. Ducancel, *Fr. Pat.* 395806, 1908).

Cupric sulphide CuS occurs as *covelite* or indigo copper in blue flexible plates, in Vesuvian lava, in Chile, and in the copper-mines of Mansfeld. It may be prepared by heating cuprous sulphide with sulphur at a temperature not above the boiling-point of sulphur; by digesting cuprous sulphide with cold strong nitric acid; or by precipitating a copper solution with sulphuretted hydrogen. On the large scale it is obtained as a paste by precipitating a solution of the sulphate with sodium sulphide. This paste is used in calico printing for the development of aniline black.

The preparation and use of copper sulphide for thermo-couples has been described (*Eng. Pat.* 11300, 1905).

Rieder has used (*Zeitsch. Elektrochem.* 1902, 370) an electrolytic method for the preparation of this compound.

A brownish-red *persulphide of copper* has

been obtained by Bodroux by adding a solution of calcium pentasulphide to a solution of copper acetate at 0° (Compt. rend. 130, 1397).

Copper acetate *v. Metallic acetates*, art. ACETIC ACID.

Copper arsenite *v. Scheele's green*, art. ARSENIC.

Cupric phosphate is of no technical interest. A brilliant green colour containing a basic phosphate, prepared by heating a mixture of copper acetate, sodium phosphate, and ammonia. has, however, been used in calico printing (Bourcart, Mon. Sci. [3] 4).

Phosphorus combines in several proportions with copper, and produces true alloys, which in many cases are of great value.

Heyn and Bauer state that the phosphorus exists in the alloy as Cu_3P and Cu_2P_2 (J. Soc. Chem. Ind. 1906, 1047). The latter compound has been obtained by Rub'novitch by the action of phosphine on copper sulphate (Compt. rend. 127, 270).

Copper silicide (*Cuprosilicon*) Cu_4Si is obtained when copper and silicon are heated together in the electric furnace (Vigouroux, Compt. rend. 1896, 122, 318; Lebeau, *ibid.* 1906, 142, 154). It is now manufactured in Germany and America by this process (Steinhart, Eng. and Min. J. 1899, 67, 710), and is used for purifying and hardening copper, and for adding to tin-, zinc-, and aluminium-bronzes to increase their tensile strength and hardness.

Cuprosilicon can be prepared pure by heating together 17 parts silicon and 9 parts copper in hydrogen, and removing the excess of silicon by solution in sodium carbonate. It is silver-white, with a metallic lustre, and is hard and brittle. The sp. gr. is 7.58, and it is attacked by chlorine and *aqua regia* (Vigouroux, Compt. rend. 1906, 142, 87; see also Philips, *Métallurgie*, 1907, 4, 587; and Lebeau, *ibid.* 141, 828).

Copper carbonates. The normal salt has not been prepared, but several basic carbonates are known, and used as blue and green pigments. Basic copper carbonate occurs native as *malachite* $Cu(HO)_2 \cdot CuCO_3$, and as *azurite* or *chessylite* $Cu(HO)_2 \cdot 2CuCO_3$. When ground, these minerals form a fine but expensive pigment.

An anhydrous basic carbonate is precipitated on addition of a solution of sodium carbonate to a hot solution of copper sulphate or nitrate. (For a complete description of all the known basic carbonates of copper, see Pickering, *Chem. Soc. Proc.* 1909, 188.)

Under the names *Verditer green*, *Verditer blue*, *Bremen green*, and *Bremen blue*, this salt is largely prepared for paper staining &c. According to Habich (*Technologiste*, 17, 413), the following processes are in use. A hundred parts of old copper sheathing from which impurities, oxide, &c., have been removed by digestion in dilute sulphuric acid, is cut into pieces and mixed with a paste formed by moistening a mixture of 99 parts potassium sulphate and 100 parts common salt, and the mixture is stirred occasionally for some months to ensure thorough exposure to the atmosphere. The action appears to consist in the production of cupric chloride, which, in presence of the metal, becomes converted into a basic chloride, and finally, by the action of the oxygen, into an oxychloride. If

the oxidation be incomplete, the subchloride is not completely oxidised, and, as it, when subsequently decomposed by alkali, gives an orange-red precipitate of suboxide, the pigment would be lowered in value. The oxychloride may also be similarly prepared from a mixture of 100 parts copper, 60 parts common salt, and 30 parts strong sulphuric acid diluted with three times its volume of water; or by treatment, with free atmospheric exposure, of copper with a solution of cupric chloride in hydrochloric acid.

To 100 kilos. of this thick magma of oxychloride, which has been washed by decantation, a concentrated solution containing 7 kilos. copper sulphate and 40 kilos. concentrated soda solution (32°-36°Bé.) is added. The mixture is vigorously stirred and poured at once into 150 kilos. of soda solution (20°Bé.). The precipitate is washed, passed through a fine hair sieve, and dried spontaneously or at a temperature below 25°. If hot air be used in the drying, it must be quite free from acid or sulphur gases. To produce the finest colour, desiccation must be perfect.

Habich recommends the following process for making a *verditer* which has a very different composition from the above. A solution of copper oxide in nitric acid is treated with potassium carbonate, which is added in portions until most, but not all, the copper has been precipitated. The green precipitate is washed and introduced into a solution of copper nitrate whereby it is converted into a heavy green insoluble basic nitrate. This is digested in a solution of potassium zincate (formed by dissolving zinc in caustic potash solution). A dark-blue pigment, of great 'body' but little weight, is thus produced. It contains zinc and copper, apparently combined as a double oxide or as 'copper zincate,' and a small quantity of basic copper nitrate.

Verditer may be prepared by agitating a solution of copper nitrate with chalk. The washed pasty precipitate is mixed with 8-10 p.c. of freshly burnt lime with production of a fine velvety blue pigment. The precipitate without addition of lime is green.

According to Gentele, the following process is adopted at Bremen, Cassel, &c.: 225 lbs. sea salt and 222 lbs. blue vitriol, both free from iron, are mixed dry and ground between millstones with water to a thick paste. This paste is mixed in strata with 225 lbs. of clean copperplate cut into pieces about 1 inch square, in wooden chests made without nails, and the mixture is digested for about 3 months with the maximum exposure to air, the whole being well mixed and exposed about once a week. When the action is complete, the undissolved metal is removed and the precipitate is washed with a minimum of water, filtered and thrown into a tub. To 180 lbs. of the magma 12 lbs. of hydrochloric acid (13°Bé.) is added, and the mixture is stirred and left for 24 or 36 hours. Six volumes of this solution is mixed with 15 volumes of caustic alkali (19°Bé.) followed after an interval by 6 volumes of water. The mass is well mixed and left for 36-48 hours, and is then well washed by decantation, filtered, exposed for some time in a moist condition to the air, and finally dried (*v. also Copper monoxide*).

COPPER-GLANCE or **Chalcocite**. Native cuprous sulphide Cu_2S , crystallising in the orthorhombic system. Excellent twinned crystals were formerly found in abundance in the neighbourhood of Redruth in Cornwall (hence the name redruthite) and Bristol in Connecticut; usually, however, the mineral is found as compact masses. It is iron-black with metallic lustre, but, on exposure to light, it soon becomes dull with a powdery black coating. It is soft ($H. = 2\frac{1}{2}$) and sectile, and can be readily cut with a knife; sp.gr. 5.7. It occurs in veins of copper ore, and is often of importance as an ore, especially when it contains small amounts of silver. Isomorphous with copper-glance is the mineral *stromeyerite* $(Ag,Cu)_2S$, which has been found in considerable quantities in the Altai Mountains in Siberia. L. J. S.

COPPER PAINT v. **COPPER**.

COPPER-PYRITES or **Chalcopyrite**. A sulphide of copper and iron $CuFeS_2$, containing when pure 34.5 p.c. of copper, and the most important of the ores of copper. It has a characteristic brassy-yellow colour with metallic lustre, and on the surfaces often displays a brilliant iridescent tarnish (peacock-copper-ore). It often occurs together with, and intimately intermixed with, iron-pyrites, from which it can be distinguished by its deeper colour and lower degree of hardness; copper-pyrites ($H. 3\frac{1}{2}$ -4) is readily scratched with a knife, giving a greenish-black powder, whilst iron pyrites ($H. 6$ -6 $\frac{1}{2}$) is scratched only with difficulty or not at all. It occurs in mineral-veins and in bedded deposits, and by its alteration gives rise to many secondary copper minerals. Crystals are tetragonal with inclined hemihedrism, but only rarely are they distinctly developed; sp.gr. 4.2. L. J. S.

COPRA and **COPRA OIL** v. **COCOA-NUT OIL**.

COPROLITES. Concretionary mixtures of calcium phosphate and calcium carbonate, derived from the excrements of certain extinct fishes and reptiles. Formerly much used in the manufacture of superphosphate of lime (v. **FERTILISERS**).

CORAL is the calcareous substance secreted by many varieties of five kinds of organisms, viz. (1) *Actinozoa*, the principal constituents of coral reefs; (2) *Hydrozoa*, the large common corals known as millepores; (3) *Bryozoa*, delicate corals in various forms, resembling mosses, branches, thin filamentary deposits, or more solid masses (in the Palæozoic limestone formations this species of coral abounds); (4) *Foraminifera*, chambered shells belonging to lowly organisms, mostly of very minute size; (5) *Nullipores*, which, although closely resembling millepores, are veritable algæ or sea-weeds; they may be readily distinguished from the millepores by the absence of perforations.

Coral is simply a secretion corresponding to the bone of vertebrates or the shell of mollusca, and is composed almost entirely of calcium carbonate derived from sea-water and from the food of the coral-making polyps.

Ordinary coral is somewhat harder than limestone or marble, and, when tapped with the hammer, gives out a ringing sound clearer than is elicited from ordinary calcium carbonate. The sp.gr. of 15 specimens examined by Silliman, averaged 2.523.

COMPOSITION OF CORAL.

Small and variable quantities of magnesium carbonate, calcium sulphate, calcium fluoride, alkaline chlorides, silica, and oxide of iron are found in corals.

The red coral, *Corallium rubrum*, varies in colour from crimson to rose, the latter being the rarest and, therefore, the most prized. It is gathered from the rocky bottom and shores of the Mediterranean; and it occurs most abundantly at a depth of 25-50 feet; although, according to Dana, it may be found as deep as 1000 feet. Forchhammer found 2.1 p.c. magnesia in *Corallium rubrum*, and 6.36 in *Isis hippuris*. According to Trommsdorff, the red pigment of coral is a resin soluble in oil of turpentine, and, after removal from the coral by this solvent, is easily soluble in alcohol and ether, but insoluble in caustic potash. In a red madreporæ, Vauquelin found a red colouring matter, which was turned violet by alkalis. Moseley has described in some corals and allied organisms a red colouring matter (*Polyporphyrin*) which is insoluble in water, glycerol, alcohol, ether, and in strong solutions of ammonia and potash. It is soluble in moderately strong sulphuric, nitric, or hydrochloric acids. For the formation and distribution of coral and coral-reefs, &c. v. Corals and Coral Islands, J. D. Dana; Coral-Reefs, Darwin; Murray, in Proc. Roy. Soc. Edinb. 1880, 505. See also Forchhammer, J. Pharm. Chim. 49, 52; J. 1847, 1291; 1849, 813; 1851, 865; 1852, 958-961; Sharples, l.c.; Moseley, Quart. Journ. Microscop. Sci. xvii. 1877; also Max Bauer, Edelsteinkunde, 2nd ed. 1909, Eng. trans. Precious Stones, L. J. Spencer, 1904.

It is now known that the materials constituting coral-reefs sometimes undergo remarkable chemical changes, and that the calcium carbonate is largely replaced by magnesium carbonate or calcium phosphate. In 1846 J. D. Dana and B. Silliman showed that the rock of an upraised coral-reef in the Pacific contained as much as 38 p.c. of magnesium carbonate. The deep boring made in the Atoll of Funafuti in 1897-8, yielded a series of cores, of which a chemical examination was made by E. W. Skeats and Hart Smith in the laboratories of the Royal College of Science. It was found that down to the depth of

637 feet dolomitization had only gone on to a small extent, the proportion of magnesium carbonate never exceeding 16 p.c.; but the lower portions of the core were very rich in the magnesium salt, containing from 30 to 43 p.c., the rock thus becoming almost a true dolomite. A large collection of coral limestones obtained by Alex. Agassiz, from reefs in the Pacific, was subsequently examined by Skeats, who showed that they contained varying amounts of magnesium carbonate up to nearly 42 p.c. Specimens from Christmas Island in the Indian Ocean gave similar varying results, per centages of magnesium carbonate up to over 43 p.c. being found. A coral limestone obtained by boring at Key West, Florida, yielded to G. Stigler, in the laboratories of the U.S. Geological Survey, over 14 p.c. of magnesium carbonate.

Coral reefs that have been covered by deposits of guano are found to have their carbonates largely replaced by phosphates. Thus the rocks of the coral reef known as Christmas Island in the Indian Ocean have been largely worked for the deposits of calcium phosphate, and Teall has shown that Clipperton Atoll in the North Pacific contains rocks with as much as 38½ p.c. of phosphoric acid.

(For changes in the chemical composition of coral rock, see Dana and Silliman, Amer. J. Sci. 2, i. 1846, 189; Judd, Chemical Examination of Materials from Funafuti, in 'the Atoll of Funafuti', Phil. Trans. 1904, 362-389; Skeat, The Chemical Composition of Limestones from Upraised Coral Islands, Bull. Mus. Comp. Zool. Harvard, xlii. 1903, 53-126; Teall, Quart. Journ. Geol. Soc. liv. 1898, 230-232.)

CORALLIN, CORALLINPHTHALIN, PHE-NOLCORALLIN v. AURIN.

CORDIALS and **LIQUEURS** are spirituous compounds flavoured with essences obtained from fruits, herbs, spices, or other substances, usually sweetened with sugar or glycerol, and often strongly coloured. They are manufactured and used to a much greater extent in France and other European countries than in the United Kingdom, and although there is no essential difference between them, the term 'cordials' is by many restricted to British, and 'liqueurs' to the foreign preparations.

The spirit in the best qualities of liqueur is derived from the grape, but grain and other spirit is frequently employed, especially in cordials; but, whatever the origin of the spirit, it should be highly rectified and neutral in character, so as not to impair the flavour of the finished product. The alcoholic strength of cordials and liqueurs varies greatly, but, on the average, they contain from 30 to 40 p.c. of alcohol, or 50 to 70 p.c. of proof spirit. The sugar must be pure, and is added in the form of a clear syrup.

The principal flavouring ingredients employed are (a) those used solely on account of their essential oils, as aniseed, bitter almonds, caraway, juniper berries, mint, lemon peel, orange blossom, &c.; (b) those valued for their bitter principles as well as their essential oils, as cinnamon, cloves, curaçoa apples (a kind of orange), gentian, ginger, orange-peel, sweet calamus, wormwood, vanilla, &c.; and (c) fruits, chiefly cherries, pineapples, raspberries, and strawberries. The flavourings are

obtained either by digesting the flavouring ingredients (bruised or cut up) with alcohol and distilling the mixture to obtain an essence, or by filtering the alcoholic extract to form a tincture, or by simply expressing and clearing the juice of fruits or digesting the latter for a more or less prolonged period in spirit.

Artificial essences simulating the above flavourings are frequently employed, but their use in beverages is questionable, since it seems probable that their physiological action differs from that of the natural flavouring substances which they are intended to imitate.

The colouring matters most commonly used are as follows. *Red*, aniline red, brazilwood, cochineal, cudbear, and sandalwood; *yellow*, saffron and turmeric; *blue*, indigo; *green*, chlorophyll (from nettles, parsley, spinach, &c.) and mixtures of blue and yellow colourings; *violet*, aniline violet; and *brown*, a solution of burnt sugar or caramel (*v. LIQUEURS*).

CORIOPHOSPHINES v. ACRIDINE DYESTUFFS.

CORK. Cork is derived from the bark of two evergreen species of oak tree, the cork oak, *Quercus suber* (Linn.) and *Q. occidentalis* (Gay). The former yields the best cork, and grows mostly in those countries bordering on the Mediterranean up to the 45° lat. The latter occurs on the Atlantic seaboard of Portugal, Spain, and France up to 48° lat.

The cork tree is from 30 to 60 feet high, and 3-4 feet thick. It grows slowly and reaches the age of 150-200 years. The tree has the peculiarity of throwing off its outer bark when it reaches a certain age, and then reproducing it. It is this that makes the cork industry possible. The chief countries in which cork is produced are:

1. *Spain*. Particularly the province of Catalonia. Here the best cork is grown. Seville is the chief market.

2. *Portugal*. Centres: Lisbon and Oporto.

3. *Algeria*. Here the cork trees form great forests; those belonging to the State were some years ago fully 600,000 acres in extent.

4. *Southern France* and the *Pyrenean district*. Large forests of *Q. suber* exist in the more mountainous parts, but in the low-lying 'Landes' the tree is *Q. occidentalis*, which grows as far north as Belle Isle.

5. *The Adriatic coast*. Some is produced in the Austrian provinces, but it is of inferior quality.

6. *Sicily, Sardinia, and Corsica* also yield cork of good quality.

Speaking generally, the cork tree seems to thrive best on dry granitic and sandy soils, and not to do well in damp or limestone soils.

The complete bark of the cork tree consists of two layers:

(1) The dry dead bark, comprising the epidermis and the cork proper, with the mesodermis.

(2) The green living skin which clothes the wood immediately under the dry bark. This may be looked upon as the active cork-producing

layer, and contains bast fibres and the epidermis.

The epidermis on one-year-old twigs is green and smooth, but in the second year between it and the green under-skin irregular white waxy masses are formed; these represent the beginning of the cork formation and increase from year to year, changing gradually into cork proper. At the end of the third year the epidermis dries up and cracks.

Barking the trees. This is the most important operation in the management of a cork forest, because on the care with which it is carried out depends the life of the trees and the regularity of the slabs produced.

In barking, the workman takes a special tool and makes a cut round the stem above and below the portion of bark to be removed. A vertical cut or cuts are made so that the bark may be stripped off the tree, in which operation the shaft of the tool is used as a lever. Care must be taken not to bruise the green underskin, the real producer of the cork.

The first barking produces so-called 'virgin cork,' which is of little value, as it has not elasticity enough for use as bottle corks. It was formerly used for the production of Spanish black, but of late years it has been employed in the manufacture of ground cork.

During the first year of growth the tree produces from 3 to 5 mm. of cork, but afterwards less, the mean for the first 9 years being about 2.1-3 mm., giving a total thickness of 20½ mm. After 9 or 10 years, when barking usually occurs, the growth is slower, but where thicker cork is required, the period is of course longer. The first stripping usually takes place on the 15-20 year-old tree. The best cork is yielded by trees of from 50 to 100 years old. Those growing in the mountainous districts yield a smaller quantity but better quality of cork.

After the cork bark has been removed from the tree, it is stacked and weighted with heavy stones to flatten it, and when dry it is scraped with an iron tool to remove the epidermis. The cork is then immersed for 5 or 6 minutes in a tank of boiling water, when it swells, and, according to the quality, retains this swelling more or less permanently. The water also removes tannin, vegetable acids, and their salts. In Spain the cork is occasionally passed through a fire, whereby it is superficially blackened, acquiring, it is supposed, by this treatment especially good qualities or 'nerve.'

After steeping, the plates are placed in heaps, weighted, and by hydraulic presses compressed into bales and bound with hoop iron.

Chemistry of cork. Cork extracted with hot water under pressure, yields gallic acid, colouring matters, iron and magnesium salts. By extraction with alcohol it yields 'cerin,' or cork wax $C_{32}H_{20}O$. Siewert examined the alcoholic extract and isolated from it 'deacrylic acid' $C_{10}H_{18}O_2$.

The composition of cork has been further studied by Kügler (Arch. Pharm. 1884, 217); Gilson (*ibid.* 1890, 690); and Hy. Ingle (J. Soc. Chem. Ind. 1904, 1197).

Suberine, according to Kügler, is a real fat, which cannot be entirely extracted by solvents, because they do not penetrate the material sufficiently.

Gilson saponified cork from *Q. suber* with

3 p.c. alcoholic potash, and isolated from the filtrate 44 p.c. of fatty acids, consisting of: *Phellonic acid* $C_{22}H_{32}O_2$, m.p. 95°-96°, a mono-basic acid giving a violet colour with zinc chloride-iodine solution; yield 8 p.c. *Suberinic acid* $C_{17}H_{30}O_3$, a semi-fluid sticky substance; 36 p.c. *Phloionic acid* $C_{22}H_{40}O_7$; fine white needles, m.p. 120°-121°; in small amount.

Gilson considers suberine not to be a true fat, but rather a mixture of complex esters and possibly condensation products of different acids.

Treated with iodine solutions cork does not give the cellulose reaction, and there is some dispute as to whether cellulose or a pentosan is the carbohydrate present in cork. Gilson, from microscopic examination, considers that cellulose is present.

Cork also contains certain aromatic compounds, tannin and the aromatic aldehyde of wood, hadromal, besides coniferin and vanillin.

Treated with strong nitric acid, cork produces suberic acid $(CH_2)_6(COOH)_2$, oxalic acid, and other products. Strong sulphuric acid chars it, but it is little affected by hydrochloric acid. Chlorine, bromine, and iodine cause cork to shrink, the two former first bleaching it. Ignited it burns, swells up, and forms a charcoal called Spanish black.

Physical properties.—The sp.gr. of cork is variously given from 0.12 (Rollmann) to 0.24 (Muschenbroek); on the average 0.16.

The uses of cork depend on its compressibility, elasticity, imperviousness to liquids, its lightness, its stability to weathering, &c. It is used in making stoppers, mats, soles, linings, springs for heavy waggons, as anti-vibratory and sound-deadening materials.

Waste cork is granulated by suitable machinery, sifted, and then ground to powder. The finest dust is mainly used in the manufacture of linoleum. Slightly coarser cork is used for the manufacture of cork carpet, but in both cases the binding material is prepared linseed oil.

Still coarser cork, of the size of peas, mixed with a proportion of fine, is employed in the manufacture of mats, insulating materials for water and steam pipes and cold storage chambers, packing, artificial corks for bottles, &c.

In order to bind the particles of cork together are employed (1) collodion; used for bath mats and stoppers. The granulated cork of various grades in suitable proportions is mixed with the solution and the pasty mass pressed into perforated moulds; these are then heated in a suitable chamber provided with a condensing appliance to recover the solvents, ether and alcohol. 'Suberite' belongs to this class. The mat is removed from the mould and 'buffed' (sand-papered) on a buffing machine similar to that used by cabinet makers. Cork stoppers are made in a similar manner, and also insulating slabs and tubes for covering steam and water pipes.

(2) Gluten, casein, and glue mixed with oily materials and resins and dissolved in suitable solvents, after mixing with the cork (rendered more or less insoluble by means of formalin, tannin, dichromates, lime, &c.), have also been used and patented for the production of cork slabs, &c., from granulated cork. The cork of various degrees of fineness is

mixed with the cement, subjected to powerful hydraulic pressure in moulds, and in some cases heated up to 200° to harden the albuminous matters of the cement.

(3) Mixtures of cork with silicate of soda and barytes or other pigment have been used for steam-pipe coverings.

Slabs of cork have also been made by soaking cork in soap solutions, then drying, treating with milk of lime, again drying and pressing the resultant mass into heated moulds.

Another use for cork waste, more or less finely ground, is in the production of floors. In this operation ground cork is mixed with a cement, such as Portland cement, or more often a mixture of cork and calcined magnesia is mixed with a solution of magnesium chloride and the pasty mass spread on the floor and allowed to harden; other salts, such as lead acetate, are sometimes added.

Cork dust is also used as a packing for the hollow spaces between the walls of cold-storage chambers, round the pipes of ice plants, &c., no binding materials being employed. Mixed with pitch, granulated cork is used as the filling between the outer and inner soles of boots, especially American. It forms a warm, water-proof and resilient layer.

Granulated cork of various degrees of fineness is also mixed with the paint used to coat iron surfaces where there is danger of the condensation of moisture, such as in the cabins of steamers, in breweries, factories, laundries, and the like.

CORNISH CLAY *v.* CLAY.

CORNISH STONE *v.* CLAY and CHINA STONE.

CORN OIL *v.* MAIZE OIL.

CORNUTINE *v.* ERGOT OF RYE.

CORONITE. An explosive consisting of nitroglycerine, 38-40 parts; nitro-cotton, 1-1½ parts; ammonium nitrate, 26-28 parts; potassium nitrate, 3-5 parts; aluminium stearate, 11-14 parts; rye flour, 8-11 parts; wood meal, 2-4 parts; liquid paraffin, 2-4 parts (*v.* EXPLOSIVES).

CORROSION OF IRON. All forms of metallic corrosion are probably primarily due to electrolytic action, and if it were possible to obtain absolutely pure iron, it might be found to be as resistant to atmospheric action as pure zinc is to dilute sulphuric acid; but with cast or wrought iron and steel, protection from air, moisture, and carbon dioxide is a necessity if the metallic form is to be preserved.

Iron rust, the result of atmospheric action under normal conditions, consists mainly of a mixture of ferric oxide Fe_2O_3 , and ferric hydroxide $Fe_2(OH)_6$, but a sample of fresh iron rust will be found to contain, in addition, ferrous oxide and ferrous carbonate. These two compounds, however, soon become oxidised, the latter setting free carbon dioxide and forming ferric oxide.

If a piece of iron be immersed in pure water, no action will be found to have taken place even after the lapse of some time, the presence of oxygen or air, which, however, must be quite free from any trace of carbon dioxide, in no way affecting the result; but the moment any carbon dioxide finds its way into solution in the water, rusting rapidly commences, and hence it is clear that the carbon dioxide dissolved in the

water and forming carbonic acid is the prime factor in starting the corrosion of iron and steel.

When iron or steel is acted upon by water free from any dissolved oxygen, but saturated with carbon dioxide, ferrous carbonate is formed, together with free hydrogen:

The solution remains clear, the salt being soluble in the excess of carbon dioxide present, until it is exposed to air, when the oxygen oxidises the ferrous carbonate to ferric oxide, setting free the carbon dioxide.

The ferric oxide then combines with some of the water to form ferric hydroxide:

The carbon dioxide which is set free then reacts with more of the oxygen and moisture to attack a fresh portion of the metal, the action, moreover, being aided by the electrical difference in potential between the hydrated oxide and the metal, so the result is that in time the whole of the metal is destroyed by its reversion to its original condition of hydrated oxide.

In large towns considerable quantities of sulphur acids are found in the atmosphere, owing to the combustion of bituminous coal, containing a small percentage of iron pyrites, leads to the formation of sulphur dioxide, and this dissolving in rain rapidly oxidises to sulphuric acid, giving the rain water an acid reaction. It has been shown that in the industrial quarters of a large manufacturing town this acidity will sometimes represent as much as 90 lbs. of sulphuric acid per acre per annum, whilst in the residential quarters it will probably not be more than about 25 lbs. The sulphuric acid, however dilute, coming in contact with iron-work, accelerates the rusting, and by its corrosive action renders more difficult the protection of the metal.

The usual methods of protecting iron and steel from atmospheric corrosion may be divided roughly into two classes; the first consists in coating them with another metal less liable to be acted on than the iron, and the second in the use of protective paints. Under the first category comes the coating of iron and steel by zinc, as in the process of galvanising; with tin, as in the manufacture of tin plate, whilst for small articles nickelling and also protecting by the Bower-Barff process, in which the iron is coated with a homogeneous film of the magnetic oxide, may be used. In the case of zinc, this metal, being electro-positive to the iron, forms a good protection until acid in the atmosphere or abrasion damages the surface, when, forming a galvanic couple with the iron, it is rapidly destroyed. The other coatings are all electro-negative to the iron, with the result that any break in the coating leads to far more rapid destruction of the iron than if none had been present. For the protection of large structures, coating with paint of suitable composition is the only practicable method of rust prevention.

The best paints for this purpose consist of

boiled linseed oil mixed with suitable pigments. When linseed oil is heated for some hours to about 200°, its oxygen-absorbing properties, upon which its drying depends, are very largely increased, and if it be boiled with oxides of lead, calcium, or manganese, the drying action is still further accelerated, owing to the formation of small quantities of oleates of the metals which dissolve in the oil. On exposing the boiled oil to air, oxygen is rapidly absorbed, and drying is brought about by the conversion of the liquid oil into a solid resin. If white lead (oxycarbonate of lead) or red lead (an oxide) be thoroughly ground in such oil, a paint is formed which has great covering power, and which, in air, forms the best protection the iron can have, as microscopic examination shows that the dry film of paint contains no pores, and so forms an impervious coating.

The covering power and impervious nature of such a paint are due to the fact that the lead compound has formed with it a soap (oleate of lead), whilst in most other pigments no such combination takes place, and the particles of colour are merely mechanically carried by the vehicle.

Such paint will resist atmospheric influence for a long time, but eventually the protecting skin becomes hardened and brittle, so as to be easily chipped off, whilst as the decomposition proceeds still further, it loses all its adhesive powers and flakes off from the metal. Red oxide of iron free from foreign matters and any trace of acid also forms a good pigmentary material for a protective paint, and is especially popular with paint manufacturers, as its colour masks any rusting that may go on below it.

Many cheap paints of this character, however, prove unsatisfactory, owing to the oxide of iron being largely adulterated with finely powdered barium sulphate, which, being very heavy, is often used as a 'loading.'

The best treatment for large iron structures is, in the first place, to entirely free them from all traces of 'bloom' or mill scale which may be adhering to them, this being done either by pickling in dilute sulphuric acid with subsequent neutralisation of the acid, which should be done before erection, or by allowing them to flake off by the formation of a film of rust from exposure, and then wire-brushing the surface until it is free from any trace of oxide.

The surface so prepared should, at the time of painting, be thoroughly dry, and under these conditions a coating of hot linseed oil, followed by two coats of red lead paint, and finished off with two coats of iron oxide paint, will give the best protection that can be obtained.

Varnish paints, such as will be described later, for use in coating ships, are not to be recommended for outside work, as under atmospheric influences they often tend to become brittle.

Almost equally good as the red or white lead paints as a protection is a bituminous paint made from pitch, the distillation of which has not been carried too far. This must be absolutely free from free carbon and tar acids or ammonium salts, and if applied hot to the structure to be protected, gives very good results, the colour being the main drawback.

There are many circumstances under which

such a bituminous paint is preferable to an oil paint, as, for instance, in gas works, urinals, or slaughter houses, where there is much ammonia in the air, which has an extraordinarily destructive effect upon oil paints.

In the manufacture of paints for protective purposes it is essential that the materials should be ground to the utmost degree of fineness, and great attention should be paid to the thorough incorporation of the pigment with the vehicle, whilst where several coats of paint have to be superimposed on each other, the composition should be so arranged that the rate of drying of each coat should be a little less than the one below, as this prevents any chance of the upper film hardening before the lower coating, which would result in cracking the coating of paint. It must also be borne in mind that in painting an iron structure, the skin left by the paint should have the same rate of expansion and contraction as the metal, or be sufficiently elastic to prevent any cracking away from it.

In cases where rusting begins to show itself by the blistering and upheaval of the paint surface, the plating at that point should be scraped down to the bare iron, and well scrubbed with a wire brush in order to remove the traces of foreign matter that are probably giving rise to rapid corrosion due to electrolysis.

V. B. L.

CORROSION AND FOULING OF STEEL AND IRON SHIPS, AND ITS PREVENTION.

In the days of wooden ships the hull troubles that had to be guarded against were the attacks of wood-boring animals and the loss of speed due to the growth of weed and shell at and below the water line; but with the launch of the first sea-going vessel built of iron, in 1822, comparatively simple problems became of great complexity, and at the present time the protection of our Navy and mercantile marine from corrosion and fouling is a question of the greatest importance, affecting, as it does, both the life and speed of the vessels.

Corrosion.—The troubles due to corrosion are by no means limited to the exterior plates of the ship, but also affect the interior of the structure, boilers, and condensers.

The corrosion of iron and steel is brought about by the actions which ultimately result in the conversion of the metal into oxides, and these being accelerated by galvanic actions, which it is almost impossible to eliminate in a huge metallic structure like the hull of a modern ship in the presence of sea water, makes prevention far more difficult than in the case of an iron building or bridge.

In sea water the process of corrosion is accelerated by the salts contained therein, as these aid the galvanic action set up in the metal by various means, such as impurities in the iron, the presence of mill scale on the plates, high temperature, or even the different stresses imparted to portions of the same plate, whilst in certain waters, such as the mouths of rivers on the west coast of Africa, or in harbours where the water contains much sewage, the sulphates are decomposed by various vegetable and animal organisms with evolution of sulphuretted hydrogen, which greatly increases the corrosion of the metal.

The examination of the condition of the

bottom plates of vessels that have been at sea for long periods, shows, when the protective paints and compositions have been removed, that three distinct forms of rusting may be distinguished.

1. Rust patches, generally near the edges of the plates, consisting of small areas of fine rust, probably caused by moisture on the plate when the protective paint was put on. These patches are never thick, and cause but little damage to the plates if all rust be removed before a new coating of paint is put on.

2. Rust nodules are a more localised form of corrosion which has attacked the metal where particles of mill scale have been left on the surface of the new plate, or where small particles of slag or foreign matter have been rolled into the plate during manufacture. These give slight pitting of the plate, but seldom to a serious extent.

3. Rust cones are an accentuated form of rust nodules, and are due to the most local form of galvanic action, caused by the presence of a speck of deposited copper, lead, or other foreign metal, or even a small particle of rust or mill scale left on the surface of the iron, and covered by the compositions used as protectives and antifoulers. As soon as the sea water penetrates these, galvanic action is set up, water is decomposed, rust formed, and the escaping hydrogen pushes up the composition, forming a blister; the hydrogen escapes and water leaks in, the action becoming more and more rapid, and the blister gradually filling with the product of the action—rust. The blister bursts, but the cone of rust has by this time set fairly hard, and continues to grow from the base, the layers of rust being easily distinguished in a well-formed cone, and when the rust cone is detached, the pitting of the metal at the base of the cone is, as a rule, found to be of considerable depth.

Extensive researches by Andrews, Phillips, and others show that, as a general rule, steel corrodes more quickly than iron in sea water, and that the rate of corrosion increases very rapidly with the length of exposure, owing to the galvanic action exerting a greater influence as the amount of oxide increases; but with the almost universal adoption of mild steel as the material for the construction of the hulls of modern ships, this trouble has not proved as serious as was at first feared would be the case.

Certain portions of a ship's hull are exposed to special risk of corrosion from galvanic action, owing to the bearings of the screw shaft and valves for the escape of waste water, bilge, &c., being made of alloys containing copper. In order to prevent this, zinc protectors, consisting of heavy masses of the metal, are placed round all openings where copper or copper alloys are present, and the zinc, being more electro-positive than the iron, places the iron in the electro-negative condition, so that whilst the iron escapes injury the zinc rapidly dissolves.

Protection of iron from corrosion.—In order to protect the outer surface of iron and steel structures, two different methods have been tried. The first process is to coat the iron with another metal which is less liable to be attacked by the moist carbon dioxide and oxygen, or which is electro-positive to iron, whilst the

second is to cover it with some paint or varnish which will prevent these harmful compounds from acting on it.

The chief metals which have been tried for coating the iron are zinc, tin, nickel, and copper. Of these zinc has been very extensively used, and the galvanising of the thin plates used in many forms of craft proved a very valuable protection, but the sheathing of vessels with zinc, which has also been tried, never proved very successful. With the other metals, as long as the iron is protected by the coating remaining intact, no corrosion will result, but as soon as the surface of the metal becomes abraded, the iron will rust at a much greater rate than if it had been left unprotected, as the two metals will set up a galvanic current, in which the iron is the electro-positive element, which vastly increases the corrosive effect, and at the present time this class of protection has practically been abandoned for ships.

The second method of protecting the exterior of the bottoms of iron and steel ships from corrosion, and which is the one most universally adopted, is to coat them with so-called anti-corrosive or protective paints and varnishes. In order that this should be successful, much depends upon the state of the hull at the time at which the protective is put on.

The bottom plates of the newly built vessel are thickly coated, as a rule, with mill scale or magnetic oxide of iron Fe_3O_4 , which is formed on the surface of the plate during rolling, and which, if it remains perfectly intact, would be an excellent protective, as it forms, indeed, the basis of the Bower-Barff process for the protection of iron; but during the shearing and rivetting of the plates this scale gets broken off and exists only in patches, which, if left upon the plate, would excite rapid local galvanic action, owing to the fact that this scale is strongly electro-negative to the iron, so that it would need only the exciting influence of the sea water to start the action.

In naval vessels, the plates are pickled in dilute sulphuric acid until all the scale is removed, and all traces of the acid are in turn destroyed by immersing the plate in lime water or other alkaline solution, a precaution which is extremely necessary, as, if any trace of iron sulphate is left on the plate, this again is actively corrosive.

In the mercantile marine it is an ordinary practice to launch a vessel without any paint on the hull, leaving the active, but fairly even, rusting which ensues to remove the scale, the ship being scrubbed down and then protective compositions painted on when it is docked.

This method has the advantage of cheapness, and also of giving a very slightly roughened surface, to which the protective composition adheres firmly, and answers well with tramp steamers and other craft where speed is not an object of paramount importance; but with service vessels and liners, slight as the roughening is, it undoubtedly has an influence on the speed.

The hull of the vessel, being perfectly free from mill scale, and as free as it can possibly be got from the ordinary oxide, is then painted with the protective, but for this to prove effective, the hull must be absolutely dry, a condition which is exceedingly difficult to obtain, as the big mass of iron is generally a few degrees

in temperature below that of the moisture-laden air, and under these conditions a trace of moisture condenses on the surface, which is spoken of as 'sweating' of the metal, and this prevents the proper adhesion of the paint to the metallic surface, and also starts rusting under the paint.

With electricity available for utilisation in an air heater, it would, in most cases, pay to dry the hull with a hot-air blast, while the first coat of protective is being put on.

The anti-corrosion or protective paints used for coating ships' bottoms may be classified as :

1. Oil paints.
2. Heavy hydrocarbons, such as pitch, asphalt, or tar.
3. Varnishes, resins, and gums dissolved in volatile solvents.
4. Varnish paints, containing metallic oxides to give them body.

Oil paints are the oldest form of protectives in use, and, when the plates are painted when hot and dry, amongst the best and most lasting; but the drying of such paints, being dependent upon the slow oxidation of the boiled oil by air into a resin, requires that a considerable time must elapse between the painting of the ship and the coating becoming hard enough to allow of the anti-fouling composition being painted on over it, and as a rule so short a time is allowed for docking that this is a great drawback.

The old paints for this class of work used to consist of red or white lead mixed with boiled linseed oil, but it was shown by M. Jouvin that with the perishing of the vehicle the lead compounds were converted into chlorides and oxychlorides by the sea water, and these were then reduced by the action of the iron of the hull with formation of crystals of lead, which set up galvanic action and led to rapid corrosion.

A ship before her launch often receives a coating of such paint from the builder, which is generally scraped off before she is finally coated for service with her protective and anti-fouling compositions.

Undoubtedly the best and most lasting protectives belong to the second class, and a good pitch containing little or no free carbon, or an asphalt painted on when liquefied by heat, gives perfect protection to the metal below it. Unfortunately, the pitch and tar made at the present time are unfitted for such work, as the high temperature employed in gas making has ruined the quality of the tar, which often contains over 30 p.c. of free carbon and naphthalene.

In case tar or tar products are used, care must be taken to free them from all traces of tar acids or ammonium salts, both of which tend to increase corrosion.

The third and fourth classes of protectives came into use when it became necessary to cut down the time expended in docking, and they owe their rapid drying powers to the fact that, instead of waiting for oxidation to form a resinous mass, as in the drying of boiled oil, a resin is dissolved in a highly volatile solvent, being mixed with boiled linseed oil to give the necessary elasticity, and when this is painted on the hull of the vessel, the rapid evaporation of the solvent leaves the resin and oxidised oil binding the body colour together.

Shellac, rosin, kauri, and many other gums and resins are used, whilst the solvents may consist of light hydrocarbons, such as the various grades of solvent naphtha, alcohol, and even fusel oil, but in the Navy very low flash-point solvents have now been discarded owing to the danger in storage.

In most of the various paints red oxide of iron is used to give body and colour to the mixture, and, as it is the same colour as the rust that may form under it, it is very popular with the composition manufacturer, and, providing it be free from acid and soluble sulphates, is unobjectionable; but perhaps a better material would be the mixture of finely divided zinc and zinc oxide, such as is obtained in the Belgian process of distilling zinc, as, even after the varnish had perished, the zinc would afford a further term of protection.

The drawbacks to the last two classes of protectives are that the solvents employed for dissolving resins and gums are mostly affected by water, with the result that if the plates are not dry, the resins are apt to be deposited in a pulverulent condition, whilst the cold produced by the rapid evaporation of the solvent tends to increase the amount of moisture deposited, which assists in the deterioration of the coating.

These varnishes also, even when dry, are not impervious to gases and liquids. Under a microscope the coating is seen to be full of minute tubes, through which the sea water finds its way to the iron beneath, and, when once corrosion has been started, the protective coating is gradually forced away from the surface of the iron, exposing more metal to be acted upon. The best results are secured by employing several coats of the varnish, and applying it only in weather favourable to the operation, plenty of time being given for the thorough hardening of the material before water comes in contact with it.

The protection of the interior surface of the hold of a ship presents some special complexities, as it is exposed to the wear and tear of taking in and discharging cargo, and one has to take into consideration such sources of trouble as the action of bilge water, the high temperature, and the presence of foreign bodies such as coal-dust and leakages from cargo. There are three classes of protectives used for the interior portion of a ship :

- Cements;
- Bituminous coatings;
- Paints.

Although cement is very largely used, yet there are certain drawbacks attached to it which render it by no means the ideal material. It has a certain amount of porosity, so that any corrosive liquid penetrates it and acts on the iron beneath; its rigidity causes it to come away from the metal on any strain being thrown on the latter, variations in temperature having the same effect, and where the coating has parted from the iron, corrosion will start and remain unseen until perhaps too late.

Bituminous coatings applied hot are far preferable to cement, but are rather more troublesome to put on.

Corrosion of boilers.—A serious form of corrosion is to be found in the rusting and pitting of the plates and tubes of high-pressure

boilers. Before the adoption of mineral lubricants, it was supposed that the decomposition of the lubricating oils by the superheated steam in the cylinders caused the corrosion owing to the fatty acids liberated, but the same effect has been found with hydrocarbon oils, so that the pitting is evidently not due to this cause.

There are several causes which lead to the corrosion found in boilers, amongst which are ordinary corrosion, set up by the carbon dioxide and oxygen which occur naturally in all water, and which act on the metal when the boiler is out of use. This form of corrosion can be prevented by filling the boiler quite full with boiled water rendered slightly alkaline with a little lime and closing air-tight whilst at rest. Secondly, galvanic action, induced by the difference in potential between the rust formed by ordinary corrosion and the iron, and also by metallic impurities in the iron and specks of foreign metals deposited upon it. This action can be prevented to a great extent by the use of zinc blocks inside the boiler and in metallic connection with the iron of the plates. A third cause of corrosion is to be found in the solvent action of distilled water upon the metal of the boiler, the action getting less with increase in the quantity of salts in solution in the water. The fourth cause arises from the high local temperature brought about by incrustation or deposits on the surface of the tubes or plates; at such places the temperature often is not far below that of a dull red heat, and then iron is able to decompose water, forming black magnetic oxide of iron and liberating hydrogen:

The obvious remedy for this trouble is, of course, to prevent the formation of incrustation by paying attention to the water with which the boiler is fed, and with the use of 'softened water' or condenser water, which has been passed through an oil filter, the trouble disappears.

Corrosion of condenser tubes.—Alloys of copper and zinc in certain proportions, when subjected to the corrosive action of sea water and carbon dioxide, gradually lose the zinc from the alloy, and this leads to serious pitting, and corrosion, especially in the case of condenser tubes, which are made of copper-zinc alloys, and are exposed to the action of sea water used for cooling on one surface and to the solvent action of distilled water on the other.

It has been found, however, that the addition of 1 p.c. of tin to a brass containing at least 70 p.c. of copper practically puts an end to the trouble. Even where a good brass has been used for the condenser tubes, it is occasionally found that corrosion takes place, but the cause is probably the presence of some foreign material or want of uniformity in the composition. Bronze does not corrode readily when in contact with iron, but is slowly attacked when associated with copper.

Fouling of ships and its prevention. The question of the fouling of ships' bottoms is one that has existed from the earliest days, and was, indeed, of even more importance 200 years ago than it is at the present time, owing to the increase in dock accommodation allowing the more frequent cleaning and painting of the ships; but even now in the case of war the

loss in speed during blockading operations, owing to the fouling of the vessels, might prove an important factor in a struggle for supremacy.

Fouling consists of various marine growths, both animal and vegetable, which attach themselves to the bottom of the vessel, and by increasing the skin friction whilst the vessel is in motion, seriously reduce its speed, and it is by no means an uncommon thing for a tramp steamer, with a normal speed of 9 knots, to be reduced to 5 or 6 knots by such fouling.

The nature of these growths needs to be studied in properly equipped marine biological laboratories, as but little is at present known of the life-history of many of the organisms which are found on a ship's bottom. The main factors, however, are that it is only during the germ or spore period of their existence that they can attach themselves to the bottom of the vessel, and that although the full-grown results are found when the vessel is docked, these growths have taken place *in situ*.

The open ocean and the northern seas are comparatively free from these organisms, but directly inland seas or tropical waters are reached they increase to an enormous extent in variety and numbers, and some harbours, such as the port of Sourabaya, are noted for the fouling influence of their waters. Moreover, it is found that the period of the year exercises a very important influence upon the fouling nature of the water, the spring and early summer being the chief time for these growths to find a lodgment on the bottom of a vessel.

The more common growths are serpulæ, generally called coralline, barnacles, mussels, membranæ, and oysters, usually classified together under the name of 'shell,' whilst at or near the water line are found luxuriant growths of sea grass (*Enteromorpha compressa* and *Zostera marina*), and towards the bottom ribbon and other weeds, like the tufted weed or bugula, flourish.

Fouling commences with the deposition of a slight slime on the side of the vessel, which is apparently of an albuminous nature, and contains the germs and spores of various marine growths, and is so slight as to escape notice.

The first visible sign of fouling on a ship is the appearance of green grass at the water line, and this, in bad waters, will begin to show after a few weeks, whilst the growth will spread downwards from the surface for 5 or 6 feet, but rarely extends below 10 feet, as the growth needs plenty of light and warmth.

It is the most widely distributed form of fouling, and appears in nearly all waters, and, once formed, the grass protects the germs of other growths, and so helps on the general fouling.

In northern waters fouling seldom goes beyond the 'grass,' but in warm climates, especially if long in port, 'shell' soon begins to appear, unless a really good anti-fouling composition is employed for coating the vessel's bottom.

Ships trading to or stationed near the mouths of rivers often show curious results in the kind and extent of the fouling, the marine growths being often killed by the fresh water, but such vessels foul again very rapidly when once more going to sea, owing to slight deposits of mud and calcium carbonate from the river water.

With wooden ships the necessity of protection against the wood-boring teredo worm as well as fouling led to the adoption of copper sheathing, and when the metal used was of a fairly pure character, it was found to be thoroughly satisfactory, and not only to give complete protection to the vessel, but also to enable it to remain at sea for a very considerable period. The cost, however, was high, and attempts were made to prevent the excessive waste of the copper by using zinc protectors, as advocated by Sir Humphry Davy, but it was soon found that with the prolongation of the life of the copper plates, fouling again became serious, whilst when later rolled sheets of alloys containing zinc, such as Muntz metal, were tried, the same trouble again appeared, and it has been clearly proved that the power a copper plate exercises in preventing fouling is inversely proportional to its power of resisting the action of the sea water.

The action of the copper in anti-fouling is that, in the first place, the salts in solution in the sea water act upon the copper with the formation of chlorides and oxychlorides, the former poisonous to all forms of marine life in the germ state, whilst the latter formed a coherent pellicle to which the growths attached themselves and which was torn off during the passage of the vessel through the water by the skin friction, thus enabling it to shed any form of growth that might have attached itself to the plate.

It was found, however, that if the copper were not of the purest, coralline growths very soon attached themselves so firmly through the surface of the skin of copper compounds that it was difficult to remove, and gave points of adherence for fresh vegetable growths.

With the introduction of steel and iron ships, as was natural, attempts were made to utilise the same form of protection from fouling which had proved so satisfactory with wooden ships, and from time to time during the past 80 years efforts have been directed to sheathing iron ships with copper in the same way. It was soon found, however, that this sheathing set up such severe galvanic action with the hull of the vessel as to be impracticable, and although these attempts were abandoned at a very early period in the mercantile marine, the naval services of several countries have tried its use for service vessels, the generally adopted method being to sheathe the iron hull with wood and to attach to this the copper in such a way as to be insulated from the electro-positive iron.

These experiments met with more or less success, but with increase in dock accommodation, the tendency has been more and more towards the use of anti-fouling paints or compositions, which could be painted on over the protective coating of the vessel, and some 80 compositions have been placed on the market with varying success for this purpose.

When anti-fouling paints were first manufactured, the only fact at the service of the maker was the experience which had been gleaned from copper sheathing, and on the assumption that the action had been due to the poisonous character of the chloride and oxychloride of copper produced on the plates by the salts in the sea water, compositions were made contain-

ing large quantities of corrosive metallic poisons, which, held in a varnish of a more or less lasting character, gave the protection from fouling for a few months.

As has already been pointed out, the action of the copper sheathing was due to two causes: first, the poisonous action of the copper salts on the germ life; and, secondly, the stripping of the pellicle by skin friction when any quantity of growth had formed on its surface, an action termed 'exfoliation.' How important this latter action was may be judged from the fact that when the vessel remained at anchor in a harbour, the sheathing would last from 10 to 12 years, whilst when on active service the same sheathing would last for only 4 or 5.

Finding that poisons alone gave very unsatisfactory results, the manufacturers of anti-fouling compositions began to make perishable varnishes and grease paints, which should, by the deterioration and wasting of their surface, imitate as nearly as possible the exfoliation of the copper sheathing, and such anti-foulers gave under certain circumstances much more successful results. The idea was that the ship, having been coated with a protective paint or composition to preserve the iron, a second or more coatings was put on over the protective, consisting of varnish paints which should slowly yield soluble poisons to the sea water, and in doing so would lead to the disintegration of the varnish surface, which, being washed off, exposed fresh quantities of the poisons to the water.

Such compositions proved very satisfactory in the mercantile marine, and all the time that a vessel was actively engaged in going from port to port gave excellent results, but directly these same compositions, which had gained a reputation in the merchant service, were tried on Service vessels, they were found to be as unsatisfactory as those which before had been in use. The reason for this failure is evident. Take the case of a liner trading between New York and England: she is run at a high speed between these two ports for the main portion of her life, remaining in the basin for as short a period as possible in order to utilise to the full her money-earning capacity; for such works it is easy to arrange an anti-fouling composition, which, with the aid of the skin friction of the vessel, would cause just sufficient wasting of the coating to give the best results. When, however, this is applied to a Service vessel, she probably goes out from dock into the basin and remains there stationary for perhaps months, and then goes to sea, where she is kept manoeuvring at various rates of speed for a considerable period. During the period she is in the basin, the composition undergoes practically no wasting, and a thin film of carbonate of lime and mud deposits on the surface, which forms an excellent foothold for any germs and spores that may be in the water, and which, on going to sea, have often advanced too far for the growth to be readily got rid of.

The bad results so obtained led to a composition being put on which wasted with sufficient rapidity to prevent any such deposition in harbour, with the result that when the vessel went to sea, the deterioration being accelerated

to an enormous extent by skin friction, the composition was practically all exhausted in a very short time.

In the Service this trouble will never be got rid of until the painting of the bottoms of the vessels is placed in the hands of an expert, with a knowledge of the work which a vessel has to perform, and who can adjust the composition to the duty which has to be done. In the merchant service, where this is well known and can be provided for, very little trouble now exists.

The most efficient anti-fouling compositions all contain copper or mercury as the poison. In some cases soluble salts of these metals are employed with a fairly strong and lasting varnish; in others oxides or insoluble salts are used with varnishes which perish more rapidly on their surfaces and allow the action of the sea water to convert the compounds into soluble salts.

It is evident that with compositions containing such metallic compounds every attention must be paid to the protection of the hull, as otherwise the formation of soluble salts of copper and mercury might result in the deposition on the iron of these metals by reduction, in which case rapid galvanic action would be set up, and would lead to serious pitting of the plates of the vessel.

The compositions of the present day may be divided into two classes:

1. Grease paints containing a metallic poison;
2. Quick-drying varnish paints, also charged with the same poisonous constituents.

The former class has met with a considerable degree of success, but they have also several very serious drawbacks. As regards the prevention of fouling, they give results not very far removed from the best varnish paints, and in certain waters, such as the Mediterranean, have proved themselves to be excellent anti-foulers, but they undoubtedly increase the skin friction of the vessel, and so tend to diminish speed; whilst a second trouble is that, although a varnish paint may often be scrubbed and touched up where fouling has been but slight, with a grease paint the whole has to be removed before recoating, and they are much more costly than the varnish paints, with the result that in the merchant service they are used only to a very limited extent. Another drawback to their use is that it is impossible to properly scrape and recoat the vessel during the short period of docking which would suffice for a varnish paint.

In the manufacture of varnish paints it is necessary to mix with the solution of gum or resin in a volatile solvent a sufficient proportion of linseed oil to give elasticity to the vehicle, and these paints have been in use in England since about 1870, the greatest advance in them being due to the introduction of the hot process in their manufacture, which enables a more intimate mixture to be made with greater adhesive power and a smoother surface.

The rate at which disintegration of these paints takes place is governed largely by the kind of gum used in the varnish, and by the amount of mineral matter introduced as colouring and poisonous material, the solubility of

these having a considerable influence on the rate of disintegration.

With a tough and tenacious vehicle, which by itself would undergo but little disintegration under the action of sea water, it is quite possible to use soluble mercury or copper salts, which are liberated only very slowly during the gradual destruction of the varnish. On the other hand, if a rosin varnish be employed, insoluble bodies, like the oxides of copper and mercury, the sub-chloride of mercury, or Scheele's green (copper arsenite) may be used, the oxides and other salts, when exposed to the sea water, being very slowly converted into soluble chlorides.

Many compositions contain arsenic and arsenic compounds, such as sodium arsenite, as these had been found effective as weed killers under ordinary conditions, and it was expected that in a composition they would prevent the growth of grass at the water line, which, as it caught the eye, gave the impression of the ship being very foul. Experience showed, however, that the arsenic had but little effect, and mercury and copper still remain pre-eminently the metallic poisons of the greatest value in anti-foulers.

One of the most difficult portions of the ship to deal with is what is known as the 'boot top,' that is, the portion between the heavy and light load line, as when a ship is discharging cargo the anti-fouling composition over this portion is exposed to the sun and rapidly perishes and peels off, whilst when the ship is again loaded, it is once more immersed, and the alternate action of sunshine and air and sea water perishes the paint at the very spot where it is most likely to be abraded by contact with lighters and barges, the result being that it is often necessary to touch up this portion of the vessel with paint during the voyage, and as good anti-fouling paints are rarely carried for this purpose, this portion of the ship is often painted with ordinary paint, and hence is liable to more damage than other parts of the vessel.

In some anti-fouling varnish paints the poisonous metals themselves have been carried in a very fine state of division, some paints containing very finely divided copper, precipitated from the solution of a copper salt by iron or zinc; whilst others contain metallic mercury in a comminuted condition, obtained by adding stannous chloride to the solution of a mercurous salt; these paints, however, show but little advantage over those containing salts of the metals.

CORROSIVE SUBLIMATE (*Mercuric chloride*)
v. MERCURY.

CORUBIN v. ABRASIVES.

CORUNDUM. (*Corindon*, Fr.; *Korund*, Ger.) Native alumina; so called from its Sanskrit name *korund*, whence it is assumed that the mineral was originally brought to Europe from India. From its hardness, which is second only to that of the diamond, it is sometimes known as *adamantine spar* (*Diamantspat*, Ger.). Emery is an impure variety, never crystallised (v. EMERY). Corundum crystallises in the rhombohedral system, usually in double six-sided pyramids and rhombohedra, with the basal plane. The crystals sometimes show a lamellar parting parallel to the faces of the rhombohedron or the base. The lustre is vitreous, and

therefore different from that of diamond; some varieties exhibit a pearly lustre on the basal plane. It is optically uniaxial; double refraction negative, $\omega = 1.769$, $\epsilon = 1.759$. The coloured varieties are markedly pleochroic. H. 9; sp.gr. 3.9-4.1. Infusible before the blow-pipe; but with borax fuses, with difficulty, to a clear glass. Unattacked by acids. The fine powder, strongly heated with cobalt solution, gives the characteristic blue colour of alumina.

The dull-coloured and opaque varieties, to which the term 'common corundum' is sometimes applied, occur chiefly in India, China, Siberia, and the United States. The mineral has been obtained for ages from the old crystalline and metamorphic rocks of Southern India, notably from the Salem district, Madras. Large deposits of grey, red, or purple tints occur near Singrauli, in South Rewah, where it is systematically worked. The hardness of the mineral renders it difficult of extraction, and fire is often lighted against the face of the rock to aid in loosening fragments. According to Newbold, the Indian corundum occurs in gneiss, mica-schist, or hornblende-schist. (On Indian corundum, v. T. H. Holland, *Man. Geol. Ind.* 2nd ed. 1898.)

In America large deposits of corundum occur in the older rocks of the Atlantic States, especially in North Carolina and Georgia. In 1871 it was discovered by C. W. Jenks at Corundum Hill, Macon Co., North Carolina, where the common varieties passed into brightly coloured transparent forms, sufficiently fine in some cases to be cut as gem-stones, and interesting as affording the first instance of the occurrence of ruby and sapphire in their original matrix (*Quart. J. Geol. Soc.* 30, 1874, 303; J. W. Judd and W. E. Hidden, *Min. Mag.* 1899, xii. 139).

This deposit, as well as that at Laurel Creek, Georgia, has been extensively mined. The corundum at both localities occurs in association with peridotite and hornblende-gneiss. Blocks weighing as much as 5000 lbs. each have been extracted. The corundum is prepared for the market by a succession of crushings and washings, the dressed mineral being finally sifted so as to separate it into various grades of fineness, distinguished in trade by numbers; the finest being known as 'flour.' The crushing is performed by means of stamps and rollers, but these require frequent repair in consequence of rapid wear due to the extreme hardness of the mineral. It is more difficult to crush corundum than emery, in consequence of its superior hardness.

Corundum is largely used as an abrading agent. Taking the abrasive power of sapphire as 100, that of the American corundum varies from 90 to 97, while that of Naxos emery is only between 40 and 57. The abrasive power, or 'effective hardness,' is estimated by rubbing a weighed sample of the mineral on a piece of plate-glass; the glass is weighed before commencing the operation, and is re-weighed from time to time during the grinding, when its loss affords an estimate of the abrading power of the substance. Of late years corundum has been largely used in the form of 'corundum wheels,' which are prepared by incorporating the coarsely crushed mineral with a medium that admits of being readily moulded. (On American corundum,

v. J. H. Pratt, *Bull. U. S. Geol. Surv.* No. 269. 1906; J. H. Pratt and J. V. Lewis, *North Carolina Geol. Surv.*, i. 1905.)

The transparent variety of corundum, when cut and polished, is highly valued as a gem-stone. When blue, it is termed *sapphire*, while the clear colourless stones often pass under the name of *white sapphire*. The red varieties are known as *ruby*, or as *oriental ruby*, the qualifying word being used to distinguish it from inferior stones, such as spinel, which are also termed 'ruby' ('spinel-ruby' and 'balas-ruby') *Barklyite* is a turbid magenta-tinted corundum from Victoria. The other coloured corundums are generally known as 'oriental' stones; thus the yellow varieties, though sometimes called *yellow sapphire*, are usually termed '*oriental topaz*'; the purple stones are distinguished as '*oriental amethyst*'; and the green corundum, which is the rarest of all, is prized as '*oriental emerald*.' The following analyses of some typical forms of corundum were made by J. Lawrence Smith (*Amer. J. Sci.* 1851, [2] 11, 54):

	Al ₂ O ₃	Fe ₂ O ₄	SiO ₂	CaO	H ₂ O
Sapphire (India)	97.51	1.89	0.80	—	—
Ruby (India)	97.32	1.09	1.21	—	—
Corundum (India)	93.12	0.91	0.96	1.02	2.86
Corundum (Asia Minor)	92.39	1.67	2.05	1.12	1.60

It is believed that the ruby owes its colour to the presence of oxide of chromium. When strongly heated, it becomes green, but regains its normal colour on cooling. The nature of the colouring matter of sapphire is not well understood; and though cobalt has been suggested, its presence has not been proved, and it seems likely that some compound of chromium is here also the tinctorial agent. Certain sapphires become decolorised by heat. It is notable that in many sapphires the pigment is locally distributed, so that the stone is parti-coloured.

Haidinger's dichroscope, which is frequently used to distinguish one gem-stone from another, may sometimes be usefully applied to the coloured corundums. In many sapphires the two images differ greatly in tint, one being dark blue while the other is pale bluish-green, or even yellowish: in other sapphires, however, the difference of tint is very slight. In dealing with highly pleochroic stones, the phenomenon may be observed with the unaided eye. Thus certain sapphires appear blue when viewed in the direction of the optic axis or along the principal axis of the prism, and green at right angles to this direction or perpendicularly to the prismatic faces. In ruby the dichroism is not so marked as in sapphire. Viewed in the dichroscope, one image may be deeper than the other: the red of the one inclining to violet, that of the other to yellow.

The ruby may be distinguished from all other red stones by its superior hardness. From spinel and rubellite it may be separated by its high sp.gr. If the dichroism can be detected, this character will distinguish it from either garnet or spinel, since these minerals crystallise in the cubic system, and are consequently not pleochroic.

Coloured corundums frequently contain minute fluid cavities and microscopic crystals, which have been studied by H. C. Sorby and

P. J. Butler (Proc. Roy. Soc. 17, 1869, 291). According to these observers, the fluid cavities are more numerous in sapphire than in ruby; while the enclosed crystals are more abundant in ruby than in sapphire. The inclusions often give a milky and defective appearance to the stone, and when definitely orientated produce curious optical phenomena. It seems due partly to these lines of inclusions, and partly to a system of striations intersecting at 60° , that certain corundums, when cut with a convex surface, display by reflected light a luminous six-rayed star. This phenomenon is not uncommon in blue-grey opalescent sapphires, which are consequently known as *asterias* or *star-sapphires* (*Saphir asterié*; *Sternsapphir*). It is notable that the hardness of the sapphire slightly exceeds that of the ruby.

Sapphires are found as rolled crystals and pebbles in detrital deposits in Ceylon; and they occur with rubies in Upper Burma. Some years ago fine sapphires were discovered in the Zanskar range of the Himalaya Mountains; and large deposits of dark-coloured stones have been found in the province of Battambang in Siam. Near Helena, in Montana, U.S., rolled crystals of sapphire are found in placer mining. In Europe small sapphires occur in certain basaltic rocks, as in the Siebengebirge on the Rhine, and at Expailly, near Puy-en-Velay in France: but the European stones are worthless.

Sapphire is not uncommon in the gold-bearing drifts of New South Wales and Victoria, but the ruby is rare. The late A. M. Thomson, of Sydney, made the following analyses, cited by A. Liversidge, in the Min. of N. S. W. 1888, 196:—

	Al_2O_3	Fe_2O_3	CaO	MgO
Sapphire (Mudgee)	98.57	2.25	0.45	—
Ruby (Two-Mile Flat)	97.90	1.39	0.63	0.52

Most, if not all, of the so-called 'Australian rubies' and 'Adelaide rubies' are merely garnets. In like manner, the garnets from the diamond-mines at Kimberley pass in trade under the name of 'Cape rubies.'

The true ruby is of much more limited distribution than the sapphire. It occurs but sparingly in the gem-bearing detritus of Ceylon, where sapphires are common. The chief ruby locality is at Mogok, in Upper Burma, where the rubies occur in detrital deposits and in a bed known locally as *byon*. The mother rock of the Burmese ruby is a white crystalline limestone occurring as thick bands, interfoliated with gneisses (C. B. Brown and J. W. Judd, Phil. Trans. 1896, 187, A, 151; T. H. Holland, l.c.).

The artificial production of ruby has been effected at various times by Gaudin, Elsnor, Ebelmen, De Senarmont, Sainte-Claire Deville, and Caron and Debray; but it was not until the experiments of Frey and Feil in 1877 that the substance was obtained well crystallised in any quantity. By fusing a mixture of alumina and red lead in a fireclay crucible, these experimentalists obtained a fused aluminate of lead, which was decomposed by the silica of the crucible with formation of silicate of lead, while free alumina crystallised out, on cooling, as white corundum. By the admixture of from 2 to 3 p.c. of potassium dichromate with the original materials, the resulting alumina separated

in the form of ruby, while the association of a small proportion of oxide of cobalt with the potassium dichromate determined the production of sapphire (Compt. rend. 1877, 85, 1029). E. Frey and A. Verneuil also obtained fine artificial rubies by the reaction of barium fluoride at a red heat on amorphous alumina containing traces of potassium dichromate. The substance thus obtained possesses all the physical characteristics of natural rubies, and Des Cloizeaux has shown that they agree in crystalline form (Compt. rend. 1888, 106, 565, 567).

The jewellery trade was much disturbed about 1886 by the appearance of large numbers of rubies of fine colour sold by a house in Geneva. Having excited suspicion, the stones were placed in the hands of C. Friedel for examination. He found them to agree with the natural ruby in all respects, except that they contained little spherical blebs, readily seen with a hand-lens, whence he concluded that they had been formed by the fusion of a number of small rubies. Stones of small size are of comparatively little value, while a large ruby, of fine colour, always commands a very high price. Terrell and Verneuil have fused amorphous alumina in the oxyhydrogen blowpipe, and E. Jannettaz has examined the behaviour of this product when subjected to electric discharge in Crookes' exhausted tubes, and found it to agree with that of the Geneva rubies and the natural corundum by glowing with a vivid red light (Bull. Soc. Fr. Min. 9, 1886, 321).

In 1904, A. Verneuil devised a still more successful process, by which fine gem-stones of almost any size can be produced with ease. The material he uses is pure alumina (precipitated by ammonia from a solution of ammonium-alum), which, in a powdered form, is fed through the oxygen tube of an inverted oxygen-coal-gas blowpipe. The alumina falls as a molten drop on a pedestal beneath, and there crystallises as corundum. As the operation is continued, the corundum grows upwards as a pear-shaped drop or 'boule.' Although these drops have a smooth rounded exterior, with no external crystal faces, they each consist of an individual crystal with an internal crystalline structure, and identical in all their characters with naturally occurring corundum. From natural corundum they can only be distinguished by the presence of microscopic air bubbles, and very fine internal streaks, which are curved (and not straight, as in the natural stone). When the alumina is quite pure, and no colouring materials have been added, the artificial corundum so prepared is colourless: a fine ruby-red colour results by the addition of some chromium-alum to the ammonium-alum. Attempts to produce a sapphire-blue colour by the addition of cobalt at first were not successful, but this has been obtained by adding magnetic oxide of iron (1.5 p.c.) and titanium dioxide (0.5 p.c.) (Compt. rend. 1910, 150, 185). Excellent gem-stones are now produced in large quantities by this process. I. J. S.

COSMOS REDS v. AZO-COLOURING MATTERS.

COTO BARK. True coto bark is obtained from Bolivia, the Amazons (Brazil), and Venezuela. It has been considered identical with Winter's bark [from *Drimys Winteri* (Forst.)], but its source is really unknown (Jobst and Hesse, Annalen, 282, 191). It comes into the market in long strips about 8 cm. broad and 12 mm. thick, and is tough and hard. The colour is cinnamon brown, and a cross section shows numerous yellow spots. It has an aromatic odour, and contains *cotoïn*, *dicotoïn*, *hydrocotoïn* and *methyl-hydrocotoïn*, resins, tannin, &c. The supply of the true coto bark is limited, so inferior barks, chiefly *para-coto bark*, are sold. These contain little or no *cotoïn*, but instead *protocotoïn* and *methyl-protocotoïn*.

Cotoïn is the monomethyl ether of benzoylphloroglucinol $C_6H_5 \cdot CO \cdot C_6H_2(OH)_2 \cdot OCH_3$ (Ciamician and Silber, Ber. 1894, 27, 409; Pollak, Monatsb. 1901, 22, 996). It is the active principle of coto bark, and is obtained by extracting the bark with ether, evaporating the solution, adding light petroleum to precipitate the resin, decanting off the solution and allowing to crystallise (Jobst and Hesse, Annalen, 199, 17). *Cotoïn* forms pale-yellow prisms or tables, m.p. 130°, sparingly soluble in cold water, more easily in hot, and easily soluble in alcohol, chloroform, ether, benzene, &c. It has a sharp, astringent taste. It dissolves in alkalis with a yellow colour, and in nitric acid with a deep-red colour. The alcoholic solution gives a red-brown colouration with ferric chloride, and on boiling a rich brown precipitate is obtained.

Cotoïn is used therapeutically in the treatment of diarrhœa, cholera, colic, &c., and for rheumatism, neuralgia, and gout. The dose is: for children, 0.05–0.15 gram; for adults, 0.20–0.60 gram. It is also administered in ethereal solution by subcutaneous injection.

An extract of the bark may be used medicinally, but has unpleasant after-effects.

Dicotoïn $C_{22}H_{20}O_6$ is probably a compound of *cotoïn* and phenyl-coumalin

(Ciamician and Silber, Ber. 1895, 28, 1549). It is obtained by boiling *cotoïn* with water, and forms lustrous, colourless plates, m.p. 74°–77°, easily soluble in alcohol, ether, &c. (Jobst and Hesse, *ibid.* 1878, 11, 1031).

Hydrocotoïn, methyl *cotoïn*

forms brilliant, pale-yellow prisms, m.p. 98°, soluble in alcohol and in boiling water.

Methyl-hydrocotoïn $C_6H_5 \cdot CO \cdot C_6H_2(OCH_3)_3$, obtained from coto bark or by the methylation of hydrocotoïn, forms small colourless crystals, m.p. 113° (Ciamician and Silber, Ber. 1893, 26, 2340; 1894, 27, 419).

Protocotoïn

forms bright-yellow monoclinic prisms, m.p. 141°–142°. It is soluble in organic solvents but insoluble in water.

Methyl-protocotoïn

crystallises from alcohol in colourless prisms, m.p. 134°–135° (Ciamician and Silber, Ber. 1891, 24, 2977).

Hesse has examined a coto bark from Bolivia, which contained no *cotoïn*, but a neutral substance, *cotellin* $C_{13}H_{14}O_4(OCH_3)_2$, which forms glistening leaflets or pyramids, is tasteless, and melts at 169° (J. pr. Chem. 1905, 72, 243).

COTTON consists of the long hairs which cover the seeds of various species of *Gossypium*, a genus of the nat. ord. *Malvaceæ*. The botanical classification of cotton is in a confused state, and this is doubtless mainly due to the cultivation of the plant for extensive periods, the large interchange of seed which has taken place between the different countries of production, and the consequent gradual modification of the distinctive characters of the original species.

American cottons.—The ordinary Upland cotton is fairly generally considered to be derived from *Gossypium hirsutum* (Linn.). Some authorities, however, are of opinion that it is derived from *G. herbaceum* (Linn.), whilst others regard these two species as identical. Sea Island cotton has usually been regarded as *G. barbadense*, but is considered by Watt (Wild and Cultivated Cotton Plants of the World) to be a hybrid form.

Egyptian cottons.—The Egyptian cottons probably cannot be referred to any particular species, but are mostly hybrid forms of *G. barbadense* with other species. Most commonly, Egyptian cottons are regarded as *G. barbadense*, but Watt places them under *G. peruvianum* (Cav.), which some authorities consider as identical with the former.

Indian cottons.—With reference to these varieties, G. A. Gammie, of the College of Science, Poona, writes, in his monograph on The Indian Cottons: 'It is clearly evident that we have at the most only one true species of cotton in India, *Gossypium obtusifolium*, with its two sub-species, *G. arboreum* and *G. herbaceum*. All other forms should be treated as derivatives of these.' Other botanists, however, regard the Indian cottons as derived from various distinct species, including *G. herbaceum*, *G. neglectum*, *G. Wightianum*, and *G. arboreum*.

Brazilian and Peruvian cottons.—Brazilian cotton is generally considered to be the product of *G. brasiliense* (Macf.), and rough Peruvian cotton that of *G. peruvianum* (Cav.).

The cotton plant grows as a shrub or small tree. It is of perennial habit, but, in cultivation, is usually treated as an annual. In certain districts of Brazil and Peru, however, arborescent forms are grown, which are allowed to remain in the ground for several years. When the flower-bud first opens, the petals are generally white or pale yellow, but they gradually become darker and redder until the third or fourth day, and then fall to the ground. The young fruit remains attached to the flower-stalk and enveloped in the calyx; it gradually increases in size, and is known as the 'boll.' When the boll is ripe, it dehisces by from three to five valves, exposing the cotton, which, now that the pressure on it is released, rapidly expands and forms a large fluffy mass. As soon as the boll has opened completely, and is quite dry, the cotton is ready to be gathered. The seeds, with the cotton fibre adhering to them, form the product known as 'seed cotton'; this is collected from the ripe bolls, and the cotton (or 'lint'), after being torn from the seeds by

the process of 'ginning,' constitutes the raw cotton of commerce. Seed cotton usually consists of about one-third of its weight of cotton fibre and two-thirds of seeds.

The cotton fibre is composed of a single hollow cell, and, while unripe, has the form of a long narrow tube. As the fibre matures, it becomes more or less flattened, and presents the appearance of a narrow, somewhat opaque ribbon or band, with slightly thickened, rounded edges. The ripe fibre possesses a peculiar characteristic twist. This twist appears to be an acquired character; it is not present in wild cotton, and is increased by care in cultivation. The number of twists in a given length is very variable, and, as a rule, is, roughly speaking, inversely proportional to the diameter of the fibre, the twist being most numerous in the finest variety (Sea Island). Unripe cotton consists of thin, transparent fibres with little or no twist. Such fibres are known technically as 'dead cotton,' and, being very weak and brittle, they break up in the process of manufacture, thus increasing the amount of waste, and also tending to weaken the yarn or fabric into the composition of which they enter; they also possess the defect of not being able to take dyes satisfactorily.

According to the length of the individual fibres, cottons are classed in commerce as long-, medium-, or short-stapled. The long-stapled cottons are $1\frac{1}{4}$ inches or more in length, the medium-stapled are about 1 inch long, and the short-stapled are less than 1 inch. The principal long-stapled varieties are Sea Island cotton, Egyptian varieties, and the improved American Upland forms, which have been evolved from the ordinary Upland kinds by continuous selection and careful cultivation. The Brazilian and Peruvian cottons vary from about 1 to $1\frac{1}{2}$ inches, and are, therefore, either medium- or long-stapled. The chief medium-stapled cottons are the ordinary American Upland kinds, and the short-stapled class is represented by the Indian varieties.

Sea Island cotton is grown in South Carolina, Georgia, Florida, and the West Indies. The fibre is very long, fine, silky, and of a lustrous creamy tint, and this cotton is therefore the most valuable variety. It is used in commerce for spinning the finest and best yarns. Considerable care is required in the cultivation of this cotton, and the yield per acre is usually lower than that of other kinds.

American Upland cottons are produced in enormous quantities in the United States, and are the principal kinds used in the Lancashire spinning industry. They are of longer staple and better quality than the Indian varieties, and are employed for the manufacture of yarns of medium quality.

Egyptian cottons exist in several varieties, most of which yield a fibre of a brownish tint. These cottons are long, strong, and fine, and more lustrous than American Upland, but inferior to Sea Island cotton. Egyptian cotton is preferable to American Upland for the manufacture of goods requiring a soft, smooth finish and high lustre.

The Indian cottons are mostly short and coarse, and are consequently less valuable than American Upland kinds. The chief markets for

these varieties are Japan and Germany, comparatively little being imported into the United Kingdom.

Brazilian cotton is harsh and wiry, of medium strength and of good length. One of the varieties grown in North Brazil is a tree cotton, which lives for 8 years or more. The ordinary annual cottons are more largely cultivated and are more productive than the arborescent form, but the fibre of the latter has the longer staple.

Peruvian cotton is chiefly of two kinds, known respectively as 'rough' and 'smooth.' The former is the product of a tree cotton which is allowed to remain in the ground for from 4 to 6 years; the fibre is well known for its peculiarly harsh and crinkly character, which renders it especially useful to spinners for mixing with wool. 'Smooth' Peruvian is very similar to American Upland cotton, and is used for the same purposes.

The following table gives the approximate length and average diameter of the fibres of the principal commercial varieties. The diameters of the fibres of any one variety show great variation among themselves, but the figures given under this head are the average of a large number of determinations by various observers, and can, at least, be regarded as relatively accurate:—

Variety	Usual length	Average diameter
	inches	inch
Sea Island	1.6-2.2	0.00064
American Upland	0.8-1.1	0.00077
Egyptian	1.3-1.6	0.00068
Indian	0.6-1.0	0.00084
Brazilian	1.1-1.4	0.00080
Peruvian (rough)	1.2-1.5	0.00078
„ (smooth)	0.9-1.1	0.00077

Cotton consists of about 90 p.c. of cellulose (*q.v.*), together with 7-8 p.c. of water, 0.4 p.c. of wax and oil, 0.6 p.c. of nitrogenous substances, and about 1 p.c. of mineral matter (ash).

The wax is present as a thin layer on the surface of the fibre, and renders it incapable of absorbing water readily. This substance, to which Schunck (Manchester, Mem. Lit. Phil. Soc. [iii.] 4, 95) has given the name 'cotton wax' resembles other vegetable waxes, such as cerosin prepared from the leaves of the sugar-cane, and the waxes from the leaves of the carnauba palm [*Copernicia cerifera* (Mart.)], and the raphia palm [*Raphia pedunculata* (Beauv.)]. It is insoluble in water, but soluble in alcohol or ether; it melts at 86°, and solidifies again at 80°-82°. Pure cotton wax is insoluble in solutions of caustic alkali; it contains C 80.4, H 14.5, O 5.1. Associated with this wax is a fatty acid, which was regarded by Schunck as margaric acid, but is more probably a mixture of stearic and palmitic acids; it melts at 55.5°, and resolidifies at 50.5°.

The oil in the cotton fibre appears to be identical with that contained in the seed. In the preparation of the so-called absorbent cotton wool, the wax and oil are removed by boiling the fibre with dilute caustic alkali under pressure; the material is subsequently washed, treated

with bleaching powder and hydrochloric acid, again washed, and dried.

The nitrogenous constituents of cotton consist of the remains of the cell protoplasm and allied substances.

The mineral substances contained in the fibre are chiefly phosphates, chlorides, and sulphates of potassium, sodium, magnesium, and calcium, together with small quantities of iron and traces of aluminium. If the amount of ash is much more than 1 p.c., the excess is probably due to the presence of sand and other mechanical impurities.

When cotton is immersed in a strong solution of caustic soda, it undergoes certain remarkable changes, the chief of which is the production of a silky lustre. This phenomenon was discovered by John Mercer in 1844, and has led to results of great commercial importance. The process is now carried out on an extensive scale under the name of 'mercerisation' (*q.v.*), and is sometimes applied to the yarn and sometimes to the woven fabric. The material is either kept in a state of tension during the operation, or is allowed to shrink in the alkaline liquid, and afterwards stretched to its original length before being washed. The process not only produces an exceedingly high lustre on the cotton, but also increases its power of absorbing dyes. The structure of the cotton fibre undergoes alteration; the flattened, twisted tube, characteristic of ordinary cotton, swells out, and is thus converted into a hollow, cylindrical form. This change is accompanied by a decrease in length and also by an increase in tensile strength, mercerised cotton being in some cases as much as 50 p.c. stronger than ordinary cotton. Egyptian cotton generally mercerises better than ordinary American cotton.

When cotton is treated with a mixture of nitric and sulphuric acids, it is converted into nitro-cellulose or gun-cotton (*v. EXPLOSIVES*). On dissolving gun-cotton in ether, or a mixture of ether and alcohol, the product known as collodion is obtained (*v. PHOTOGRAPHY*). Nitro-cellulose also enters into the composition of celluloid (*q.v.*).

Among the more important works on this subject may be mentioned *The Cotton Plant*, Bull. No. 33, Office of Expt. Stat. U.S. Dept. of Agric.; *Bowman's Structure of the Cotton Fibre*; and *Oppel's Die Baumwolle*. E. G.

COTTON BROWNS, SCARLETS, YELLOWS,
v. AZO-COLOURING MATTERS; PRIMULINE.

COTTON FLOWERS. Among the various portions of the cotton plant which have been industrially employed must be included the flowers which constitute one of the numerous Indian dyestuffs. According to Watt (*Dictionary of the Economic Products of India*), they are thus utilised in the Manipur district.

Gossypetin $C_{15}H_{10}O_8$. The flowers are extracted with boiling alcohol, the extract evaporated, treated with water, and the mixture extracted with ether to remove chlorophyll and wax. The aqueous solution, containing the glucoside of gossypetin, is digested at the boiling temperature with sulphuric acid, and, on cooling, a precipitate of the crude colouring matter separates. It is dissolved in alcohol, the solution poured into ether, and, after removal of precipitated impurities, the liquid is washed

with water and evaporated. The yellow residue is best purified by acetylation, and the acetyl derivative, after repeated crystallisation from alcohol, is hydrolysed in the usual manner (Perkin, *Chem. Soc. Trans.* 1899, 75, 826). Gossypetin forms yellow needles, closely resembling quercetin in appearance, and is readily soluble in alcohol, but only very sparingly in water. Concentrated alkaline solutions dissolve it, forming orange-red solutions, which, on agitation and dilution with water, become green, and finally assume a dull-brown tint. Alcoholic lead acetate gives a deep-red precipitate in the cold, passing into dull-brown at the boiling-point, and alcoholic ferric chloride a dull olive-green liquid.

Gossypetin, like quercetin, forms compounds with mineral acids which crystallise in orange-red needles, and with alcoholic potassium acetate the monopotassium derivative $C_{15}H_9O_8K$ is produced. The *hexacetyl* derivative

forms colourless needles, melting at 226° - 228° (*ibid.* 1909, 95, 2188). By fusion with alkali, *protocatechuic acid* and a phenol, the identity of which has not been established, are produced.

On mordanted wool gossypetin gives the following shades:—

Aluminium	Tin	Chromium	Iron
Pale orange brown	Orange red	Dull brown	Deep dull olive

With aluminium mordant, the results vary greatly, according as chalk is present or absent in the dye bath, a result evidently due to the ready oxidation of gossypetin in the presence of alkalis or alkaline earths. Thus if the mordanted wool, which is of an acid nature, is employed alone, the above shade is produced; but if chalk is added, a deep olive-yellow is obtained. Calico mordanted with aluminium, being of a basic nature, yields this olive-yellow shade without the employment of chalk.

Gossypitrin $C_{21}H_{20}O_{13}$, the glucoside of gossypetin, is isolated with difficulty, and has only been prepared in very small quantity. This arises from the fact that the flowers (that is, the Egyptian variety) also contain the two glucosides *quercinmeritrin* and *isoquercitrin* (see glucosides of quercetin), and the separation of the three substances involves many tedious operations.

Gossypitrin consists of pale orange-yellow needles, melting at about 200° - 202° . It is hydrolysed by boiling dilute acids into gossypetin and probably glucose, according to the following equation:—

The dyeing properties of the flowers are very different from those of gossypetin; this is due to the fact that they contain the three glucosides described above, and that there is no free colouring matter present. The following are the shades produced on mordanted woollen cloth with this material:—

Aluminium	Tin	Chromium	Iron
Dull yellow	Orange brown	Dull brown-yellow	Dull olive

It has not yet been determined if any special difference exists in regard to the constituents of the Indian and Egyptian varieties of the cotton flower. Both contain a glucoside of gossypetin,

but the existence in the former of quercimnerin and isoquercitrin is at present uncertain.

A. G. P.

COTTON SEED OIL is obtained on a large scale from the seeds of the several varieties of the cotton tree, *Gossypium*. In the United States, *Gossypium hirsutum* (Linn.), 'Upland cotton,' covered with 'linters,' is extensively cultivated, whereas the plant grown in the Sea Islands and in Egypt is *G. barbadense* (Linn.). The Indian variety of cotton seed is generally assumed to be *G. neglectum* and *G. arboreum*. Up to 60 years ago, the seed not required for planting was mostly wasted, as the oil contained therein could not be refined. Cotton seed oil was first expressed in this country in the year 1847. Since then the industry has assumed such enormous dimensions that the annual import of cotton seed to this country from Egypt, the East Indies, and South America amounts to more than 600,000 tons; in addition very considerable quantities of cotton seed oil are imported from the United States, which produce almost 200,000,000 gallons of oil per annum, of which approximately 50,000,000 gallons are exported to Europe.

The seed contains, on the average:—

	Per cent.
Oil	20.0
Water	8.5
Albuminoids	20.0
Carbohydrates	32.0
Crude fibre	15.0
Ash	4.5

The proportion of oil in the seed varies considerably with the origin of the seed. Thus Egyptian seed contains up to 24 p.c. of oil; East Indian seed on the average only 18 p.c.; American 'Uplands' and Jamaica seed, 23-24 p.c.; and Brazilian and Peruvian no more than 20-21 p.c. of oil. The seeds consist on an average of 60 p.c. of kernel and 40 p.c. of husk.

A distinction must be made between seed which must be decorticated before crushing, owing to the fine 'linter,' which cannot be removed readily, and seed which is crushed in the undecorticated state. Undecorticated seeds are chiefly crushed in England, France, and Germany, from Egyptian, Bombay, and also Smyrna seeds, whereas the vast majority of the American 'Upland seed' must be decorticated before being crushed. In some European establishments Bombay seed is decorticated before crushing.

The kernels ('meats') are permeated with cells containing a deep-brown colouring matter; hence the crude cotton seed oil running from the hydraulic presses has a ruby-red to almost black colour. The depth of the colour of crude cotton oil depends, in the first instance, on the state of freshness of the seed. The American seed, which is, as a rule, crushed shortly after having been harvested, yields a crude oil of a much paler colour than that of crude oil obtained in England, France, and Germany from Egyptian seed. The palest Egyptian crude oil is obtained from fresh seed arriving in October. When the seed is stored it undergoes deterioration ('heating,' which may also occur during the voyage); hence the crude oil obtained from Egyptian seed in July and August has a very dark colour.

In the American trade three grades of crude

cotton seed oil are recognised, viz. 'prime,' 'choice,' and 'off' qualities. The crude oil is refined by treatment with a dilute caustic soda solution, at a temperature not exceeding 120°F., whereby the free fatty acids are neutralised; the soap so formed falls to the bottom and carries with it the brown colouring matter, so that the supernatant oil is of a bright-yellow colour. The oil is then washed free from soap, or, in the case of a technical oil, is treated with bleaching powder, to yield the bright-yellow oil of commerce. The first qualities of cotton seed oil which are not bleached with chemicals are used as edible oils, and are consumed in enormous quantities either as such, as a cooking oil, for tinning sardines, table oil, &c., or in the manufacture of lard substitutes, under such names as salad oil, sweet nut oil, butter oil. The last-named product is chiefly used in the manufacture of margarine and compound lard.

Cotton seed oil is, at the ordinary temperature, a pale-yellow oil of characteristic, but not unpleasant, taste. At about 12°, 'stearine' deposits. This 'stearine' would interfere with the use of cotton seed oil as a table oil or salad oil: therefore the 'stearine' is removed on a large scale by cooling the oil to a low temperature, and filtering off the deposit. The filtered oil is known in commerce as 'winter oil' ('demargarinated cotton seed oil'). According to the requirements of the market, it will not 'cloud' at 40°F. or 32°F., or even at 28°F. The sp.gr. of cotton seed oil is 0.923-0.925 at 60°F. The saponification value varies from 190 to 193, and its iodine value from 105 to 115.

The solid fatty acids in cotton seed oil consist chiefly of palmitic acid; small quantities of arachidic acid seem to be present, but stearic acid appears to be absent. The liquid fatty acids would seem to consist of oleic and linolic acids only.

Cotton seed oil eminently typifies a semi-drying oil. In the Livache test (see OILS AND FATS) it absorbs 5.9 p.c. of oxygen in 24 hours. By blowing air through cotton seed oil at a temperature of about 90°-100°, oxygen is absorbed, with the formation of a small amount of oxidised acids, the acetyl value of the oil rising at the same time considerably. This reaction is used on a large scale in the preparation of 'Blown Cotton Seed Oil' (see OILS AND FATS), which is used in considerable quantities as a lubricating oil in admixture with mineral oils, to produce the 'Marine Lubricating Oils' of commerce.

A reliable test for the identification of cotton seed oil, and for the detection of it in other oils and fats, down to even 1 p.c. (under favourable circumstances), is the *Halphen* colour test, which is carried out in the following manner: 1-3 c.c. of the oil is dissolved in an equal volume of amyl alcohol; to this is added 1-3 c.c. of carbon disulphide, holding in solution 1 p.c. of sulphur flowers. The test-tube is immersed in boiling water, or, better, in boiling brine, the carbon disulphide being allowed to evaporate off. In the course of 5-20 minutes, a deep-red colouration appears, the intensity of which stands in direct proportion to the amount of cotton seed oil in the sample. Although the test cannot be used as a quantitative one, yet it must be considered, if positive, as one of the

best means of recognising the presence of cotton seed oil qualitatively. A negative Halphen test is, however, no conclusive proof of the absence of cotton seed oil in a mixture, as the colouring matter is destroyed by heating cotton seed oil to 250°, or by keeping it at 200° for some prolonged time, or by 'blowing' it. Hence 'blown cotton seed oils' do not show the Halphen colour reaction.

J. L.

was obtained by Vogel (Gilb. Ann. 64, 161), in 1820, from the tonka bean (the seed of *Dipteryx* (*Coumarouna*) *odorata*, Willd.), or from the melilot (*Melilotus officinalis*, Lam.), and from the woodruff (*Asperula odorata*, Linn.); but was mistaken by him for benzoic acid. Guibort, however, showed that the crystalline odoriferous principle of the tonka bean was distinct from benzoic acid, and named it *coumarin*. It occurs in *Peristrophe angustifolia* (Nees), *Achylis triphylla* (DC.), and in many other plants, and is a normal constituent of lavender oil. It is present in plants as a glucoside, which is decomposed by a ferment present in the plant. This ferment is destroyed by alcohol or boiling water (Molish, J. Pharm. Chim. 1902, 279).

It was first obtained synthetically by Perkin by heating the sodium compound of salicylaldehyde with acetic anhydride (Chem. Soc. Trans. 1868, 53); or more simply by boiling together salicylaldehyde, acetic anhydride, and dry sodium acetate (*ibid.* 1887, 388; see also Tiemann and Herzfeld, Ber. 1877, 284). Acetyl coumaric acid is first formed:

which then parts with acetic acid, yielding coumarin:

By treating salicylaldehyde (1 molecule) with excess of acetic anhydride (4 molecules) for 6 hours at 180°, coumarin is formed (Reychler, Bull. Soc. chim. 1897, 17, 517).

Coumarin is also formed in small quantity by heating a mixture of phenol and malic acid with sulphuric acid:

(Von Pechmann, Ber. 1883, 2119; 1884, 929, 1649).

Substituted coumarins may be obtained by condensing phenols with acetoacetic ester or with malic acid in the presence of concentrated sulphuric acid.

Coumarin forms rhombic crystals melting at 67°; boils at 290°-290.5°; has a pleasant, aromatic odour; is scarcely soluble in cold water, readily soluble in boiling water, very soluble in alcohol and ether. Crude coumarin may be

purified by repeated boiling with light petroleum (Claassen, Pharm. J. 1897, 161).

It dissolves in caustic alkalis, and is re-precipitated on addition of acids. If, however, it is heated for some time with concentrated caustic alkali, or better, with sodium ethoxide, a solution is formed from which acids precipitate coumaric acid $C_6H_4 \begin{array}{l} \text{CH:CH-COOH} \\ \text{OH} \end{array}$ (1, 2).

This compound can be reconverted into coumarin by heating it with acetic anhydride; but when heated alone it is decomposed, yielding phenol and other substances. Reduction of coumarin with zinc in alkaline solution or sodium amalgam in aqueous solution yields melilotic acid as the chief product; with sodium amalgam, and alcohol hydrocoumaric acid is formed (Williamson, J. 1876, 587).

In Germany, woodruff (Ger. *Waldmeister*) is steeped in white wine, to which it imparts the pleasant aroma of coumarin (*Maiwein*, *Mai-trank*). Instead of woodruff, an alcoholic solution of coumarin is employed for the same purpose under the name of *Maiweinessenz*. In larger doses coumarin is stated to have a narcotic action.

Coumarin has the agreeable odour of asperula, and is used in perfumery for the preparation of asperula essence. It is also frequently used to adulterate extract of vanilla (*g.v.*) (v. LACTONES).

tained from the coal-tar fraction boiling between 165° and 175°. After the pyridine bases and phenols have been removed by acid and alkali, it is obtained as the dibromide on addition of bromine. The dibromide is reduced to coumarone by alcoholic potash and sodium amalgam (Kraemer and Spilker, Ber. 1890, 78). It can also be obtained from this source by adding picric acid to the mixture of oils, whereby the picrate of coumarone crystallises out. This is separated, decomposed by hot water or dilute alkali, and the coumarone obtained by steam distillation. The picric acid is recovered and used for another operation (Ch. Fab. Act. ges. Hamburg, Eng. Pat. 1422; D. R. P. 53793; Ber. 1891, Ref. 233). Coumarone has been synthesised by heating *o*-hydroxy- ω -chlorocinnamene $OH\text{-C}_6H_4\text{-CH:CHCl}$ with potash, hydrogen chloride being eliminated (Komppa, Ber. 1893, 2968). It has also been prepared by heating phenoxyacetaldehyde with zinc chloride in glacial acetic acid (Stoermer, *ibid.* 1897, 1700).

Coumarone boils at 174.0° (corr.) (Perkin, Chem. Soc. Trans. 1896, 1249). It is unacted upon by potash or by hydrochloric acid. Sulphuric acid reacts with coumarone in benzene solution, producing a soluble resinous material paracoumarone (C_9H_8O)₂, which is used to preserve wood and paper. Other polymerides are known. Coumarone is of interest as, when passed through a red-hot tube with benzene, phenanthrene is produced, and with naphthalene, chrysene is produced (Kraemer and Spilker, Ber. 1890, 84). The methyl coumarones are present in the coal-tar fraction of b.p. 185°-195° (Stoermer and Boes, *ibid.* 1900, 3013).

COUPIER'S BLUE v. INDULINES.

COVELLITE. Native cupric sulphide CuS crystallising in the hexagonal system. Crystals

are rare and have the form of thin six-sided plates. The mineral has a characteristic indigo-blue colour, hence the name *indigo-copper* (German, *Kupferindig*). It occurs in most copper-mines as a blue, earthy coating on other sulphide ores of copper, and is sometimes found in sufficient quantities to be of importance as an ore. e.g. at Butte in Montana, and Copiapo in Chile. Covellite containing platinum (as the mineral sperrylite, PtAs₂) is mined in the Medicine Bow Mountains in Wyoming.

L. J. S.

COW TREE WAX v. WAXES.

CRANBERRY, the fruit of *Vaccinium Oxycoccus* (Linn.).

American analyses give as the average composition of the berries:

Water	Protein	Fat	Carbohydrates	Ash
88.5	0.5	0.7	10.1	0.2

König gives:

Water	Protein	Free acid	Sugar	Other carbohydrates	Ash
89.6	0.12	2.3	1.5	6.3	0.15

The juice of cranberries was examined by Mach and Portele in 1888 (Landw. Versuchs. Stat. 1889, 38, 69), who found a litre of the fresh juice to contain (in grammes)

Invert sugar	Acidity (as malic acid)	Benzoic acid	Tannic acid	Ash	Nitrogen
87.1	19.0	0.75	2.2	3.0	0.11

The sp.gr. of the juice averaged 1.0591.

The juice will not ferment with yeast, owing, it is said, to the presence of benzoic acid, but this may be due to the poverty of the juice in nitrogenous matter, for Otto (Bied. Zentr. 1899, 28, 284) found that bilberry juice would only ferment vigorously with yeast after the addition of asparagine (about 0.6 gram per litre) or of ammonium chloride (about 0.3 gram per litre).

Classen (*ibid.* 16, 70) isolated a bitter substance from cranberries, to which he gave the name *oxycoccin*, and which he found to give reactions similar to those of arbutin C₁₂H₁₆O₇, occurring in the leaves of the red bearberry, *Arctostaphylos Uva-ursi* (Spreng.).

The ash of cranberry juice contains about 3 p.c. of phosphorus pentoxide and 47 p.c. of potash.

H. I.

CREAM OF TARTAR v. TARTARIC ACID.

CREATINE, *Methylglycocyanine*, *Methylguaninoacetic acid* H₂N·C(NH)NMe·CH₂·CO₂H, H₂O discovered by Chevreul (Annalen, 1835, 4, 293) in muscular flesh (χρῆμα=flesh), occurs in human flesh and in the flesh of many warm and cold blooded animals (Liebig, Annalen, 1847, 62, 257; Gregory, *ibid.* 1848, 64, 105; Schlossberger, *ibid.* 1848, 66, 80; Voit, Z. Biol. 1868, 4, 77; Price, Chem. Soc. Trans. 1851, 3; Marcet, *ibid.* 1864, 2, 406); the amount varies with the species, the flesh of fowl yields 3.21 p.c.; of pigeon, 0.825 p.c.; of ox, 0.697 p.c.; of ox heart, 1.375 p.c.; of herring, 1.324 p.c.; and of brill, 0.614 p.c. (Gregory, *l.c.*).

According to Folin (Amer. J. Physiol. 1905, 13, 45, 66, 117), van Hoogenhuyze and Verploegh (Zeitsch. physiol. Chem. 1908, 57, 161), and Mellanby (J. Physiol. 1908, 36, 447), muscular creatine has its origin in the liver. This organ is continuously forming creatinine from substances carried to it by the blood from other organs, and in the developing muscle. This is changed to

creatine, until the muscle is saturated with creatine, when the excess of creatinine is excreted by the kidneys. The creatine is presumably combined with the muscular protoplasm, for though a readily dialysable substance, it does not pass into the surrounding lymph or blood *in vitro*, nor is it readily obtainable by diffusion from muscular flesh (Urano, Beitr. Chem. physiol. Path. 1907, 9, 104).

In order to extract creatine, the flesh is heated with its own weight of water at 60°, and the juice expressed. The flesh extract is then heated to coagulate the protein, and filtered; the filtrate is treated with basic lead acetate until no further precipitation occurs, and again filtered after removing the excess of lead from the filtrate by sulphuretted hydrogen, when it is evaporated until creatine separates on cooling; this is washed with alcohol and recrystallised from water (Neubauer, Zeitsch. anal. Chem. 1863, 2, 26; 1867, 6, 33).

Creatine is prepared synthetically by heating sarcosine with cyanamide at 100°.

(Volhard, Z. Chem. N. F. 1869, 5, 318; Strecker, J. 1868, 686); or, together with creatinine, by fusing sarcosine with guanidine carbonate (Paulmann, Beilstein Suppl. i. 657).

Creatine forms colourless transparent monoclinic prisms, containing 1H₂O, which it loses at 100°; it dissolves in 74.4 parts of water at 18°; or in 9810 parts of cold absolute alcohol, and is insoluble in ether (Liebig, Annalen, 1847, 62, 257). The presence of urea, creatinine, or certain salts, raises the solubility of creatine in water and alcohol (Neubauer, *l.c.*). The aqueous solution is neutral, and has a bitter, harsh taste.

Creatine is decomposed by boiling baryta water into sarcosine, urea, and methylhydantoïn

(Neubauer, Annalen, 1866, 137, 294); or by mercuric oxide and water into oxalic acid and methylguanidine; or by heating with soda lime into ammonia and methylamine. When potassium hydroxide is added to an aqueous solution of creatine and silver nitrate until the white precipitate first formed just redissolves, the liquid solidifies to a transparent gelatinous mass immediately reduced on heating, or in the course of a few hours at the ordinary temperature. The addition of potassium hydroxide to a solution of creatine and mercuric chloride precipitates a white crystalline compound (C₂H₄O₂N₂)₂Hg·HgO (Engel, Compt. rend. 1874, 78, 1707; 1875, 80, 885). Creatine is converted into creatinine by heating with dilute mineral acids for some hours (Dessaignes, J. 1857, 544), or at 117° for 15 minutes (Benedict and Myers, Amer. J. Physiol. 1907, 18, 362); or by heating with water only in sealed tubes at 100° for 2-3 days (Neubauer, Zeitsch. anal. Chem. 1863, 2, 33).

Creatine forms soluble normal salts with the mineral acids (Dessaignes, Annalen, 92, 409), and readily soluble compounds with zinc chloride C₄H₉O₂N₃·ZnCl₂; and cadmium chloride

($C_4H_7ON_3$) $_2 \cdot ZnCl_2$, almost insoluble in alcohol (Heintz, J. 1847, 48, 883); with mercuric chloride $4(C_4H_7HgON_3 \cdot HCl) \cdot 3HgCl_2 \cdot 2H_2O$ (Johnson. Proc. Roy. Soc. 1886, 43, 493).

Creatinine is converted into creatine by the action of cold dilute ammonia or calcium hydroxide solutions; boiling baryta solution converts it into ammonia and methyl hydantoin; with alkaline oxidising agents it yields methyl-guanidine and oxalic acid, but is comparatively stable towards acid permanganate solutions (Jolles, Ber. 1902, 35, 160).

The presence of creatinine in dilute solution or in urine can be detected by (1) Maschke's test (Zeitsch. anal. Chem. 1878, 134), which consists in the formation of a sparingly soluble double compound of creatinine and cuprous oxide, when the suspected solution is heated at 50° - 60° with Fehling's solution; as the cuprous oxide is formed by the oxidation of part of the creatinine, it is advisable to add a little glucose to the mixture; the test is sufficiently delicate to allow of the detection of $\frac{1}{10000}$ part of creatinine. (2) Weyl's test (Ber. 1878, 11, 2175) consists in the production of a ruby-red colouration, changing to yellow when, to a solution of creatinine, a few drops of 10 p.c. sodium nitroprusside and the same quantity of 10 p.c. sodium hydroxide or carbonate solution are added. On acidifying the solution with acetic acid and boiling, the colour becomes emerald green, changing to blue, due to the formation of Prussian blue (Salkowski; Colasanti, Gazz. chim. ital. 1887, 17, 129). Guareschi (Ber. 1888, 21, Ref. 372) has shown that this reaction is given by other compounds than creatinine containing the $-CO \cdot CH_2-$ complex. (3) Jaffe's test (Zeitsch. physiol. Chem. 1886, 10, 399) is the production of a deep-red colour, when picric acid and an excess of sodium hydroxide solution are added to the liquid containing the creatinine. Chapman (Chem. News, 1909, 100, 175) has shown that the colour is due to the sodium salts of aminodinitrophenol (picramic acid), and diamino-nitrophenol formed by the reduction of the picric acid by the creatinine; if the creatinine is present in excess, reduction to the colourless triaminophenol occurs.

The older methods for the estimation of creatinine were based upon the isolation of the base in the form of its sparingly soluble double salt with mercuric or zinc chloride, and either weighing the precipitate or estimating the metal or the nitrogen in the compound (Neubauer, Annalen, 119, 35; Salkowski, Zeitsch. physiol. Chem. 1886, 10, 113; Grocco, Chem. Zentr. 1887, 17; Kolisch, *ibid.* 1895, i. 814; Ladd and Bottenfield, Amer. Chem. J. 1898, 20, 869; Edleson, Chem. Zentr. 1903, i. 108) recommends precipitating the sulphate in the presence of alcohol and ether, dissolving it in water, and titrating the solution with standard barium hydroxide solution, using phenol phthalein as indicator.

The method generally adopted for estimating creatinine in urine is Folin's colorimetric method, based on Jaffe's reaction (Zeitsch. physiol. Chem. 1904, 41, 223). N/2 potassium dichromate solution is placed to a height of 8 mm. in one tube of a Dubosq colorimeter; 100 c.c. of the urine is placed in a 500 c.c. flask with 10 c.c. of

a 1.2 p.c. solution of picric acid and 5 c.c. of a 10 p.c. solution of sodium hydroxide, left for a few minutes and made up to the mark. If x is the length of this solution in the second tube required to give the same colour effect as the 8 mm. of the standard dichromate solution in the first tube, then $8 \cdot 1 \times 10/x = \text{mg. of creatinine in the 10 c.c. of the urine}$. If x is less than 5, only 5 c.c. of urine should be used; if x is greater than 13, then 20 c.c. of urine should be used. If creatinine is also present in the urine, the amount may be estimated by first determining the creatinine as above, then converting the creatine in another 10 c.c. of the urine to creatinine by heating it with 5 c.c. of N/2 HCl on the water-bath for 3 hours or for 15 minutes at 117° under pressure (Benedict and Myers, Amer. J. Phys. 1907, 18, 362), and estimating the total creatinine. The difference between the two results represents the amount of creatinine equivalent to the creatine originally present. (For precautions to be observed regarding temperature, time, and dilution, in applying this method for the estimation of creatinine, compare Chapman, Chem. News, 1909, 100, 175.)

Two isomeric *nitrosocreatinines* were obtained by Dessaignes (Annalen, 1856, 97, 341) and Märcker (*ibid.* 1865, 133, 305) by passing the nitrous fumes from the action of nitric acid on arsenious oxide into an acid solution of creatinine. The less soluble α -nitrosocreatinine $C_4H_7O_2N_4$ decomposes at 210° , forming a colourless liquid that quickly solidifies to a brown mass from which a new base $C_7H_{12}O_2N_{10}$ (?) can be extracted; it forms a crystalline nitrate, hydrochloride, and platinichloride, and yields the bromo-derivative $C_7H_{12}O_2N_4Br$. The more soluble β -nitrosocreatinine $C_4H_8O_2N_4$ melts at 195° to a brown liquid and decomposes at 220° .

According to Kramm (Chem. Zentr. 1898, i. 37), the yellow colour formed by the interaction of sodium nitroprusside and sodium hydroxide on creatinine (*cf.* Weyl, Ber. 1878, 11, 2175), is due to the formation of a *nitrosocreatinine* $C_4H_7O_2N_4$, which can be isolated as a colourless crystalline precipitate by adding acetic acid to the yellow alkaline solution and shaking vigorously.

The following *acyl-* and *alkyl-* derivatives of creatinine have been prepared: *Benzoylcreatini-*ne $C_{11}H_{11}O_2N_3$, pale yellow needles, m.p. 187° (Urano, Beitr. Chem. Physiol. Path. 1907, 9, 183); *methylcreatini-*ne $C_5H_9ON_3 \cdot H_2O$ and its salts and platinichloride (Korndörfer, Arch. Pharm. 1904, 242, 641); *ethylcreatini-*ne

methylaminoisovaleroeyamidine*α-aminocaproeyamidine*

(Duvillier, Compt. rend. 1882, 95, 456; 96, 1583; 97, 1486; 100, 916; 103, 211; 104, 1290).—For *Xantho-*, *Cruso-* and *Amphi-creatinine v. Xanthocreatinine*. M. A. W.

CREOLIN. A disinfectant consisting of a mixture of coal tar with colophony or Venetian turpentine, in a caustic soda solution.

CREOSOTAL (*Creosote carbonate*) is a mixture of carbonates of the phenols present in wood creosote, of which the chief are guaiacol and creosol.

It is produced by heating creosote with a benzene solution of carbonyl chloride (phosgene) under pressure (Heyden, Eng. Pat. 19074, 1890), but is generally prepared by passing phosgene gas through a solution of beech-wood creosote in caustic soda solution. The carbonate separates as an oil, and is washed with dilute caustic soda and finally with water.

Creosotal is a viscid yellowish liquid, insoluble in water, but soluble in alcohol, chloroform, benzene, &c. (Aufrecht, Pharm. Zeit. 1908, 53, 480). When it is boiled with caustic potash, the odour of creosote is evolved. It is quite odourless, tasteless, and non-irritant in its action upon the mucous membrane, and is therefore much used as a substitute for creosote in the treatment of bronchial affections and pneumonia, especially in children (Weber, Pharm. J. 68, 115; Toff, *ibid.* 73, 414). The dose for adults is about 60 grains daily, and it is usually given in an emulsion (Haefelin, Pharm. Zeit. 49, 141).

CREOSOTE or **KREOSOTE** (from *κρέας*, contracted genitive of *κρέας*, meat, and *σωζέω*, I save or preserve). Wood tar, and coal tar, when subjected to distillation, yield fractions technically known as 'creosote,' both of which, the latter more especially, find extensive and important uses in the industrial arts.

Reichenbach, in the year 1832, applied the term 'kreosote' to a substance derived from wood tar, and which has been found to possess powerful antiseptic properties; shortly afterwards, Runge discovered carbolic acid in coal tar, and the two products were, for a considerable time, regarded as identical; similar compounds, however, have since been procured from other sources, and in order to prevent confusion, it has been suggested to restrict the use of the term 'creosote' to the use in a generic sense as referring to all the phenols and phenoloid bodies derived indifferently from coal, wood, coke-oven, blast-furnace, and shale-oil tars. The enormous extension of the use of creosote oil from coal tar for the preservation of timber has resulted in the terms 'creosote' and 'creosote oil' being used commercially as meaning the heavier distillates from coal tar and coke oven-tar, the oils from blast-furnace tar being distinguished as 'blast-furnace creosote.'

Wood-tar creosote. The tar derived from the distillation of beechwood, when subjected to further distillation, yields certain fractions that

are heavier than water, and which, after agitation with solution of caustic soda, and separation from insoluble oils, are boiled with free access of air in order to oxidise various impurities present; the alkaline solution thus obtained is decomposed with dilute sulphuric acid, the crude creosote which separates is again submitted to a similar alkaline and acid treatment, and the product finally distilled, reserving the fraction passing over between 200° and 220°.

This represents the ordinary 'wood-tar creosote' of commerce. It is a complex mixture of phenoloid compounds, the proportions of which are materially influenced by the method originally followed in distilling the beechwood from which it was obtained.

Wood-tar creosote, when freshly prepared, is a colourless, transparent liquid of an oily consistency, and which retains its fluidity at a very low temperature; its sp.gr. varies from 1.037 to 1.087; it boils at 205°–225°, and dissolves in about 200 parts of water; its odour is strong and penetrating, resembling that of wood smoke, or rather of smoked meat; it refracts light powerfully and burns with a very sooty flame. Wood-tar creosote is powerfully antiseptic, but its power of coagulating albumen has been denied; nevertheless, it preserves animal substances as effectively as carbolic acid. It is less caustic than carbolic acid, and is not poisonous. Wood-tar creosote may be regarded as consisting of a mixture of compounds included in several homologous series, chiefly of acid methylic ethers of catechol, and the presence of the following bodies has been established:—

Name	Formula	Bolling-point
1. Monohydric phenols:		
Phenol, carbolic acid	C ₆ H ₅ OH	182°
Creols, cresylic acid	C ₆ H ₄ (CH ₃)OH	203°
	(1-2, 1-3, 1-4)	
Xylenols or phlorols	C ₆ H ₃ (CH ₃) ₂ OH	220°
	(1-3-4, 1-3-5)	
Ethyl-phenol (1-2)	C ₆ H ₄ (C ₂ H ₅)OH	203°
2. Methyl ethers of dihydric phenols:		
Guaiacol or methyl-catechol	C ₆ H ₃ {OCH ₃ } ₂ {OH}	200°
Creosol or methyl-homocatechol	C ₆ H ₃ (CH ₃) ₂ {OCH ₃ } ₂ {OH}	219°
Dimethyl-homocatechol	C ₆ H ₃ (CH ₃) ₂ (OCH ₃) ₂	214°–218°
Homoceosol or dimethyl-guaiacol	C ₆ H ₂ (CH ₃) ₂ {OCH ₃ } ₂ {OH}	230°
Ethyl-guaiacol (1-3-4)	C ₆ H ₃ (C ₂ H ₅) ₂ {OCH ₃ } ₂ {OH}	—
Cœrulignol or propyl-guaiacol	C ₆ H ₃ (C ₃ H ₇) ₂ {OCH ₃ } ₂ {OH}	241°
3. Methyl ethers of trihydric phenols:		
Dimethyl-pyrogallol	C ₆ H ₃ {OCH ₃ } ₃ {OH}	253°
Dimethyl-methyl-pyrogallol	C ₆ H ₂ (CH ₃) ₂ {OCH ₃ } ₃ {OH}	265°
Dimethyl-propyl-pyrogallol (pleamar)	C ₆ H ₂ (C ₃ H ₇) ₂ {OCH ₃ } ₃ {OH}	285°
Methyl-propyl-pyrogallol	C ₆ H ₂ (C ₃ H ₇) ₂ {OCH ₃ } ₃ {OH}	290°

Of these compounds, phenol is present in extremely small quantity, paraceosol in larger, and phlorol in notable proportion, but the two principal constituents of creosote are guaiacol and creosol, although not equally present in all varieties; guaiacol, according to Allen, predominates in Rhenish creosote, whilst with Morson's creosote from 'Stockholm tar,' creosol

is the chief constituent. Homocresol and α -rulingol are present in small quantity only, but, according to Grätzel, the latter body possesses such energetic and astringent qualities that a single drop placed on the tongue causes bleeding; purified creosote should therefore be absolutely free from this compound, which may be detected by the blue colouration produced by barium hydroxide.

The less valuable portions of wood-tar creosote have been found by A. W. Hofmann to contain the methyl ethers of pyrogallol and its homologues; these bodies are of interest from the remarkable colouring matters (originally discovered by Runge) which may be derived from them by oxidation; thus, if the sodium derivative of dimethyl-pyrogallol be mixed with the sodium derivative of dimethyl-methyl-pyrogallol and excess of sodium hydroxide and heated in the air, a substance called eupittonic acid is formed, according to the following equation:—

Eupittonic acid has the constitution of a hexamethoxyl aurin $C_{15}H_8(OCH_3)_6O_2$. Reichenbach's 'pittical,' called by Wichelhaus 'eupitton,' was a salt of eupittonic acid. Wood-tar creosote has been met with adulterated to a considerable extent with crude carbolic and cresylic acids, and from the fact that the reactions of these substances closely resemble those of wood creosote, the distinction between the two, especially when in admixture, is attended with some difficulty. Genuine beech-wood tar is soluble in solutions of caustic alkalis, and forms a crystalline compound with potassium hydroxide, but not with sodium hydroxide; on the other hand, it is practically insoluble in strong ammonia.

An alcoholic solution should give no colouration whatever (blue or red) with baryta water; such colouring indicates the presence of α -rulingol and other impurities.

The composition of beechwood and oak creosotes, freed from hydrocarbons, is given by Behal and Choay (Compt. rend. 1894, 119, 166), as follows:—

	Beech	Beech	Oak
Distillation temperature. °C. . .	200–220°	200–210°	200–210°
Specific gravity . . .	1.085	1.085	1.068
Monophenols . . .	39.0	39.0	55.0
Guaiaacol . . .	19.7	26.5	14.0
Cresols and homologues . . .	40.0	32.1	31.0
Loss . . .	1.3	2.4	—

Owing to the demand for guaiacol for pharmaceutical purposes, wood-tar creosote, as it occurs in commerce, is frequently found to have been deprived of part or the whole of the guaiacol it contained.

Methods for the determination of guaiacol in wood creosote are given by Behal and Choay (Compt. rend. 1893, 116, 197); M. Adrian (Nouv. Rem. 13, 97); L. F. Kebler (Amer. J. Pharm. 1899, 409).

Wood-tar creosote is sharply distinguished from the coal-tar acids by its insolubility in

absolute glycerol; it is also distinguished from the coal-tar acids by its reaction with an ethereal solution of nitrocellulose; shaken with half its volume of collodion, B.P., Calvert's No. 5 carbolic acid coagulates the gun-cotton. Morson's creosote does not precipitate the nitrocellulose from collodion, but mixes perfectly with the ethereal solution; when a mixture of equal volumes of Morson's creosote and Calvert's No. 5 acid is treated with the collodion, the precipitation is very marked.

Coal-tar creosote, Heavy oils, Dead oils. This substance, both as regards the magnitude of its production, and the extensive uses to which it is applied, occupies a position of considerable interest and importance. As a distillate derived from coal tar, it represents the fraction passing over between 204° and 404°.

As far as can be gathered from trustworthy statistics, the annual production of creosote from gas-works and coke-oven tar in the United Kingdom amounts to about 49,000,000 gallons. The census of production gave 45,303,000 gallons in 1907, the major part of which is disposed of in the creosoting of timber, very large quantities being shipped to America in bulk in special tank steamers. Considerable amounts are also used for softening hard pitch; as liquid fuel for lighting; in the production of lampblack; as an antiseptic, and as a cattle wash for the destruction of animal parasites.

Coal-tar creosote differs considerably in appearance and character; that known as 'London make' exhibits a deep greenish shade, and is more or less fluorescent; it is highly charged with naphthalene, and is not unfrequently viscid or semi-solid at ordinary temperatures. 'Midland or country' creosote shows less fluorescence, and is both thinner and more volatile. The 'Scotch' creosotes derived from canal coal are still thinner and proportionally more volatile, and not unfrequently lighter than water; creosote oil from London coal tar is always heavier than water; the specific gravity of the portions last distilling reaching as high as 1.10, but the mean of the mixture may be taken at 1.065, while for country make it seldom exceeds 1.05. Coal-tar creosote possesses a strong unpleasant odour, highly characteristic of the fluid, and which readily distinguishes it from all others.

Any attempt to determine the absolute composition of coal-tar creosote is attended with much difficulty, but the following substances are known to be present: naphthalene, phenanthrene, anthracene, pyrene, chrysene, carbazole, benzerythrene, and other hydrocarbons accompanying the distillation of tar.

Various phenoloid bodies are also present, consisting of carbolic and cresylic acids, with higher phenols, concerning which little is really known. Basic substances, consisting of the heavier members of the pyridine series, cryptidine, quinoline, and acridine, are also present, together with the so-called indifferent oils, fluid at ordinary temperatures, and about which still less is known. Carbolic and cresylic acids vary greatly in the proportion found; for 'London creosote' the average yield of total tar acids may be stated at 4 to 7 p.c.; while for 'country make' the quantity is often considerably higher. The bulk of the pyridine or basic bodies

contained in the coal tar passes over in distillation of the lighter oils.

Employment of creosote oil for preserving timber (creosoting) (v. WOOD PRESERVATIVES).

Employment of creosote oils for softening pitch (v. PITCH).

Employment of creosote oils for lighting.—Creosote oil has long been employed as a source of light in the construction of harbours and outdoor work, where smoke was of little consequence or inconvenience; but when it is wished to burn this oil to the greatest advantage and with the least possible amount of smoke and soot, it becomes necessary to employ lamps so constructed that a jet of air or steam, more or less superheated, may be introduced in such a manner as to ensure more perfect combustion. Hartmann and Lucke (D. R. P. 9195, Aug. 9, 1879) constructed a lamp specially intended for the consumption of creosote oils, in which the oil is automatically supplied to a dish-shaped receptacle, over which is placed a funnel-shaped cylinder. In the centre of the dish or receptacle receiving the oil from its attached reservoir, is placed a conical tube, reaching a little above the surface of the oil, and through which a jet of superheated or dry steam may be driven. In using the lamp, the dish or receptacle referred to is allowed to fill with oil; it is then ignited at its surface, the funnel-shaped cylinder placed over it, and steam cautiously admitted through the conical tube. It will readily be seen that the arrangement closely resembles the old 'Herapath blowpipe,' with the difference that the steam is forced through a body of combustible fluid, issuing just above its surface, in place of air forced through a body or envelope of combustible gas, and issuing at a point or position that may be called its surface.

The oil thus burns without wick or chimney, and affords a light of 180 standard candles, with an hourly consumption of a little over 2 lbs. of creosote.

An apparatus for a similar purpose has been patented by Lyle and Hannay, under the name of the 'Lucigen.' It consists of an oil tank or reservoir, fitted with a special burner at the top of a tube, which may be extended to any length; into this reservoir compressed air is introduced by an indiarubber pipe, so attached as to make the 'Lucigen' portable. On the compressed air being admitted into the oil tank or receptacle, it forces the oil up through an internal tube, and, escaping at the same time with the oil in the burner, produces a spray which is set on fire. A light of about 2000 candle-power is given by the 'Lucigen.' The flame is large, the light well diffused, and the eyes are not dazzled by it. There is little or no smoke from the flame, and the lamp burns equally well under heavy rain or spray; it requires no lantern, and has no parts which can be damaged by rough usage. In the 'Doty' and 'Wells' lights, pressure is brought to bear on the surface of the oil or creosote by means of an air pump, whereby the oil is forced through a coil surrounding the lower portion of the flame, and becomes distilled into gas.

Creosote oil has also been employed for the purpose of illuminating and heating, by direct conversion into permanent gas. A ton of creosote is capable of yielding 13,300 cubic feet

of gas, with an illuminating power of 14 candles; a yield of 29,300 cubic feet may be obtained, but of $8\frac{1}{2}$ candle-power only; the chief drawback to this method of utilisation is the high temperature necessary to decompose the oils, and which results in the production of low candle-power gases.

Employment of creosote as fuel.—Creosote oil is extensively used as a fuel, both for marine and stationary purposes and especially for furnaces for heating iron rods for the manufacture of bolts and rivets, and, from theoretical considerations, would appear to be eminently adapted to the purpose, 1 lb. of coal-tar creosote, when effectively burnt, being capable of evaporating 11.24 lbs. of water, a result which is considerably in excess of that obtained from coal or coke.

Various methods have been devised for burning the oil to the greatest advantage. These may be briefly summarised under the following heads:—

1. Injection into the furnace by means of compressed air with 'atomising' apparatus.

2. Injection into the furnace by means of steam with 'atomising' apparatus.

3. Feeding into the furnace by simple gravitation, alone or in combination with coke.

G. F. Dexter (Journ. Gas Lighting, June 29, 1886, 1242–1244), in a table showing the relative calorific values of certain coal-tar distillates, refers to creosote, or heavy oils, as under:

Average formula $C_{14}H_{16}$; b.p. 240° to 270° and upwards.

Proportionate weight of constituents:

Carbon	0.93913
Hydrogen	0.06087

Calorific value:

Carbon units	497
Hydrogen units	210

Employment of creosote oil as an antiseptic and for the purposes of a cattle wash and sheep dip (v. DISINFECTANTS).

Creosote oil is also now largely used to absorb benzene from coke-oven gas. The gas, after the extraction of the ammonia, is passed up towers or scrubbers down which a shower of creosote oil falls. The creosote oil takes up from 3 to 4 p.c. of benzene, and this is regained by distillation with steam, the creosote being used over and over again until, by the accumulation of dirt and tar, it becomes too viscid, when it is generally run into the tar well. This fact should not be lost sight of when estimating the proportion of creosote in coke-oven tars.

The heavier portions of creosote oil are also used to absorb naphthalene from coal gas; the gas is passed through washers containing the oil. As the oil tends to abstract some of the illuminants from the gas, it is best to add to the oil before use a small proportion of benzene sufficient to saturate the oil so that no more is absorbed from the gas.

The heavier oils are also used as a rough lubricant for brick-making machinery, and for injecting into the brick kilns during the burning of the bricks to impart a superficial blue colour to them. The creosote acts as a reducing agent on the iron compounds in the clay, and the red colour is changed to blue.

A preparation of heavy creosote or anthracene oil with lime is used as a cart or axle grease.

The examination of creosote oil usually comprises the determination of the specific gravity, the percentage of tar acids, the amount of water present, the point at which it liquefies, and the distillation temperatures. The methods employed will be described in the article on WOOD PRESERVATIVES.

Creosotes from other sources (blast-furnace and shale oil).—Several creosotes of this character have been studied by Watson Smith and A. H. Allen. They have been found to differ materially from those derived from coal and wood tar, occupying an intermediate position. The waste gases issuing from blast furnaces fed with coal instead of coke, deposit a considerable quantity of tar yielding a creosote greatly resembling that furnished by gas tar; it differs, however, in having a lower specific gravity and in the character of the phenoloids obtained from it. The phenoloids from blast-furnace tar, extracted by Watson Smith, contained only 1.33 p.c. of real phenol, boiling at 182°, whereas the tar acids from Lancashire tars yielded 65 p.c. of crystallisable carbolic acid.

The fractions passing over between 210° and 230° contain phlorol and cresol, and those following at a higher temperature, viz. 360°, furnish compounds allied to the eupittonic acid obtained from wood tar.

The tar obtained from producers using bituminous coal also furnishes creosote strongly resembling that from blast-furnace tar.

The pyrogallic ethers, boiling respectively at 253°, 265°, and 285°, found by Hofmann in wood creosote, have also been separated from shale creosote. Blast-furnace creosote oil is now produced in vast quantities in Scotland, and the question of its application has received a considerable amount of attention. It is employed to a certain extent for creosoting timber, in producing the 'Lucigen' light, and as a liquid fuel. It furnishes from 20 to 35 p.c. of phenoloid substances soluble in caustic soda, as against 4 to 7 p.c. in London coal-tar creosote, and about 16 p.c. for Midland and country make. Allen and Angus, who have closely studied these bodies, have secured by patent their use as an antiseptic under the name of 'neosite,' a word signifying 'new preserver' (Eng. Pat. 11689, August 29, 1887). Experiments have shown that the substance compares favourably with carbolic acid, whilst its caustic properties, when applied to the skin, are very much less marked. When freshly prepared, the fluid is almost colourless, and bears the greatest resemblance to wood-tar creosote.

CRESOL $C_6H_4(CH_3)OH$. The three isomeric cresols exist in coal tar (Williamson and Fairlie, Annalen, 92, 319; Ihle, J. pr. Chem. [2] 14, 442; Tiemann and Schotten, Ber. 11, 767, 783) in about the following proportions: orthocresol, 35 p.c.; metacresol, 40 p.c.; and paracresol, 25 p.c. (Schulze, *ibid.* 20, 410).

The cresols can be separated from the oily, non-crystallisable mother liquors obtained in the purification of crude phenol by fractiona-

tion and crystallisation, by dissolving them in soda lye, freeing the solution from naphthalene or other hydrocarbons by a current of steam, and then fractionally precipitating with sulphuric acid. The first fractions, owing to the greater acidity of phenol, contain chiefly cresols, and are further purified by distillation (Müller, Zeitsch. Chem. 1865, 270).

Various processes have been patented for obtaining meta- and para-cresol from crude cresol. Raschig (Eng. Pat. 18334; D. R. P. 112545; J. Soc. Chem. Ind. 1900, 37), by repeated fractionation of the crude cresol, obtains a mixture containing 60 p.c. of meta- and 40 p.c. of para-cresol. This mixture is then sulphated by means of concentrated sulphuric acid, in which *m*-cresolsulphonic acid is easily soluble, but the *p*-compound only with great difficulty. The mixture is allowed to stand for a week, and the crystals of the *p*-sulphonic acid are removed, or a soluble sodium salt, such as the sulphate, may be added in quantity sufficient to form the sodium salt of the *p*-cresolsulphonic acid. The latter is separated from the mother liquor, which consists of *m*-cresolsulphonic acid and a little sodium sulphate. The two cresols are obtained from their respective sulphonic acids by hydrolysis with superheated steam. In another process (Raschig, Eng. Pat. 25269; J. Soc. Chem. Ind. 1900, 1099) the mixture of the two sulphonic acids is subjected to the action of superheated steam at 120°–130°, the *m*-cresolsulphonic acid alone being hydrolysed under these conditions. The *m*-cresol distils off, and on raising the temperature to 140°–160° the *p*-sulphonic acid is hydrolysed and *p*-cresol is obtained.

According to the Chem. Fabr. Ladenburg (D. R. P. 148703; Chem. Soc. Abstr. 1904, i. 312), separation of *m*- and *p*-cresols, by partial sulphonation, is incomplete. The process recommended is to heat crude cresol with sodium hydrogen sulphate at 100°–110°, dissolve the product in water, when *p*-cresol separates out as an oily layer, the *m*-cresol alone being sulphated. Superheated steam, at 180°, is passed in to obtain *m*-cresol, after the *p*-cresol has been separated.

Another process of the same firm (Eng. Pat. 1881; Fr. Pat. 339880; D. R. P. 152652; J. Soc. Chem. Ind. 1904, 759) consists in saturating the crude cresol with milk of lime, when the calcium salt of *m*-cresol, which is much less soluble than that of the *p*-cresol, separates out. This is filtered off, decomposed with acid, and relatively pure *m*-cresol is obtained. The crystals of the calcium salt, before decomposition with acid, may be washed with benzene to free them from the last traces of mother liquor. Reihm (D. R. P. 53307; Frdl. ii. 9) separates *m*-cresol from *p*-cresol by means of their barium salts.

Rütgers (Fr. Pat. 317512; D. R. P. 137584 and 141421; J. Soc. Chem. Ind. 1902, 1410) treats the commercial mixture with anhydrous oxalic acid or an anhydrous acid oxalate. By this means, the oxalic ester of *p*-cresol alone is formed and separates out. This ester is separated and decomposed by water into *p*-cresol and oxalic acid; the *m*-cresol is obtained from the mother liquors.

Synthetical preparation of ortho- and para-

cresol.—Pure ortho- and para-cresol can be obtained by fusing the potassium salts of the corresponding toluenesulphonic acids with alkali (Engelhardt and Latschinow, *Zeitsch. Chem.* 1869, 620), or by diazotising the corresponding toluidines. For this purpose the toluidine (15 parts) is dissolved in sulphuric acid of sp. gr. 1.8 (15 parts) diluted with 500 parts of water, treated with an aqueous solution of potassium nitrite (12 parts), and the product gradually heated with steam. The resulting cresol is then distilled with steam, the distillate treated with soda lye, then with sulphuric acid, and the liberated cresol extracted with ether and finally distilled in a current of carbon dioxide (Tiemann and Schrotter; Ihle (*loc. cit.*)).

Orthocresol can also be obtained from carvacrol by treatment with phosphorus pentoxide (Kekulé, *Ber.* 7, 1006). It is crystalline, melts at 30° (T. and S.); Ihle; Béal and Choy, *Compt. rend.* 118, 1211), at 31°–31.5° (K.); boils at 178.5° (B. and C.), 188° (T. and S.), at 191° (corr.) (Perkin, *Chem. Soc. Trans.* 1896, 1182), is soluble to the extent of 2.5 vols. in 100 vols. of water, and on fusion with caustic potash is converted into salicylic acid. When nitrated, it yields dinitro-orthocresol (m.p. 86°–87°) (Nölting and Salis, *Ber.* 14, 987).

Metacresol is prepared by heating thymol (100 parts) with half its weight of phosphorus pentoxide for 10–12 hours until propylene ceases to be evolved, adding the product to 115–120 parts of fused alkali, and further heating the fused mixture for 5–10 minutes to decompose the cresyl phosphate formed. The melt is then dissolved in water, treated with ether to remove any undecomposed cresyl phosphate and other impurities, then acidified with hydrochloric acid, and the separated metacresol extracted with ether, and finally distilled in a current of carbon dioxide (E. and L.; T. and S.).

Metacresol is also prepared from naphthalene 1.3.3', 1.3.6, or 1.3.8- trisulphonic acids, from analogous hydroxy- or amino-naphthalene mono- or di-sulphonic acids or from trihydroxynaphthalene; e.g. 1.3.3'-naphthalene trisulphonic acid together with half its weight of caustic soda and three quarters of water, is heated for 5 hours at 280°. The product is poured into water, acidified, boiled to expel sulphurous acid, and filtered: *m-cresol* separates out on cooling (Kalle & Co. Eng. Pat. 16559; D. R. P. 81484; J. Soc. Chem. Ind. 1895, 1800). It is ordinarily a liquid, but has been obtained in crystals, melting at 3°–4° (Städel, *Ber.* 18, 3443; B. and C.); it boils at 200° (B. and C.), 201° (Oppenheim and Pfaff, *Ber.* 8, 886), 202° (corr.) (P.); and is soluble to the extent of 0.53 vol. in 100 vols. of water. Its aqueous solution is coloured blue by ferric chloride. When fused with caustic potash, it is converted into metahydroxybenzoic acid, and on nitration it yields a trinitro- derivative (m.p. 105°–106°) (Nölting and Salis, *Ber.* 14, 987; 15, 1858).

Paracresol crystallises in prisms, melts at 36° (Barth, *Annalen*, 154, 358 [B. and C.]), 36°–37° (T. and S.), and boils at 198° (I.), at 198°–199° (T. and S., B. and C.), at 202° (corr.) (P.); and is soluble to the extent of 1.8 vols. in 100 vols. of water. Its aqueous solution gives a blue colour with ferric chloride. When fused with caustic potash, it is converted into parahydroxybenzoic

acid, and on nitration it yields a dinitro- derivative (m.p. 85°) (Richter, *Annalen*, 230, 313; Nölting and Salis, *l.c.*).

The crude cresol, as obtained from coal tar, is only slightly soluble in water, but its solubility, in an aqueous solution of potassium cresol, renders its employment as an antiseptic possible. This solution is named *solvol* (Lacroix-Hunkiabýendian, *J. Pharm. Chim.* 28, 34). The crude cresol is also frequently mixed with soaps, and is used in that form for disinfecting purposes (Dammann, D. R. P. 52129; *Frld.* ii. 538; Holmers, D. R. P. 76133 and 80260; *Frld.* iv. 1119 and 1120; Raschig, D. R. P. 87275; *Frld.* iv. 1121; Engler and Dieckhoff, *Arch. Pharm.* 230, 561; 232, 351).

Oxidation with peroxides at a high temperature converts the cresols into the corresponding hydroxybenzoic acids (Friedländer and Löw-Beer, D. R. P. 170230; *J. Soc. Chem. Ind.* 1907, 434).

A mixture of nitro- derivatives, obtained by sulphonating coal-tar cresol and nitrating the sodium salt of the resulting cresolsulphonic acid with nitric acid of sp. gr. 1.2, has been employed, under the names 'Victoria yellow,' 'safron surrogate' (*q.v.*), as a dye for wool and silk; and, although poisonous (compare Weyl, *Ber.* 20, 2835; 21, 512), is occasionally used as a colouring matter for butter, cheese, &c. By heating crude cresol with sulphur and alkali sulphide, or with alkali polysulphides, or with a mixture of sulphur and alkalis, at a high temperature, brown sulphur compounds are obtained which are used for dyeing cotton (Farb. vorm F. Bayer & Co., D. R. P. 102897; *Chem. Zentr.* 1899, ii. 352).

CRESOLIN. A disinfectant composed of crude phenol and rosin soap.

CRESOLINE YELLOW *v.* AZO- COLOURING MATTERS.

CRESORCINOL *v.* PHENOL AND ITS HOMOLOGUES.

CRESYLIC ACID. The non-crystallisable, higher boiling portion of the phenols obtained in the purification of phenol (*q.v.*) is, after redistillation, known commercially as cresylic acid or liquid carbolic acid. It is a colourless, oily, refractive liquid, does not solidify at –80°, has a sp. gr. 1.044, and consists of 40 p.c. metacresol, 35 p.c. orthocresol, and 25 p.c. paracresol (Schulze, *Ber.* 1887, 410). It is much less soluble than carbolic acid in water, ammonia, glycerol, or caustic soda, but more readily so in petroleum spirit. It boils at a higher temperature (about 185°–203°), gives a mixture of *m*-tribromo and *o*- and *p*-dibromo derivatives with bromine. It is even more readily acted upon by concentrated sulphuric and nitric acids than carbolic acid (Lunge, *Coal Tar and Ammonia*, ed. 1900, 182; *v. also* Allen, *J. Soc. Chem. Ind.* 1890, 141). Its antiseptic properties are more marked than those of carbolic acid or of either of the three cresols.

CRESYL BLUE *v.* OXAZINE COLOURING MATTERS.

CRITH. The weight of a litre of hydrogen at 0° and 760 mm. pressure—viz. 0.0896 gram.

CROCEÏN, BRILLIANT, ORANGE, SCARLETS, *v.* AZO- COLOURING MATTERS.

CROCEÏNE *v.* AZO- COLOURING MATTERS.

CROCIDOLITE. (*Krokydolith*, Ger.) A mineral of the soda-amphibole group, consisting of sodium and iron (ferric and ferrous) silicate, $\text{NaFe}^{III}(\text{SiO}_3)_2\text{Fe}^{II}\text{SiO}_3$. It is known only in a finely fibrous form, its name, in fact, being from *κροκός*, *κροκίδος*, wool. In the trade it is known as *blue asbestos*, and it is worked for the same purposes as the other varieties of asbestos (*q.v.*). It is, however, more readily fusible (to a black magnetic glass) than are tremolite-asbestos and serpentine-asbestos. The mineral has been long known from the Asbestos Mountains near the Orange River in Griqualand West, South Africa, where it occurs abundantly as veins, 1 or 2 inches in thickness, in jasper-schists. The closely aggregated parallel fibres are arranged perpendicularly or nearly so to the walls of the veins; and the material is extracted as slabs. Over 100 tons a month are mined for commercial purposes (H. F. Olds, *Trans. Inst. Mining and Metall.* 1899, vii. 122).

Being an alkali silicate with ferrous iron, crocidolite is especially liable to decomposition when exposed to weathering; sodium is removed, and the iron oxidised and hydrated to form limonite, while the silica is set free. There then results a ferruginous quartz possessing the finely fibrous structure of the original mineral; or, in other words, a pseudomorph of quartz and limonite after crocidolite. This material is coloured a rich golden yellow, and displays a silky lustre, and being at the same time very

hard, it is well adapted for ornamental purposes. When cut and polished with a convex surface, it displays a cat's-eye effect, and it is extensively used for making knobs, umbrella handles, beads, &c. Such material is known as *tiger-eye*, though unfortunately in the trade, the name crocidolite is very frequently misapplied to it. The name *pseudo-crocidolite* would be more appropriate. In some stones there has been silicification without oxidation, and the indigo-blue colour of the original crocidolite has been preserved: material of this kind is known as *hawk's-eye*.

L. J. S.

CROCOISITE. Native lead chromate (*v.* CHROMIUM).

CROOKESITE *v.* THALLIUM and SELENIUM.

CROPS. The composition of crops may be regarded from two points of view: (1) the materials they contain, which render them valuable either as food or as sources of some substance of commercial value; (2) the materials they remove from the soil, which must eventually be replaced if the fertility of the land is to be maintained.

In Table I., the composition of some of the principal crops grown in the United Kingdom is set out, cereals being excluded because they are dealt with separately. The composition of each of these materials shows considerable variations, and the analyses given are either typical or the means of a small number of determinations.

TABLE I.—PROXIMATE COMPOSITION OF CROPS.

	Water	Crude fat	Protein crude	Carbo-hydrates	Crude fibre	Ash

Seeds hay	14.30	2.70	10.20	36.10	30.20	6.50
Mustard, green	85.10	0.40	2.90	7.30	2.90	1.40

Leguminous crops. The leguminous seeds are distinguished by their high protein content. The proteins of the bean and pea and similar seeds have been studied by Ritthausen (*Eiweisskörper der Getreidearten*, Bonn, 1872) and Osborne (*J. Amer. Chem. Soc.* 1898, 20, 410; *Amer. J. Physiol.* 1908, 23, 180, &c.). The most abundant of these is the so-called legumin (*q.v.*), which, according to Osborne, is a globulin con-

taining lysine. Lentils contain a conglutin which has been hydrolysed, also some edestin.

The leguminous seeds grown in this country contain but a small proportion of oil, which has not received any special examination; the soya bean, however, yields oil up to 20 p.c., and is now being extensively imported from Manchuria and pressed for oil (*v.* SOYA BEAN).

The only carbohydrate in beans, peas, &c., that has received any attention, is the starch, which is abundant and the granules of which possess

¹ Aitken, *Trans. H. & Ag. Soc.* 1884, 16² Wilson, *ibid.* 1886, 18.

characteristic shapes. The ash of leguminous plants is distinguished by a large proportion of lime, as may be seen from analyses 5-10 in Table II.

Root crops. In these materials, the ether extract contains little, if any, true fat, the nitrogen-containing substances are also very far from being all protein; usually one-half or more of the nitrogen present is combined in various non-protein forms.

Potatoes.—The characteristic carbohydrate is starch, of which there may be over 20 p.c.; but sugars (both sucrose and reducing sugars) may be present up to 1 p.c., and dextrins or amylans are also present in about the same amount. Amongst the nitrogen compounds there are both insoluble and soluble proteins, part of the latter being coagulable by heat or acids, and a large range of amino-bodies, among which tyrosin has been identified. The non-protein nitrogen may amount to more than half the total nitrogen. The darkening of the juice of a fresh potato is due to the black substance formed by the oxidation of the tyrosine under the action of an enzyme, also present in the cells. The darkening of boiled potatoes is due to some other cause (Ashby, J. Agric. Sci. 1905, i. 348). About two-thirds of the ash of potatoes consist of phosphoric acid and potash.

Mangolds.—The characteristic carbohydrate present in the mangold is sucrose, which constitutes about 8 p.c. of the weight of the root, the total dry matter amounting to about 13 p.c. About 0.25 p.c. of reducing sugar is also present. The variation in the sugar content of mangolds has been examined by Wood (J. Agric. Sci. 1905, 1, 176), who gives the following table:—

Variety	Yield per acre—tons	Dry matter p.c.	Sugar p.c.	Nitrogen p.c.
White-fleshed globe	29.9	10.7	6.3	0.165
" intermediate	27.4	12.0	7.1	0.168
Yellow-fleshed tankard	24.6	13.1	8.0	0.186
" globe	25.0	13.4	8.2	0.191
Long red	29.9	13.1	7.9	0.157

Of the nitrogen in mangolds, only 30-50 p.c. is in the protein form, 20-40 p.c. is combined as amide or amino-acid and is liberated on hydrolysis as ammonia, while 10 p.c. may be in the nitric form.

On storage, the mangold loses sugar by respiration, and some of the sucrose becomes changed into reducing sugar, a process which is much accelerated as soon as the temperature rises in the spring (see Miller, J. Roy. Agric. Soc. 1900, 61; 1902, 63).

Sugar beet.—In the sugar beet, which has been derived from the same species of *Beta* as the mangold, the characteristic carbohydrate is likewise sucrose, which may be present to the extent of 20 p.c. It is always accompanied by a certain proportion of reducing sugars (glucose and maltose), which, in well-grown roots, should not exceed 1 p.c. of the sucrose.

The variations in the amount and nature of the sugars in sugar beet have been subjected to very detailed investigation, for accounts of which the numerous technical works dealing with the beet-sugar industry, such as Briem, *Der Praktische Rübenbau*, should be consulted.

The nitrogenous constituents resemble those of the mangold (see Lippmann, *Ber.* 1896, 29, 2645).

Swedes and turnips.—In these closely allied roots, the carbohydrates consist of sugars (chiefly reducing sugars, though few data exist) and pectic bodies yielding a mucilage on boiling with water. In Wilson's analyses, already quoted, the sugars averaged 4.72 p.c. The nitrogen compounds are also largely non-protein, only from 30 to 50 p.c. consists of protein. It is generally considered that swedes and turnips grown in the north and especially in the east of Scotland, possess a higher feeding value than the roots grown in the south; analytical data to confirm this opinion are, however, lacking, though it is certain that much larger crops are usually grown in the cooler climate of the north, where the crop can be sown earlier with success.

Ash of crops. In Table II. are collected various analyses of the ash of the crops above mentioned.

TABLE II.—COMPOSITION OF THE ASH OF FARM CROPS.

—	Ash in dry matter	N in dry matter	Fe ₂ O ₃	CaO	MgO	K ₂ O	Na ₂ O	P ₂ O ₅	SO ₃	Cl	CO ₂	SiO ₂

Analyses 8-16 are means taken from Wolff's Aschen-analysen, and have been recalculated to exclude the carbon dioxide present in the ash, as obtained after burning. Analyses 1-7 are selected from the Rothamsted records.

Materials removed from the land by average crops. Table III., compiled by Warington

from Rothamsted data, shows the amount of the three important constituents—nitrogen, phosphoric acid, and potash, which would be contained in an average crop of the magnitude indicated, and therefore have been removed from the soil by the crop, except in the case of the nitrogen contained in leguminous crops.

TABLE III.—AMOUNT OF FERTILISING CONSTITUENTS PER ACRE REMOVED BY AN AVERAGE CROP.

—	Weight of	Nitrogen	Potash	Phosphoric
	crop, dry			acid
	lbs.	lbs.	lbs.	lbs.
Wheat, 30 bushels, straw 28 cwts.	4183	50	28·8	21·1

Potatoes, 6 „ tubers	3360	46	76·5	21·5

A comparison of these figures with the amount of fertilising material usually provided for the crops in question, or the effects of particular manures in field experiments, serves to show that the data contained in Table III. afford no guidance in deciding the appropriate manure for each crop.

The earliest theory of plant manuring, that of Liebig, supposed that the requirements of the plant can best be satisfied by applying to the land exactly the constituents taken away by a good crop of that particular kind; but the results of the Rothamsted experiments, confirmed by general farming experience, very soon showed that this view was incorrect, because it failed to take into account the enormous amount of plant food contained in the soil, more or less of which would reach the plant according to the method of cultivation and the plant's habit of growth. Moreover, in practical farming the supply of manure is largely determined by the place the crop occupies in the rotation and the treatment which has been given to the previous crops. To take an example, wheat and barley withdraw almost the same fertilising materials from the soil, yet all farming experience goes to show that the yield of wheat is chiefly determined by the supply of nitrogen. If this element is present in sufficient quantity the wheat plant with its long period of growth is usually able to satisfy its requirements for phosphoric acid and potash from the soil. With barley, nitrogen is still a most important element in nutrition, but phosphoric acid also exerts a striking beneficial action and is a necessary element in the fertiliser. Neither for wheat nor barley need potash be supplied except on very light soils. A still more noteworthy example is provided by the swede turnip crop. The table shows that an average crop will take away from the soil about 100 lbs of nitrogen, 20 lbs. of phosphoric acid and 80 lbs. of potash, yet the usual fertilisers applied to swedes consist almost wholly of phosphatic compounds, with a comparatively small amount of nitrogen and no

¹ Wholly or in part derived from the atmosphere.

potash. The majority of the swedes grown in this country receive from 50 to 100 lbs. of phosphoric acid (*i.e.* about 5 cwt. of superphosphate or basic slag), and the small quantity of nitrogen that would be provided by a light dressing of farmyard manure or half a hundred-weight of sulphate of ammonia. The fertilising requirements of a crop are in fact conditioned by the soil (*q.v.*) rather than by its composition.

A. D. H.

CROTON OIL is obtained from the seeds of *Croton Tiglium* (Linn.), a tree belonging to the *Euphorbiaceæ*, indigenous to the Malabar coast, and cultivated in Southern Asia and China. The seeds contain 53-56 p.c. of oil.

The oil has an amber-yellow, orange, or brown colour, according to its age; it has a nauseous odour, a burning taste, and acts as a very powerful purgative.

The chemical composition of croton oil differs so widely from that of all other oils, that its recognition, by means of the 'quantitative reactions' (*see OILS AND FATS*), is easy. It contains a considerable amount of volatile acids; hence its Reichert-Meissl value is about 13; its iodine value is 103-104. Croton oil is strongly dextro-rotatory.

J. L.

CROWN GLASS *v.* **GLASS.**

CRUCIBLES. A perfect crucible should withstand the highest temperatures without fusion, should bear sudden changes of temperature without fracture, and should be unacted upon by the materials which are to be heated in it. A semi-automatic apparatus for moulding crucibles has been patented by Sims (Eng. Pat. 445, 1888).

Clay crucibles are prepared from selected clay; of the Stourbridge clay worked, only about 5 p.c. is available for this purpose. Its plasticity is much increased by exposure for some months in a moist condition to the air. During this process of 'weathering' it becomes disintegrated, and the removal of foreign matter is thereby facilitated. The presence of iron pyrites is especially injurious; furnace gases convert it into the oxide which acts as a flux and forms cavities

in the crucible. Lime is also hurtful, except when in very small quantities and uniformly distributed. Potash and soda are invariably present in clay, and when in small quantity increase the coherence of the crucible without appreciably impairing its power of withstanding the action of heat.

In order to reduce the tendency to crack, and to increase its refractory character, the clay is usually mixed with sand, ground flints, burnt clay (old broken crucibles), graphite or coke. These, which are either less fusible than the clay or altogether infusible, form a skeleton which upholds and prevents deformation of the crucibles at temperatures at which the clay would tend to fuse. The most refractory crucibles contain the largest proportion of silica.

The clay, which should be of the greatest possible fineness, is well beaten to remove air bubbles and mixed with the proper quantity of the refractory material. According to Berthier (*Traité des Essais*, I, 66), when silica is used, it should not be too fine, as the tendency to combine with the clay and thus increase the fusibility would thereby be increased. Crucibles of fine grain are also more liable to fracture.

Small crucibles are usually baked in a kiln, but the large casting pots of Stourbridge clay are not baked until immediately before use. When the temperature of the baking is high, the crucible is more liable to fracture on reheating.

All clay crucibles are more or less acted upon by litharge, but metals and most ores may be heated in them without danger. Berthier recommends a lining of such material as silica, alumina, or magnesia previously moistened. A lining of chalk renders a crucible less permeable to litharge.

Queneau recommends lining clay crucibles, before drying, with some substance which will

resist the chemical reactions for which they are designed and then compressing strongly, drying, and firing (Fr. Pat. 354319; J. Soc. Chem. Ind. 1905, 1071).

Crucibles may be rendered non-porous by treating with ferrous sulphate solution and firing (Mitchell, U.S. Pat. 894845; J. Soc. Chem. Ind. 1908, 886) or by the addition to the clay of chromic oxide, chromites or chrome iron ore, which also renders them much more refractory (Bach, Eng. Pat. 24041, 1903; Klein, U.S. Pat. 787770; Seigle, Fr. Pat. 383593; and Placet, Eng. Pat. 28728, 1896).

The fracture of crucibles by expansion of solidifying metal can be prevented by lining with friable material (Colby, U.S. Pat. 830208; J. Soc. Chem. Ind. 1906, 934).

Goldschmidt recommends that crucibles for the 'Thermit' process should be lined with a mixture of magnesia or carborundum and soluble glass (Fr. Pat. 354597; J. Soc. Chem. Ind. 1905, 1114).

Very large crucibles may be built up from cylinders or annular rings of refractory material, provided arrangements are made for tapping the contents without moving the crucible (Reynolds, Eng. Pat. 1004, 1901; Rousseau, Eng. Pat. 7451, 1902).

Stourbridge clay crucibles are made from a mixture of raw ground clay with about one-half its weight of powdered, sifted, old glass pots, from which all adherent glass has been removed, the mixture being made in a disc mill, and kneaded to the proper consistency. Percy gives the composition of the Stourbridge clay used for the best crucibles as silica, 79.25; alumina, 13.57; iron oxide, 1.38; lime, 0.08; magnesia, 0.42; water, 5.11.

The following analyses show the composition of certain varieties of crucibles. Nos. 1-7 are by Berthier, No. 8 by Dick, Nos. 9-12 by Brand, and Nos. 13-15 by Mène :—

Hessian crucibles are composed of equal weights of Almerode clay and sand. They are usually triangular, of coarse texture, porous, rapidly destroyed by litharge, and liable to fracture on sudden change of temperature, but will withstand a very high degree of heat.

French crucibles are made from a mixture of

1 part raw Ardennes clay and 2 parts of the same which has been burnt. They are refractory and of fine texture.

Cornish crucibles are largely used for copper assaying. They are round, of coarse grain, and of a mottled greyish-white colour. They are kiln-burnt, and withstand sudden changes of

temperature, but cannot be heated to whiteness. Cornish crucibles are now made by the Morgan Crucible Company at Battersea.

London crucibles are of reddish-brown colour and close texture. They will not stand sudden change of temperature, but withstand the action of litharge fairly well.

Silica crucibles may be made of powdered silica, mixed with a highly absorbent substance, e.g. kieselguhr, saturated with water (Sankey, Eng. Pat. 3353, 1906; J. Soc. Chem. Ind. 1907, 96). Sand, mixed with a small proportion of cement and water, moulded, dried, and heated to the fusing-point of the sand, forms a very refractory material (Reppy, U.S. Pat. 905295; J. Soc. Chem. Ind. 1909, 24). A mixture of sand with a little lime may be used (Berglund, Fr. Pat. 366830; J. Soc. Chem. Ind. 1906, 1081).

White fluxing pots are made by the Morgan Company from a highly refractory fire-clay from Rouen. Crucibles containing carbon are now largely used. For very high temperatures, crucibles cut from a block of gas carbon or similar material may be employed. Clay crucibles may also be filled with a moist mixture of charcoal with starch, treacle, gum-water, or oil, or, for large crucibles, gas tar. The mass is forced with considerable pressure into the crucible and is then cut out, leaving a coating of about $\frac{1}{8}$ inch in thickness, or the coating is put into the crucible and smoothed with a glass rod. The crucible is then filled with powdered charcoal and heated to redness.

Graphite crucibles. For the fusion of metals, plumbago or coke crucibles are of great value, but they are not largely used for assaying. At the Battersea works, the following process of manufacture is employed: hand-picked Ceylon plumbago is ground, sifted, digested with dilute sulphuric acid to remove the greater part of the iron, and mixed and kneaded to a stiff paste, with about an equal weight of fine fireclay. The mixture is passed through a pug-mill, and is cut into blocks. When required for use, the blocks are again passed through the mill, and made by hand on a wheel or moulded by machinery. They are then dried and baked in saggars. These crucibles may be protected from oxidation by lining them with clay (Woolford, Eng. Pat. 24479, 1898; J. Soc. Chem. Ind. 1900, 52; McDonald, U.S. Pat. 828954; J. Soc. Chem. Ind. 1906, 911).

They are of fine grain, and will withstand the highest temperatures and repeated sudden changes. The graphite is slowly oxidised by metallic oxides or by the furnace gases. To minimise this, the crucible may be coated by dipping in a paste of clay and solution of borax. Any iron which is present in the graphite is liable to become introduced into the melt, and the carbon itself combines with iron or steel (v. Brand, Chem. Zentr. 15, 407; and Dingl. poly. J. 256, 227).

Tar, rosin, &c., may be used to bind the clay and graphite in manufacturing these crucibles (Putz, D. R. P. 181979; J. Soc. Chem. Ind. 1907, 1030). Digby recommends (Eng. Pat. 3661, 1893) the following composition:—

Plumbago, 17-mesh granules	17 parts
Plumbago, 80-	2 „
Russian clay	5 „
China-stone	5 „
Gas carbon	2 „

The last three ingredients are ground and mixed with water and then the plumbago is added and the crucibles formed, dried at 65° and baked.

Salamander crucibles, made by the Morgan Company, contain a much smaller proportion of carbon. They withstand sudden changes of temperature perfectly.

Lime crucibles are cut from blocks of well-burnt (preferably slightly hydraulic) lime.

Magnesia was introduced by Caron as a refractory basic material for making crucibles or for lining reverberatory furnaces for melting and dephosphorising steel. Magnesia contracts considerably when heated; it is therefore necessary, before making it into bricks or crucibles, to expose it to a higher temperature than that to which it will be heated. The strongly calcined magnesia is made into a paste with 15–30 p.c. of raw (slightly calcined) magnesia, and 10–15 p.c. of water, and is moulded, dried, and baked at a red heat. The highly heated magnesia would not cohere without admixture with the raw material. Magnesia crucibles are not injured by exposure to the atmosphere. Gaudin makes crucibles from a mixture of 1 part magnesia and 1 part bauxite. They may also be formed from a mixture of calcined magnesite with from 2 p.c. to 12 p.c. of a boron compound (according to the amount of calcium present), moistened, moulded, dried and fired at a high temperature (Rawson and Littlefield, Eng. Pat. 16004, 1900; J. Soc. Chem. Ind. 1901, 992, and *ibid.* 1902, 52). The product is said to resist molten litharge. Porous crucibles for metal refining, are made from a similar mixture with the addition of sawdust (Dobell, Eng. Pat. 10715, 1897).

Alumina crucibles withstand sudden changes of temperature, and are not affected by the materials fused, even sodium being without action. According to Deville's process (Ann. Chim. Phys. [3] 46, 195), alumina precipitated at low temperature from ammonia alum solution is mixed with an equal weight of powdered marble, and is exposed to the highest temperature of a wind furnace. The mixture so produced, which may be considered as consisting of calcium aluminate, is mixed with its own weight of moist, precipitated alumina, and is made into a crucible, dried and baked (*see also* Caspar, U.S. Pat. 886111; J. Soc. Chem. Ind. 1908, 568). When the crucible is required to withstand higher temperatures, the amount of the calcium aluminate may be reduced, but the proportion of lime should not fall below 10 to 20 p.c.

Bauxite has been used to replace alumina. It is extremely refractory (v. *Baurite*, art. ALUMINIUM).

Carborundum crucibles are infusible and resistant to chemical action and have great solidity. They may be made from a mixture of commercial carborundum with sufficient clay to render it plastic (Velter, Fr. Pat. 376179; J. Soc. Chem. Ind. 1907, 1010; Engels, Eng. Pat. 14567, 1901).

A mixture of powdered silica rock or ganister with carborundum or amorphous silicon carbide, may be used. It is mixed with water-glass solution or gluc, &c., compressed to shape and heated to the temperature of the electric furnace

(Imray and Carborundum Co. Eng. Pat. 19493, 1902; 3308, 1903) (see also CARBORUNDUM).

(See further, Kerl, Handb. Thonvaaren Ind. 1879, 528-534; and Percy, Metallurgy (Fuel, &c.), 1875, 110-141.)

CRUMPSALL YELLOW v. AZO-COLOURING MATTERS.

CRURIN. Trade name for quinoline bis-muth thiocyanate, used as an antigonorrhoeic.

CRYOLITE. (*Kryolith*, Ger.) A native fluoride of aluminium and sodium, found almost exclusively in Greenland, whence it has been sometimes called 'Greenland spar.' The name cryolite, or 'ice-spar' (*Eisstein*) refers to the general resemblance of the mineral to ice (*κρῖνος*) and to its ready fusibility in a candle flame. The mineral was discovered by the Danes in 1794, and described in the following year by Schumacher. Nearly all the cryolite of commerce is obtained from a single locality at Ivigtut (or Evigtok), on Arsuk-fjord in south Greenland. This locality was visited by Giesecké, and later by J. W. Tayler (Quart. Jour. Geol. Soc. 12, 140). The cryolite occurs as a large deposit in gneiss, and contains (especially near its junction with the enclosing rock) a number of metallic minerals, such as galena, pyrites, and chalybite (v. P. Johnstrup, N. Jahrb. f. Min. 1886, 1, Ref. 28; R. Baldauf, Zts. prakt. Geol. 1910, xviii. 432).

Cryolite is usually found in cleavable translucent masses; of snow-white colour, with a vitreous lustre. H. 2.5; sp.gr. 2.9-3. Crystals are rare, and their relations have been the subject of much discussion; they are cube-like in habit, and belong to the monoclinic system. Although cryolite is usually white, it is sometimes coloured brown or reddish, and is said to pass downwards, in the Greenland deposit, into a black mass. The black variety loses its colour when heated. Before the blowpipe cryolite fuses to a white enamel.

The composition of cryolite may be represented by the formula $3\text{NaF}\cdot\text{AlF}_3$. This corresponds to 12.8 p.c. Al, 32.8 Na, and 54.4 F. An analysis of the Greenland cryolite by Chodnev yielded 13.23 p.c. Al, and 32.71 Na, with 0.83 of Mn_2O_3 and MgO (Verh. Petersb. Min. Ges. 1845-6, 209). Durnev found in the cryolite of Miask in the Urals, 13.41 p.c. Al, 32.31 Na, 0.55 Fe_2O_3 and Mn_2O_3 , and 0.35 CaO (Pogg. Ann. 83, 587). Deville found in the Greenland cryolite 0.018 p.c. of vanadic acid and a small proportion of phosphoric acid. An analysis of cryolite from near Pike's Peak, Colorado, by Cross and Hillebrand yielded Al 12.9, Na 32.4, F 53.55, Fe_2O_3 0.4, Ca 0.28, H_2O 0.3 (Amer. J. Sci. [3] 26, 1883, 271).

Cryolite was formerly a rare mineral, but about 1855 it was introduced into Europe commercially, and at once found numerous applications in the arts. About 10,000 tons are now exported annually from Greenland. By heating finely powdered cryolite with sodium or with magnesium, J. Percy and A. Dick obtained metallic aluminium (Phil. Mag. 10, 1855, 364). Deville found that fused cryolite is decomposed by the passage of an electric current, with elimination of free aluminium. At the present time, aluminium is prepared by the electrolysis of bauxite, but the addition of some cryolite is

necessary to start the process and to keep it in continuous operation.

A wide range of applications was suggested when Julius Thomsen showed in 1850 that cryolite is readily decomposed by heating with calcium carbonate, and that sodium aluminate may be thus obtained:

If heated with quicklime, a similar decomposition is effected, of course without evolution of CO_2 . The sodium aluminate has been used in the manufacture of alum, and in the preparation of caustic soda for soap making. By lixiviation, the aluminate is easily dissolved out; and by the passage of CO_2 through the solution, Na_2CO_3 is obtained, while alumina separates in a gelatinous form. The decomposition of cryolite may also be effected by boiling the finely pulverised mineral with milk of lime. By adding an excess of powdered cryolite to the resulting solution, the aluminate is decomposed, the alumina being precipitated, while sodium fluoride remains in solution:

Cryolite can be readily decomposed by the action of sulphuric acid, with formation of sodium sulphate, which can be easily converted into carbonate; but the process, after trial at Copenhagen, has been abandoned in consequence of the inconvenience arising from the evolution of hydrofluoric acid:

The manufacture of soda from cryolite is carried on at Oersund in Denmark, and at Natrona, near Pittsburg in Pennsylvania. The mineral is also employed in the preparation of an opaline glass, somewhat resembling porcelain. This glass may be formed by fusing together 100 parts of silica, 35 or 36 of cryolite, and 13 or 14 of oxide of zinc. C. Weinreb has investigated the cause of the milkiness of cryolite glass, and believes that it is due to the presence of aluminium fluoride, which on the cooling of the fused mass, separates in a highly comminuted condition, and being distributed through the glass renders it more or less opaque (Dingl. poly. J. 256, 361).

L. J. S.

CRYOSCOPY. So long ago as 1788 Blagden proved that the extent to which the freezing point of an aqueous solution lies below that of water—the depression of the freezing point, as it is called—is proportional to the concentration of the dissolved substance. Nearly a century later, the researches of de Coppet and Raoult showed that when equimolecular proportions of different substances are dissolved in equal quantities of a given solvent, the solutions so obtained have, in general, the same freezing point. It is on these facts that the use of the cryoscopic method of determining the molecular weights of dissolved substances is based.

In comparing the effects of different substances on the freezing point of a given solvent, it is obviously convenient, in view of de Coppet's and Raoult's results, to refer these effects to 1 gram molecule of solute and to some definite quantity of the solvent: in practice, 100 grams of the latter are taken as the standard amount. The depression of the freezing point for such a

concentrated solution as one containing 1 gram molecule of solute in 100 grams of solvent cannot be determined directly: it is calculated from the depression observed for a dilute solution, on the basis of the proportionality between depression and concentration. An example may be taken to illustrate this point. A solution containing 0.609 gram of ethyl alcohol in 100 grams of water freezes 0.243° below the freezing point of water; from these data it follows, if proportionality between depression and concentration is assumed, that the depression for a solution containing 1 gram molecule of alcohol in 100 grams of water would be $\frac{0.243 \times 100}{0.609} = 18.4^\circ$. Again, a solution of 4.276 grams of sucrose in 100 grams of water, freezes 0.237° below the freezing point of water; from these data it follows, as above, that the depression for a solution containing 1 gram molecule of sucrose in 100 grams of water would be $\frac{0.237 \times 342}{4.276} = 19.0^\circ$. If the depressions produced by 1 gram molecule of other non-electrolytes in 100 grams of water are similarly calculated from experimental data, values are obtained which are very close to the figures already quoted. The depression, therefore, for a solution containing 1 gram molecule of non-electrolyte in 100 grams of water is a constant, independent of the particular solute; the average value of the constant for water, deduced in the empirical way just described, is 18.5°.

For each solvent, a characteristic constant (k) can be similarly deduced from experimental data. The evaluation of this constant—the 'molecular depression of the freezing point'—is effected, as illustrated above, by the formula $k = \frac{M}{g} \cdot \Delta t$, where Δt is the depression of freezing point observed for a solution containing g grams of solute in 100 grams of solvent, and M is the molecular weight of the solute.

It has been shown by van't Hoff that, on thermodynamical grounds, the molecular depression of the freezing point for any solvent is quantitatively related to the temperature of freezing and to the latent heat of fusion. The relationship in question is $k = \frac{0.0198T^2}{\omega}$, where T is the freezing point of the solvent on the absolute scale, and ω is the latent heat of fusion per gram of the solvent. The following table shows how far the values of the molecular depression, calculated for various solvents by van't Hoff's formula, are in agreement with those deduced empirically:—

Solvent	k Empirical	k Calculated
Water	18.5°	18.6°
Formic acid	28°	27.5°
Acetic acid	39°	38.5°
Benzene	50°	52°
Naphthalene	68.5°	69°
<i>p</i> -Toluidine	51°	51°
Phenol	75°	74°

The formula $k = \frac{0.0198T^2}{\omega}$ is based on the assumption that, when a solution freezes, it is the pure solid solvent which crystallises out. It is not surprising, therefore, that in cases where the crystals separating from the solution contain some of the dissolved substance, e.g. solutions of

thiophene in benzene, the empirical value for the molecular depression, deduced in the usual way, differs considerably from the normal value. In such cases the depression observed is smaller than it would be if the pure solid solvent separated out.

When the value of k for any solvent has been ascertained, either empirically by experiments with normal substances of known molecular weight, or indirectly by van't Hoff's formula, it may be utilised in determining the molecular weights of new substances. For this purpose, the formula $k = \frac{M}{g} \Delta t$ is employed, but now k is taken as known, and M is the quantity to be evaluated: in view of this, the equation may be written $M = \frac{k \cdot g}{\Delta t}$.

It is evident that a determination of the molecular weight of a dissolved substance by the cryoscopic method depends, not on the absolute freezing temperature of the solution, but on the difference between the freezing point of the solvent and that of the solution. This difference can be determined with greater accuracy than can the freezing temperatures themselves. A thermometer with a very open scale, covering only 5°–6°, is employed, and it is convenient, as suggested by Beckmann, to have a reservoir attached to the upper end of the thermometer tube, so that the quantity of mercury in the bulb and stem may be varied according to requirements. This device permits the use of one and the same thermometer at different temperatures, and therefore with various solvents. In Beckmann's thermometer, which is the one usually employed in cryoscopic investigations, the scale degree is about 4 cm. in length and is divided in hundredths: with the aid of a lens, preferably adapted for sliding up and down the stem, it is possible to estimate 0.001°. The form of the reservoir attached to the upper end of the ordinary Beckmann thermometer is shown in the accompanying sketch.

FIG. 1.

When it is desired to adjust the thermometer for experiments with any given solvent, the bulb is immersed in water of the same temperature as the freezing point of the solvent. If the top of the mercury thread should reach a steady position on the upper half of the scale, no further adjustment is needed. Should the mercury, after sufficient time has been allowed, extend beyond the scale and into the reservoir, it is necessary to detach a portion. This is effected by putting the bulb in water 2°–3° higher than the required temperature, and then gently tapping the upper end of the thermometer until the mercury hanging at the top of the reservoir is separated from the thread. On cooling down again to the freezing temperature of the solvent, the top of the thread should now come to rest somewhere on the upper half of the scale. If the quantity of mercury in the bulb and stem is too small, so that when the thermometer is immersed in

water of the same temperature as the freezing point of the solvent, the thread does not reach the scale or appears only on the lowest part of it, the bulb is warmed until the mercury appears at the top of the reservoir. By a throwing movement, some of the mercury at the bottom of the reservoir is jerked up to the top, where it joins the end of the thread. The bulb is then immersed in water 2° - 3° above the temperature required, and the final adjustment is carried out in the way already described.

The cryoscopic apparatus commonly employed for the determination of the molecular weight of dissolved substances is that known as Beckmann's. The accuracy of this method, as ordinarily applied, is not great, the error being of the order ± 5 p.c. For most laboratory purposes, however, this is sufficient, and it is only when extreme accuracy is required, as in the investigation of very dilute aqueous solutions, that special forms of apparatus have to be employed.

The essential parts of Beckmann's apparatus are seen in the subjoined diagram. A stout glass jar, holding about $1\frac{1}{2}$ litres, is provided with a metal top, at the side of which is a hole for a stirrer, and in the middle of which is another hole capable of holding a large stout test-tube, 3-4 cm. in diameter. The lid and the tube are held in position by springs, as will be evident from the diagram. By means of a cork, there is fitted in the tube another, narrower one, to hold the liquid under investigation. This tube should preferably have a flat bottom, while the part of it which projects beyond the outer jacket is provided with an auxiliary side tube, and

FIG. 2.

is itself widened out at the upper extremity. The cork with which this inner tube—the freezing tube, as it may be called—is fitted carries the thermometer, and allows also free passage to a stirrer. The latter is best made of stout platinum wire, but silver or nickel may be used, provided that the possibility of chemical action is excluded. The thermometer must be fitted in an accurately central position, so that the stirrer may be moved up and down without grating.

When a determination of molecular weight is to be made, the freezing tube is charged with a weighed quantity of the solvent, usually 10-20 grams, and the jar is filled with water or a mixture of ice and salt kept at a temperature 4° - 5° below the freezing point of the solvent under examination. The freezing tube, with thermometer and stirrer, is immersed directly in the jar, until the temperature has fallen almost to the freezing point. It is then set in the jacket tube and the contents are stirred

regularly, while the mercury in the thermometer falls slowly. The fall continues until the solvent is more or less supercooled. In the majority of cases, freezing sets in spontaneously before the supercooling exceeds 0.5° , and the liberation of heat results in a rise of the mercury in the thermometer up to a steady maximum position. This is the freezing point of the solvent—the temperature at which liquid and solid solvent are in equilibrium with each other. It is advisable, when the thread is rising towards its steady position, to tap the thermometer before taking a reading, and so avoid the possibility of the mercury sticking in the capillary. Should the supercooling exceed 0.5° , crystallisation ought to be initiated, either by stirring very vigorously for a few moments or by introducing a tiny crystal of the solid solvent. Whenever freezing has begun, the solvent must then be stirred with uniform regularity until the constant temperature has been reached.

The freezing point of the solvent having been determined two or three times in the manner just described, a weighed quantity of the solute, enough to give a depression of not less than 0.2° , is introduced, and the freezing point of the solution is then ascertained in the same way as that of the solvent. Subsequent additions of solute are made and the resulting depressions determined as before. One addition, it is true, yields sufficient data for the calculation of the molecular weight of the solute, but it is desirable to ascertain also whether the concentration of the solute has any definite and notable influence on the value obtained for its molecular weight. It is advisable, further, to redetermine the freezing point of the solvent at the end of such a series of experiments, and so obtain a guarantee that the zero of the thermometer has not changed appreciably during the course of the work.

Various suggestions have been made from time to time with the object of rendering the simple Beckmann apparatus a more accurate instrument. Thus it has been proposed to stir the contents of the freezing tube mechanically instead of by hand. The access of atmospheric moisture to a hygroscopic solvent may be prevented by passing a current of dry air into the freezing tube during an experiment, or by using as stirrer an iron ring which is enveloped in platinum foil and is operated electromagnetically. In this latter case, obviously, communication between the contents of the freezing tube and the outside air can be completely cut off. The same end is attained by employing an ordinary stirrer with a mercury valve. (For a detailed description of these modifications and additions, see Beckmann, *Zeitsch. physikal. Chem.* 1891, 7, 323; 1896, 21, 239; 1897, 22, 616; 1903, 44, 169; also Ostwald and Luther's *Physiko-chemische Messungen.*)

For the determination of the freezing point of liquids which are obtainable only in small quantities—physiological fluids, for example—Beckmann's apparatus, in its ordinary form, is too large. Modifications of this apparatus, suitable for the investigation of blood, urine, &c., have been suggested by various authors (Guye and Bogdan, *J. Chim. Phys.* 1903, 1, 379; Burian and Drucker, *Zentr. Physiol.* 1910, 23, 772). In these instruments, only 1-2 cub.cm.

of liquid is required, and it is claimed that the accuracy is of the same order as that attainable with the ordinary Beckmann apparatus. In this connection, mention ought to be made also of Eykman's apparatus (*Zeitsch. physikal. Chem.* 1888, 2, 964; 1889, 4, 497). This consists of a small flask, holding about 10 cub. cm., into the neck of which is ground a thermometer, graduated in tenths or hundredths of a degree. There is no separate jacketing vessel, but the procedure is similar to that followed in the case of the Beckmann apparatus.

As regards the preparation of the cooling bath required in the cryoscopic investigation of aqueous solutions, the usual mixture of ice and common salt solution may be replaced in some cases by a mixture of ice and a solid salt, which gives a steady eutectic temperature. Salts suitable for this purpose, with the eutectic temperatures obtained when they are mixed with ice, are alum, -0.47° ; sodium sulphate, -0.7° ; potassium dichromate, -1.0° ; potassium sulphate, -1.5° ; copper sulphate, -2.0° ; potassium nitrate, -3.0° ; zinc sulphate, -5.0° ; barium chloride, -7.0° . Another kind of cooling bath was used by Raoult, who surrounded the jacketed freezing tube with ether, and passed through the latter a current of dry air (*Compt. rend.* 1896, 123, 476; *Zeitsch. physikal. Chem.* 1898, 27, 617). By careful regulation of the rate at which the air is forced through the ether, the bath can be adjusted to any point between room temperature and -15° .

When it is desired to find the molecular weight of a new substance, the question of the most suitable solvent arises. The choice is frequently limited by the solubility of the substance; it may be appreciably soluble in only one or two of the more common solvents. Apart from this, however, there are other considerations which must be taken into account. Extensive investigation has proved that with certain combinations of solvent and solute, the cryoscopic method gives abnormal values for the molecular weight of the dissolved substance. Pre-eminently is this the case when the solvent is water and the solute is an acid, a base, or a salt, in short, an electrolyte; under these circumstances, the value found for the molecular weight of the solute is abnormally low. On the other hand, the influence of substances containing the hydroxyl group (alcohols, acids, phenols, oximes) on the freezing point of hydrocarbons (benzene) and allied indifferent solvents, is such as to lead to abnormally high values for the molecular weight. The cryoscopic investigation of solutions of acetic acid in benzene indicates that the formula of the acid is more correctly represented by $(\text{CH}_3\text{COOH})_2$ than by CH_3COOH . Again, while the molecular weight of alcohol in benzene is nearly normal in dilute solution, the value increases rapidly as the concentration of the alcohol rises. The combinations of solvent and solute which lead to abnormally high values of the molecular weight have been studied in detail by various workers (Auwers, *Zeitsch. physikal. Chem.* 1893, 12, 689; 1894, 15, 33; 1895, 18, 595; 1896, 21, 337; 1897, 23, 449; 1899, 30, 300; 1903, 42, 513, 629; Biltz, *ibid.* 1899, 29, 249; Robertson, *Chem. Soc. Trans.* 1903, 83, 1425; 1904, 85,

1617; 1905, 87, 1574; 1906, 89, 567). It should be noted that in cases also where the dissolved substance crystallises out along with the solvent, the depression of the freezing point is abnormally small, and the value of the molecular weight calculated therefrom is correspondingly high.

For the cryoscopic determination of the molecular weights of dissolved substances a method of moderate accuracy is sufficient, and an experiment may be carried out with a comparatively small quantity of liquid. The case is different with the problem of finding the exact depression of the freezing point for very dilute aqueous solutions—a problem to which much attention has been devoted because of its bearing on the theory of solution. It was early evident that the cryoscopic investigation of very dilute solutions involves special difficulties, for the discrepancies between the results obtained by different workers were very considerable. Thus the molecular depression for water, based on experiments with sucrose in which the actually observed depressions amounted only to about 0.05° , was found by Arrhenius to be 20.2° , by Raoult, 20.7° ; by Jones, 21.8° ; and by Loomis, 18.1° , instead of the theoretical value, 18.6° . Subsequent investigations (Nernst and Abegg, *Zeitsch. physikal. Chem.* 1894, 15, 681; Abegg, *ibid.* 1896, 20, 207; Wildermann, *Phil. Mag.* 1895, 40, 119; *Proc. Roy. Soc.* 1896, 251; Raoult, *Zeitsch. physikal. Chem.* 1898, 27, 617) have made it clear what conditions must be fulfilled if the freezing point depression for a dilute aqueous solution is to be determined with certainty to 0.001° . It will be sufficient here to indicate these conditions briefly.

As regards the thermometer, it is essential that a telescope be used for reading the position of the mercury, and that the bulb of the instrument be kept at about 0° during the whole of a series of experiments. The influence of alterations in the atmospheric pressure cannot be neglected, for it appears that a difference of 1 mm. mercury has about the same effect on a Beckmann thermometer as a temperature change of 0.0002° . On similar grounds, the thermometer must be immersed always to the same depth in solvent and solutions. It should be mentioned here that platinum resistance thermometers have been used in accurate cryoscopic work instead of the Beckmann instruments (*see* Chrutchoff, *Compt. rend.* 1900, 131, 883; 1901, 133, 955; Bedford, *Proc. Roy. Soc. A*, 1910, 83, 454). The difference between the freezing points of solvent and solution has also been determined thermoelectrically (Hausrath, *Ann. Physik.* 1902, [iv.] 9, 522).

The temperature of the cooling bath is a matter which has to be carefully considered, if the freezing point depression for a dilute solution is to be correctly determined. Suppose that in an experiment with the ordinary Beckmann apparatus the aqueous solution in the inner tube cools without freezing, it is obvious that the lowest temperature to which the solution can fall must be higher than that of the cooling bath, because of the heat conducted from the air to the solution through the thermometer, stirrer, and tube, and because of the heat generated by the stirring. This lowest temperature, which the contents of the freezing tube

tend to assume when no freezing takes place, is known as the *convergence temperature*. The difference between the convergence temperature and the temperature of the cooling bath varies, of course, with each apparatus; it decreases as the facility for heat exchange between the solution and the external air is lessened, and as the rate of stirring is diminished. Suppose now that the solution under examination has become supercooled, and that it has reached the convergence temperature. The introduction of a crystal of the solid solvent at this stage initiates the freezing process; heat is liberated and the temperature of the solution rises. Inasmuch, however, as the solution is no longer at the convergence temperature, there is an influence at work tending to lower the temperature of the solution, so that the latter never reaches its true freezing point: the maximum position reached by the mercury is only what may be called the *apparent freezing point* of the solution. Similarly, when the freezing point of the solution lies below the convergence temperature, an apparent freezing point is observed which is somewhat higher than the true freezing point. In both cases, the apparent freezing point lies between the true freezing point and the convergence temperature. In view of these considerations, it is necessary, in cryoscopic work of the most accurate kind, either to adjust the cooling bath so that the convergence temperature and the freezing point are practically the same, or to apply a correction to the apparent freezing point (see Raoult, *l.c.*; Nernst and Abegg, *l.c.*).

The freezing point of a solution is the temperature at which the solution and the solid solvent are in equilibrium, and in order that this equilibrium, and therefore the freezing point, may be well defined, it is essential that a considerable quantity of solid should be in contact with the solution. In the case of aqueous solutions, this has generally been effected by supercooling to the extent of 0.5° or 1.0° , and then introducing a crystal of ice. If this method is adopted, then a correction must be made for the change of concentration resulting from the separation of ice. Some workers, however, determine the freezing point by adding the cooled solution to a fairly large quantity of finely divided ice, and then observing the steady temperature shown by a thermometer immersed in the mixture (see Walker and Robertson, Proc. Roy. Soc. Edin. 1903, 24, 363; Richards, J. Amer. Chem. Soc. 1903, 25, 291; compare also Prytz, Ann. Physik. 1902, [iv.] 7, 882). In this method of procedure, equilibrium between the two phases is very rapidly established and the concentration of the liquid is ascertained by an analysis made subsequently to the determination of the freezing point.

It has already been pointed out that the freezing point depression is proportional to the number of dissolved units. The cryoscopic method may therefore be employed, not only in the determination of the molecular weights of dissolved substances, but also in the study of the question whether in a particular case a change in the number of dissolved units takes place. It is found, for instance, that the freezing points of potassium iodide solutions are not appreciably affected by the addition of iodine, which shows

that the iodine must combine with the units already present in the solution (see Le Blanc and Noyes, Zeitsch. physikal. Chem. 1890, 6, 385; Paternò and Peratoner, Gazz. chim. ital. 1890, 21, 110). The cryoscopic method may similarly be employed in following the course of a reaction between dissolved substances which involves a change in the number of units, as for instance, the inversion of sucrose (see Kahlenberg, Davis, and Fowler, J. Amer. Chem. Soc. 1899, 21, 1).

CRYSTALLISATION. Crystals are often produced during the concentration of liquors in evaporating pans. Hand or mechanical scrapers are used for removing these crystals continuously. Such crystals are generally too impure for sale and are redissolved in sufficient hot water to produce a solution, which, after clarification by subsidence or filtration, will yield, in the crystallising pan, bright and marketable crystals. The temperature and concentration of the solution, to yield the best result, have to be determined for every substance. The mother liquor is run off and the crystals transferred to drainers or centrifugal machines to be dried before packing. In some instances, several repetitions of this treatment are made, and the crystals are washed with water or liquor after each treatment. The crystallising pans are made of materials which give the best economic result; either they resist the mother liquors or, if attacked, do not spoil the product by discolouration or too much impurity. Cast-iron tanks about 2 feet deep with bottoms sloping to the outlet and rounded corners, are common. Wooden tanks unlined or lined with sheet lead, zinc, tin, or other metal, are used largely. Some manufacturers suspend roughened strips of metal in the pans to which the crystals adhere. For rapid production, crystallisation by repose is now giving place in many industries to crystallisation in motion. The crystallising vessels are provided with circulating blades or with compressed air jets, so that the crystals as they form are prevented from adhering to the sides of the vessel, but remain suspended in the liquor, which, on complete cooling, flows directly to the centrifugal machines for the separation of the mother liquor. These crystals are purer and more convenient to handle than those obtained by repose methods. In the case of deliquescent substances and also in those instances where the mother liquor is sufficiently pure to make it unnecessary to purify by crystallisation, the liquor is concentrated in film evaporators so that only sufficient water remains in it to form the crystal. The liquor produced is run into drums and forms, on cooling, a solid block of crystals. In some works, the liquor is run into a jacketed worm conveyor so that the crystals which form, leave the apparatus in a loose state. J. W. H.

CUBA BLACK *v.* AZO-COLOURING MATTERS.

CUBES CAMPHOR *v.* CAMPHORS.

CUBES, OIL OF, *v.* OILS, ESSENTIAL.

CUCUMBER. The fruit (really a berry) of *Cucumis sativus* (Linn.). König gives as the average composition :

Nitrogenous		Other carbo-		Fibre	Ash
Water matter	Fat	Sugar	hydrates		
95.36	1.09	0.11	1.12	1.09	0.78
		0.7S		0.45	

According to Wittmann (1901), cucumbers contain about 0.2 p.c. of pentosans.

Heinze (Zeitsch. Nahr. Genussm. 1903, 6, 529) observed that large cucumbers contain a higher proportion of sugar than small ones, but less nitrogenous matter. He gives as the mean composition :

	Water	Protein	Fat	Glu- cose	Cane sugar	Other		Fibre	Ash
						carbohy- drates	H. I.		
Small	96.6	0.81	0.09	0.00	0.10	1.44	0.58	0.34	
Large	95.8	0.67	0.09	0.66	0.09	1.60	0.65	0.42	

The ash of cucumbers contains :

K ₂ O	Na ₂ O	CaO	MgO	Fe ₂ O ₃	P ₂ O ₅	SO ₃	SiO ₂	Cl
51.7	4.2	7.0	4.5	0.8	13.1	5.7	4.3	0.2

CUDBEAR *v.* ARCHIL.

CULLEN EARTH or **COLOGNE EARTH** *v.*

PIGMENTS.

CULLET *v.* GLASS.

CULM *v.* Anthracite, art. FUEL.

CUMENES. *Cumols*. The name *cumene*, originally applied to *isopropylbenzene*

to indicate its connection with *cumic acid*, from which it was obtained by distillation with lime, is frequently employed as a generic term to denote any of the isomeric benzene hydrocarbons of the formula C₉H₁₂. Theory predicts the existence of eight of these, all of which have been found in coal-tar oil.

Propylbenzenes.

1. *Normal propylbenzene* (*n-cumene*)

Present in coal-tar oil in fraction boiling at 153°-157° (Schultz and Perl, Ber. 1909, 3602). By the action of sodium on a mixture of bromobenzene and propyl bromide in ethereal solution (Fittig, Schäffer and König, Annalen, 149, 324). By the action of aluminium chloride on trimethylene bromide, propylbenzene and diphenylpropane (sym.) are formed, the latter of which, on further treatment, yields propylbenzene and cumene (Bodroux, Compt. rend. 132, 155). From benzene, aluminium chloride and propyl bromide, when kept at 0° (Heise, Ber. 1891, 768; Genvesse, Bull. Soc. chim. 9, [3] 219). From benzyl chloride, C₆H₅·CH₂Cl and zinc-ethyl (Paterno and Spiza, Ber. 10, 294). Liquid boiling at 159° (corr.), sp.gr. 0.867 at 15°/15° (Perkin, Chem. Soc. Trans. 1900, 274). Yields benzoic acid on oxidation with chromic acid.

2. *Isopropylbenzene* (*Cumene*)

Present in American petroleum (Maberry and Dunn, Amer. Chem. J. 18, 215). By distilling cumic acid C₆H₄[CH(CH₃)₂]CO₂H(1, 4) with lime or baryta (Gerhardt and Cahours, Ann. Chim. Phys. [3] 1, 87). From benzal chloride C₆H₅·CHCl₂ and zinc-methyl (Liebmann, Ber.

13, 46). Phenyl magnesium bromide reacts with acetone to give methylethylbenzene, which, on hydrogenation, yields cumene (Tiffeneau, Compt. rend. 134, 845). From benzene and either isopropyl bromide or normal propyl bromide in presence of aluminium bromide (Gustavson, Ber. 11, 1251). Liquid boiling at 152.5°-153° (corr.); sp.gr. 0.8727, 7.9°/4° (Perkin, Chem. Soc. Trans. 1900, 275). Yields benzoic acid on oxidation with chromic acid.

Methylethylbenzenes (*Ethyltoluenes*). The three methylethylbenzenes are obtained by the action of sodium on a mixture of ethyl bromide or iodide with the corresponding bromo-toluenes (ortho-, meta-, or para-).

1. *o-Methylethylbenzene*

Liquid boiling at 158°-159°; sp.gr. 0.8731 at 16°. Dilute nitric acid oxidises it to *o*-toluic acid C₆H₄(CH₃)CO₂H(1, 2).

2. *m-Methylethylbenzene*

Liquid boiling at 158°-159°; sp.gr. 0.869 at 20°. Chromic acid oxidises it to *isophthalic acid* C₆H₄(CO₂H)₂(1, 3).

3. *p-Methylethylbenzene*

Liquid boiling at 161°-162°; sp.gr. 0.8652 at 21°. Yields on oxidation *p*-toluic and terephthalic acids.

Trimethylbenzenes.

1. *Consecutive trimethylbenzene* (*Hemellitene*; *Hemimellitene*) C₆H₃(CH₃)₃(1, 2, 3). By heating the calcium salt of *α-isoduric acid*

with lime. Liquid boiling at 163°-170° (Jacobsen, Ber. 15, 1857; 19, 2517).

2. *Unsymmetrical trimethylbenzene* (*pseudocumene*) C₆H₃(CH₃)₃(1, 2, 4), occurs together with mesitylene in coal-tar (Beilstein and Kögler, Annalen, 137, 317), and is present in many petroleum (Poni, Chem. Zentr. 1906, i. 459). By the action of sodium on a mixture of either bromo-*paraxylene* or bromo-*metaxylene* with methyl iodide. In order to isolate it from coal tar, Armstrong recommends (Chem. News, 33, 5. Ber. 11, 1697) that the mixture of pseudocumene and mesitylene (*v. infra*) boiling between 160° and 170°, obtained from coal tar by fractional distillation, should be converted by treatment with an equal volume of concentrated sulphuric acid into sulphonic acids. The mixture of sulphonic acids, which separates as an oily layer on carefully adding water to the sulphuric acid solution, is heated with concentrated hydrochloric acid in a sealed tube for 1 hour at 100°. In this way, the mesitylene sulphonic acid is decomposed, regenerating mesitylene, whilst the pseudocumenesulphonic acid is not attacked. After separating the mesitylene the pseudocumenesulphonic acid is precipitated from the hydrochloric acid solution by sulphuric acid, purified by recrystallisation from dilute sulphuric acid and finally decomposed by heating with hydrochloric acid at 140°-150°, when it breaks up into pseudocumene and sulphuric acid. Jacobsen (Ber. 9, 256) treats the mixture of sulphonic acids with barium or calcium carbonate, which removes the excess of sulphuric acid and converts the sulphonic acids into

barium or calcium salts; transforms these by double decomposition with sodium carbonate into sodium salts; heats the latter with phosphorus pentachloride, with which they yield the sulphonic chlorides $C_9H_{11}SO_2Cl$; converts the chlorides into the sulphonamides

by the action of ammonia; and separates the two isomeric sulphonamides by recrystallisation from alcohol, in which mesitylene sulphonamide is readily, pseudocumene sulphonamide only sparingly, soluble. The sulphonamides are then hydrolysed by heating with concentrated hydrochloric acid at 175° .

Another method proposed by Jacobsen (Annalen, 184, 199) is to separate the two sulphonic acids by fractional crystallisation; pseudocumenesulphonic acid is soluble with difficulty in sulphuric acid and crystallises out. On heating to its melting-point (110°) and passing in steam at a temperature of 250° , pure pseudocumene is obtained (see also Schultz and Herzfeld, Ber. 1909, 3602). Pseudocumene boils at 169.8° (corr.), 166° at 712 mm., and has sp.gr. 0.877 at 18° (Schultz and Herzfeld, *l.c.*). On oxidation with nitric acid, it yields two isomeric acids of the formula $C_6H_3(CH_3)_2CO_2H$ —xylic acid and *p*-xylic acid—and a small quantity of the isomeric methylisophthalic and methylterephthalic acids $C_6H_3(CH_3)(CO_2H)_2$ (Bentley and Perkin, Chem. Soc. Trans. 1897, 165).

3. *Symmetrical trimethylbenzene (Mesitylene)* $C_6H_3(CH_3)_3$ (1, 3, 5). In coal-tar oil, in fraction boiling at 157° – 162° (Fittig and Wackenroder, Annalen, 151, 292; Schultz and Perl, Ber. 1909, 3602), and in American petroleum (Maberry and Dunn, Amer. Chem. J. 18, 215). By distilling acetone with sulphuric acid

(Küster and Stollberg, Annalen, 278, 207; Meyer and Molz, Ber. 1896, 2831), or by dissolving allylene $CH_2C:CH$ in sulphuric acid and distilling with water $3CH_2C:CH = C_6H_3(CH_3)_3$ (Fittig and Schroebe, Ber. 8, 17). (On the isolation of mesitylene from coal tar and the method of separating it from pseudocumene, *v.* preceding paragraph.) Liquid boiling at 164.5° ; sp.gr. 0.8768 at 4° (Perkin, Chem. Soc. Trans. 1896, 1193). Dilute nitric acid oxidises it to mesitylenic acid $C_6H_3(CH_3)_2CO_2H$ and uvitic acid

with potassium permanganate it yields uvitic acid and trimesic acid $C_6H_3(CO_2H)_3$ (1, 3, 5).

CUMIDINES $C_9H_{13}N$. Of the sixteen isomeric cumidines which have hitherto been obtained, pseudo- or ψ -cumidine and mesidine are perhaps the most important. These bases are derivatives of pseudocumene and mesitylene respectively, the first of which is theoretically capable of yielding three isomeric ψ -cumidines, and the latter one cumidine only.

Pseudocumidine, sym. ψ -cumidine

$(CH_3)_3C_6H_2NH_2[CH_2:CH_2:CH_2:NH_2 = 1:2:4:5]$ can be obtained by nitrating pseudocumene with fuming nitric acid in the cold, and reducing the nitro-compound (m.p. 71°) with tin and hydrochloric acid (Schaper, Zeitsch. chem. [2] 3, 12). The base is prepared technically by digesting xylylene hydrochloride with methyl alcohol in an autoclave at 280° – 300° , converting the crude product into the

nitrate, separating the sparingly soluble nitrates by means of a centrifugal machine, washing the product with water and finally treating with an alkali. The mixture of bases consisting of cumidines and xylydines is then fractionated, and the portion distilling between 225° – 245° is allowed to crystallise, and finally freed from non-crystallisable bases by pressure (Aktiengesellschaft für Anilinfabrikation, D. R. P. 22265). The cumidine so obtained contains mesidine and other impurities (Hofmann, Ber. 17, 1912; Engel, *ibid.* 18, 2229), but consists chiefly of Schaper's pseudocumidine (*cf.* Hofmann, *ibid.* 15, 2895) which can be prepared in the pure state by digesting *o*-4-xylylene [$NH_2:CH_2:CH_3 = 1:3:4$] or paraxylylene with methyl alcohol under similar conditions (Nölting and Forel, *ibid.* 18, 2680).

Properties.—Pseudocumidine crystallises in large, lustrous prisms, melts at 63° (Hofmann), at 68° (Auwers, Ber. 18, 2661), and boils at 234° . It is insoluble in water, but readily soluble in alcohol. The nitrate is characterised by being very sparingly soluble in water. Its acetyl derivative crystallises in compact white needles, melts at 161° (Edler, *ibid.* 18, 629; Nölting and Baumann), at 164° (Auwers) and boils above 360° . Pseudocumidine is used as a source of azo-dyes (D. R. PP. 3229, 1878; 22265, 1882).

as- ψ -cumidine [$CH_2:CH_2:CH_2:NH_2 = 1:2:4:6$] has been prepared by Edler (*l.c.*). It melts at 36° .

ψ -cumidine [$CH_2:CH_2:CH_2:NH_2 = 1:2:4:3$] is obtained by digesting *o*-3-xylylene hydrochloride [$NH_2:CH_2:CH_3 = 1:2:3$] with methyl alcohol in an autoclave at 300° (Nölting and Forel; *cf.* Mayer, Ber. 20, 972). It boils at 240° (Nölting and Forel), 236° and does not solidify at -15° (Mayer). Its acetyl derivative melts at 186° .

Mesidine [$CH_2:CH_2:CH_2:NH_2 = 1:3:5:2$] is obtained by treating mesitylene with nitric acid (sp.gr. 1.38) and reducing the nitro-derivative with tin and hydrochloric acid (Fittig and Storer, Annalen, 147, 3). It can also be prepared by digesting α -metaxylylene [$NH_2:CH_2:CH_3 = 1:2:4$] (Hofmann, Ber. 5, 715; 8, 61) or β -metaxylylene [$NH_2:CH_2:CH_3 = 1:2:6$] hydrochloride (Nölting and Forel) with methyl alcohol at 300° .

Properties.—Mesidine is a colourless liquid, which boils at 229° , and has a sp.gr. 0.9663. The acetyl derivative melts at 216° and crystallises in prisms.

Isocumidine [$CH_2:CH_2:CH_2:NH_2 = 1:2:3:5$], prepared by digesting the hydrochloride of γ -metaxylylene

with methyl alcohol, at 300° (Nölting and Forel; Limpach, Ber. 1888, 644), melts at 67° – 68° , boils at 245° , and yields an acetyl derivative melting at 163° – 164° .

Para-aminopropylbenzene, formed by heating aniline, propyl alcohol, and zinc chloride at 280° for 8 hours (Louis, Ber. 16, 105; Francksen, *ibid.* 17, 1221), boils at 224° – 226° . The acetyl derivative melts at 87° .

Orthoaminoisopropylbenzene, -o-cumidine, formed by heating aminocumic acid with baryta (Filetti, Gazz. chim. ital. 13, 379; *cf.* Constanam and Goldschmidt, Ber. 1888, 1158), boils at 213.5° – 214.5° at 732 mm. The acetyl derivative melts at 72° .

Para-aminoisopropylbenzene, cumidine, formed by heating isopropyl alcohol, aniline, and zinc chloride at 260°-280° (Louis, Ber. 16, 111; cf. Nicholson, Annalen, 65, 58), boils at 216°-218°. The acetyl derivative melts at 102°-102.5°. By oxidation with sodium chlorate and potassium ferrocyanide in hydrochloric acid solution, cumidine yields a dyestuff of the aniline black series (Kirpitschnikov, Chem. Zentr. 1906, i, 829). By treatment with cyanogen chloride in pyridine solution, condensation is effected and a dyestuff is produced (König, D. R. P. 155782; Chem. Zentr. 1904, ii, 1557).

Ethylorthotoluidine, prepared by treating orthotoluidine in ethylalcohol with zinc chloride at 270° (Benz, Ber. 15, 1650), boils at 229°-230°. The acetyl derivative melts at 105°-105.5°, and boils at 313°-315°.

CUMIDINE RED v. AZO-COLOURING MATTERS.

CUMIN, OIL OF, v. OILS, ESSENTIAL.

CUPFERRON v. HYDROXYLAMINE.

CUPRISIN. Trade name for a preparation of cupric cyanide and potassium cyanide, used for the treatment of trachoma.

CUPRITE. Native cuprous oxide Cu_2O , crystallising in the cubic system. Brilliant, transparent crystals of a ruby-red colour (hence the name ruby-copper-ore) are not uncommon; sp.gr. 6.0. In the variety called *chalcotrichite*, the crystals are capillary in form, being enormously elongated in the direction of one of the cubic edges, and are loosely matted together in push-like masses. Another variety, known as *tile-ore* (Ger. *Ziegelierz*), is earthy or compact and of a brick-red or brownish colour; it consists of an intimate mixture of cuprite and limonite, and has resulted from the alteration of copper-pyrites. Cuprite is sometimes of importance as an ore in the upper oxidised portions of copper veins. L. J. S.

CUPROSILICON, *Cuprous silicide* (v. COPPER).

CURARA. *Curare*, *Urari*, *Wourari*, *Wourali*, *Wourara*. Curara is the arrow poison of those tribes of South American Indians which inhabit the districts lying between the Amazon and the Orinoco. It was first brought to Europe by Sir Walter Raleigh, in 1595, and from that time to this its origin and preparation have been much discussed by travellers and botanists. A summary of the earlier observations of La Condamine, A. v. Humboldt and Bonpland, Water-ton, Schomburgk, Castelnau, Weddell, Thirion, Jobert, Crévaux, and others is given in an examination of the subject by Planchon (Pharm. J. [3] 11, 469, 491, 529, 589, 693, and 754). It is shown that curara is an aqueous extract of a mixture of many plants, one of which is always a species of *Strychnos*, and gives to it the chief toxic power, whilst the remainder contribute those other qualities which render the extract suitable for the tipping of arrow heads. The method of preparation adopted by one tribe of Indians is described by Schomburgk (*ibid.* [3] 10, 646). The product differs somewhat with the locality in which it is prepared. Planchon distinguishes four varieties: the curara of the Orinoco, of the Upper Amazon, of French Guiana, and of British Guiana. The chief active ingredient in the preparation of the first is a *Strychnos* plant, closely allied to Schomburgk's *S. toxifera* (J. Pharm. Chim. [5] 5, 20), of the

second, *S. Castelnæi* (Weddell), of the third, *S. Crevauxiana* (Baill.), and of the fourth, *S. toxifera* (Schomb.).

As seen in Europe, curara is a brown to black, nearly solid, or even brittle, extract. It has a bitter taste, and in its poisonous action it is related, though opposed, to strychnine. In medicine, it has been employed in the treatment of tetanus, epilepsy, and hydrophobia. It is best administered hypodermically in the form of aqueous solution (cf. Moss, Pharm. J. [3] 8, 421). The active part of curara is soluble in cold water, and constitutes three-fourths of the whole. This portion is nearly insoluble in alcohol, and quite insoluble in ether (Sachs, Annalen, 191, 255).

A more or less definite and active alkaloidal product of curara under the name *curarine* was described by Roulin and Boussingault (Ann. Chim. Phys. [2] 39, 24), A. v. Humboldt (*ibid.* [2] 39, 30), Pelletier and Pédroz (*ibid.* [2] 40, 213), Pryer (Zeitsch. Chem. 8, 381; Bull. Soc. chim. [2] 4, 238), Dragendorff (Zeitsch. Chem. [2] 3, 28), and Flückiger (Neues Rep. Pharm. 22, 65). Evidence of the same constituent in the root bark of *S. toxifera* has been obtained by Villiers (J. Pharm. Chim. [5] 11, 653). Pryer announced the discovery not only of crystalline salts of curarine, but of the base itself in a crystalline form, for which he proposed a formula. These results are, however, rendered doubtful by the experiments of Sachs (Annalen, 191, 254), which show that Pryer's crystalline curarine sulphate consisted of calcium phosphate, together with traces of carbonate and mechanically adhering curara, to which last its slight physiological activity is ascribed. Moreover, Pryer's formula, though derived from an undoubted platinum salt of curarine, is erroneous on account of the salt having suffered decomposition.

Sachs prepared a number of salts of curarine by precipitation from a solution of the acetate, which solution he obtained as follows. A solution of potassium mercuric iodide was added to a cold aqueous solution of curara, and the precipitate which formed, was collected. After washing, it was suspended in water and treated with sulphuretted hydrogen, which removes the mercury, while the alkaloid goes into solution. Lead acetate was then employed to separate the iodine, and finally the excess of lead was precipitated by sulphuretted hydrogen. The *platinum salt* obtained from this solution by the addition of platonic chloride and hydrochloric acid, is pale yellow, and has the composition

but changes rapidly with the formation of a violet-coloured compound of a different composition. The *gold salt* also quickly decomposes. Neither the sulphate nor the hydrochloride are crystallisable. The most stable and best-defined salt is the *picrate* $C_{18}H_{35}N \cdot C_6H_2(OH)(NO_2)_3$, from which Sachs deduces the formula $C_{18}H_{35}N$ for the free base. He also points out that the alkaloid exists in the extract combined with sulphuric acid.

Boehm (Ber. 20, Ref. 144) treats the aqueous solution of curara directly with platonic chloride, and by a series of operations, in which the presence of free mineral acid is avoided, obtains the *free base* as an amorphous yellow, or in

thicker layers orange-red, powder. If an aqueous solution of this powder, which has a green fluorescence, be evaporated with a little dilute acid, there result crystals of a physiologically inactive compound.

Further researches by Boehm (Arch. Pharm. 285, 660) show that the alkaloids of curara can be divided into two classes; (1) compounds similar to curine, partly crystalline and partly amorphous soluble in water with difficulty and precipitated from solution by ammonia, in which the characteristic toxic effect of curara is shown very slightly or not at all; (2) amorphous yellowish-red substances easily soluble in water as curarine, not precipitated by ammonia, and showing the most marked toxic action. Para curara, which is imported in bamboo tubes and is the variety now usually met with in commerce, contains about 11-14 p.c. water, 12 p.c. ash, 12-15 p.c. curine $C_{18}H_{14}O_3N$, which is isolated by extracting the raw material with water, precipitating by aqueous ammonia and extracting with alcohol. It melts at 212°, and is obtained in crystals from benzene or alcohol with one molecule of the solvent or from methyl alcohol without alcohol of crystallisation. *Paracurarine* (*tubocurarine*) was obtained as a reddish-yellow substance which forms about 9-11 p.c. of raw curara. It is not identical with the previously known curarine, isolated from calabash curara. The latter kind, which was sent over in calabashes, used to be the common variety, but is now seldom met with. Earlier investigations, as a rule, refer to this. The active principle, *curarine*, consists of hard glistening garnet-red laminae, decomposing and giving off a smell of trimethylamine when heated to 150°. A minute quantity of a second alkaloid was found to be present.

A third variety of curara occurs in the market in small jars of unburnt clay. This differs widely in respect to active principles from the other varieties. The following substances have been extracted from it: *protocurine*, colourless needles, which turn brown at 160° and melt, with decomposition, at 306°; *protocuridine*, colourless prismatic crystals, m.p. 274°-276°; and *protocurarine*, an amorphous red powder, more poisonous than the other curarines.

(For the physiological action of curara, see Nikolski and Dogiel (Pflügers Archiv. 47, 68); Frank and Voit (Zeitsch. Biol. 42, 309); Frank and Gebhard (*ibid.* 43, 117); Edmund and Roth (Amer. J. Physiol. 23, 28, 46).)

Curarine salts, according to Peliken (Ann. Chim. Phys. 44, 507), Pryer, Flückiger, and others, give a colour reaction with potassium dichromate and sulphuric acid similar to that of strychnine, but more permanent. Their behaviour towards solvents, especially water and benzene, serves to distinguish them from strychnine salts (Flückiger). Sachs obtained a red and not a blue colour by treating curarine salts with sulphuric acid, contrary to the statements of Pryer and Flückiger (*cf.* J. Soc. Chem. Ind. 1889, 476). (For extraction of curarine in poisoning cases, *cf.* Koch (Chem. Zentr. 1871, 219) and Salomon (Zeitsch. anal. Chem. 10, 454).)

A. S.

CURARE, CURARINE v. CURARA; VEGETO-ALKALOIDS.

CURCAS OIL, purging nut oil, physic nut oil (*Oleum infernale*), is obtained from the seeds of *Jatropha curcas* (Linn.), ('purging nut'), by hot expression. The seeds consist of 66 p.c. of kernels and 34 p.c. of husks. From the former there is obtained by extraction with ether 52 p.c. of oil of a pale colour, becoming yellow, with a reddish tint, on exposure to the air. Characteristic of the oil is its unpleasant odour, which assists in distinguishing curcas oil from other oils. Most prominent are the strong purgative properties of the oil, which are much more pronounced than those of castor oil. The oil belongs to the semi-drying oils; its liquid fatty acids consist of about equal proportions of oleic and linolic acids, as ascertained by the relative quantities of their oxidation products (*viz.* dihydroxystearic and tetrahydroxystearic acids). This oil is stated by Bouis to contain isocetic acid, but the existence of this acid is doubtful.

Nearly related to the above-described oil are the oils obtained from the seeds of *Jatropha oligandra* (Mull.) and *J. multifida* (Linn.).

CURCUPHENINE v. AZO-COLOURING MATTERS.

CURINE v. CURARA; VEGETO-ALKALOIDS.

CUSCAMEINE, CUSCONINE v. VEGETO-ALKALOIDS.

CUSPARIA BARK. *Angostura bark*; *Caryony bark*. (*Ecorce d'Angostura*, Fr.; *Angostura-Rinde*, Ger.) The bark of the *Cusparia febrifuga* (Hiemb.) or *Galipea cusparia* (St. Hilaire), a tree inhabiting the mountain districts drained by the Orinoco (*cf.* Benth. a. Trim. 43). Confusion has sometimes occurred between *cusparia* and *nux vomica* bark. The two barks may, however, be readily distinguished by treatment with a drop of nitric acid, which either deepens the colour of the *cusparia* or gives it a bluish shade, while *nux vomica*, similarly treated, exhibits a blood-red colour. Several other barks have, from time to time, been substituted for true *angostura*. (For these, and the mode of detecting them, *v.* Pereira (Mat. Med. 3rd ed. 2, 1915); Maisch (Amer. J. Pharm. 1874, 50); Cazeneuve (Rép. de Pharm. 1874, 261); Oberlin and Schlagdenhauffen (Pharm. Zeit. 1878, 853).)

Among early analyses of *cusparia*, those of Pfaff and Fischer (Pereira) are the most important. These observers find in the dried bark 90 p.c. of lignin, together with gum, resins, volatile oil, and a peculiar bitter extractive. The bitter extractive, examined in 1833 by Saladin (J. de Chim. Méd. 9, 388), was found to contain a crystalline neutral principle to which the name *cusparin* or *angosturin* was given. An alkaloid, *angosturine* $C_{10}H_{14}NO_{14}$, differing from the *cusparin* of Saladin, was isolated by Oberlin and Schlagdenhauffen (J. Pharm. Chim. [4] 28, 263). It melts at 85°, is crystalline and bitter. It gives with sulphuric acid a red, and with sulphuric and nitric acids a green colour. Another *cusparine* was found in the bark by Körner and Böhringer (Gazz. chim. ital. 13, 363), who announce the discovery of several new basic and acid constituents. The *cusparine* of these chemists has the composition $C_{19}H_{17}NO_3$. It

is crystalline, and melts at 92° . It is sparingly soluble in ether, but soluble in alcohol. The sulphate, oxalate, and hydrochloride are only sparingly soluble in water. The platinum salt consists of orange-yellow crystals. Treated with potassium hydroxide, cusparine breaks up into a new crystalline *alkaloid* and an aromatic crystalline *acid*. The mother liquors from which cusparine is obtained contain another alkaloid, *galipine* $C_{20}H_{21}NO_3$. It consists of white needles, melting at 115.5° . The salts are more soluble than the corresponding salts of cusparine. The sulphate contains $7H_2O$. It melts at 50° , and at 100° breaks up into the sulphate of a *new alkaloid* and a crystalline *compound*, containing nitrogen, and melting at 196° . The platinum salt of galipine crystallises in prisms. A third *base*, melting at 180° , was also obtained. It is sparingly soluble in ether, but may be crystallised from alcohol. Its salts, when in solution, exhibit a blue fluorescence.

Angostura bark has been further examined by Beckurts and Nehring (Arch. Pharm. 229, 591), who have obtained four bases—galipine, galipidine, cusparine, and cusparidine, which are difficult to separate on account of their almost identical solubilities. *Galipine* $C_{20}H_{21}O_3N$ consists of pure white needles, melting at 115.5° . It dissolves readily in alcohol, chloroform, acetone, benzene, or ether, but is sparingly soluble in light petroleum. *Galipidine* $C_{19}H_{19}O_3N$ m.p. 111° , is very similar in properties to galipine. *Cusparine* $C_{20}H_{19}O_3N$ is the alkaloid most readily separated, owing to the sparing solubility of its salts. With concentrated sulphuric acid it gives a dull-red, changing to a cherry-red colour. On treatment with fuming nitric acid, a yellow solution is obtained which, after evaporation and treatment with potash, becomes orange. Fröhde's reagent gives a brown solution, changing successively to violet, bluish-green, and deep blue (Beckurts, Arch. Pharm. 233, 410). *Cusparidine* $C_{18}H_{17}O_3N$, m.p. 78° , is very similar in properties to cusparine.

The bitter principle, angosturin, was found by Beckurts and Nehring to melt at 58° . These inquirers have also shown that the bark contains a glucoside which, however, was not obtained in a pure state; they also find that the essential oil previously studied by Herzog (Arch. Pharm. 93, 146; J. 1858, 444) and by Oberlin and Schlagdenhauffen (J. Pharm. Chim. [4] 26, 130), is present to the extent of 1.5 p.c.

A fifth alkaloid, *cuspareine*, m.p. 154° , which does not form salts, has been isolated by Beckurts and Frerichs (Chem. Zentr. 1903, ii, 1010).

The bark of *Esenbeckia febrifuga*, which enters commerce under the name of angostura bark, has been examined by Hartwich and Gamper (Arch. Pharm. 238, 568).

Cusparia is employed in medicine as a tonic in such derangements of the alimentary canal as dyspepsia, diarrhoea, and dysentery.

CUTCH. *Terra japonica* (v. CATECHU).

CYANACETIC ACID v. MALONIC ACID.

CYANELLAGIC ACID. Cyanellagic acid $C_{14}H_8O_{10}$ is prepared by heating ellagic or flavellagic acid with 100 p.c. sulphuric acid at 185° – 230° (Perkin, Chem. Soc. Proc. 22, 114),

or with arsenic and sulphuric acids at 130° . It crystallises from pyridine in small yellow prismatic needles, and is soluble in strong alkaline solutions with a green yellow tint, changing to deep blue on dilution. The hexa-acetyl derivative $C_{14}O_{16}(C_2H_5O)_6$, forms colourless needles, melts at 330° – 332° , and the hexabenzoyl compound, colourless needles m.p. 343° – 345° . Cyanellagic acid is most probably dihydroxyellagic acid, and in this case possesses the following constitution:—

It dyes mordanted fabrics more readily than ellagic acid. A. G. P.

CYANIDES. Compounds of the radicle cyanogen CN. The history of the cyanide industry begins with the discovery of Prussian blue by Diesbach in 1704 (H. Kopp, Geschichte der Chemie, 4, 369). While attempting to make Florentine lake by precipitating a mixture of cochineal infusion, alum, and ferrous sulphate with an alkali, he obtained a blue colour. The alkali used was potash, over which Dippel had distilled his animal oil, and Dippel recognised in this the source of the blue colouring matter. The new blue very quickly came into use in place of ultramarine, and in 1710 it was sold at one-tenth the price of the latter. The method of manufacture was a secret until 1724, when Woodward showed that the blue could be prepared by calcining blood with potassium carbonate and then treating the aqueous extract¹ with ferrous sulphate and alum, the greenish precipitate so obtained yielding Prussian blue when treated with hydrochloric acid.

Macquer, in 1752, showed that alum is not required, and that Prussian blue, when boiled with an alkali, yields ferric hydroxide and a soluble salt from which the blue can be regenerated. This salt, potassium ferrocyanide, was first obtained in the crystalline form by Sage in 1772.

The discoveries of Scheele, 1782–3 (Chemical Essays, London, 1786; reprinted 1901) Berthollet, 1790 (Annales de Chimie, 1790, 1, 30) and of Gay-Lussac, 1815 (*ibid.* 1815, 95, 156) cleared up the chemistry of Prussian blue and potassium ferrocyanide and of the closely related substances, cyanogen and hydrocyanic acid and their derivatives, and so laid the foundations of the industry.

Prussian blue was manufactured in Great Britain in 1770 by Bramwell & Co. of Newcastle; it sold then at 2 guineas per lb.; the price had fallen in 1815 to 10s. 6d., in 1820 to 2s. 6d., and in 1850 to 1s. 9d. Crystallised potassium ferrocyanide was first known in commerce about 1825, the price being 5s. per lb., although a solution had been sold previously (Graham, Reports of Juries, Exhib. of 1851, 1, 95).

The conversion of potassium ferrocyanide into potassium cyanide by fusion with potassium carbonate, was first described by F. and E.

¹ *Lixivium sanguinis*, or blood-lye, whence the German name of potassium ferrocyanide, '*blutlaugen-salz*.'

Rodgers in 1834 (Phil. Mag. 1834 [3] 4, 91), but the simple cyanides were not used in any considerable quantity until the process of electroplating with gold and silver, from a cyanide solution, was discovered by J. R. and H. Elkington in 1840 (Eng. Pat. 8447, of 1840).

An interesting application of potassium ferricyanide was discovered by Sir J. Herschel in 1842 (Phil. Trans. 1842). Paper, treated with a solution containing ferric ammonium citrate and potassium ferricyanide, becomes blue when exposed to light, owing to the reduction of the ferric salt and consequent formation of Prussian blue. Paper sensitised in this way is used for the reproduction of engineering drawings.

A very remarkable attempt was made by Possoz and Boissière in the year 1843, to manufacture cyanides from atmospheric nitrogen; this is described under the heading POTASSIUM CYANIDE (p. 196).

The year 1860 witnessed three important developments in the cyanide industry. Gautier-Bouchard (A. W. Hofmann, Reports by the Juris, Inter. Exhib. of 1862, 59-63) began to produce prussiates from the spent oxide of the Paris gas works. A. Gélis (Eng. Pat. 1816, of 1860) synthesised them from carbon disulphide and ammonia; and Margueritte and de Sourdeval (Eng. Pat. 1171, of 1860) attacked the problem of the fixation of atmospheric nitrogen by means of barium oxide and carbon.

The existence of cyanogen compounds in coal gas was known in 1843, and possibly still earlier. E. Jacquemyns (Annalen, 1843, 46, 236, whose attention was drawn to them by H. Rose, says that he found none in gas lime, but obtained 0.75 gram of Prussian blue per litre from ammonia liquor. The purification of coal gas by means of iron oxide was introduced in 1847. Owing to the repeated use of the same quantity of oxide, the cyanogen compounds accumulate in it in a relatively concentrated form, and it was therefore naturally the first gas works product to be used in their manufacture. Prussian blue, made from spent oxide, was exhibited by Gauthier-Bouchard at the London Exhibition of 1862.

Both the process of Gélis and that of Margueritte and de Sourdeval were soon abandoned by their inventors; the recovery of cyanides from spent oxide, on the other hand, developed fairly rapidly, and, according to Dupré (Journ. für Gasbeleuchtung, 1884, 885), there were, in 1884, 10 works making prussiate by this means. The competition of the gas works prussiate, together with the increasing cost of nitrogenous organic matters (which were being used more and more as fertilisers), soon displaced the old process in Germany. In the United States of America, it appears to have held its own somewhat longer; the returns of the U.S. Census for 1900 (Bulletin No. 210, 31, 1902) show 18 works engaged in the manufacture of cyanides with a joint annual production of 2752 tons of yellow prussiate, almost entirely made from hoofs, horns, and scrap leather, only 1200 tons of spent oxide having been used.

Between 1875 and 1885, the sulphocyanides, especially the tin and aluminium salts, appear to have been used in calico printing instead of the acetates (Bertelsmann, Die Technologie der

Cyanverbindungen, 303), and Gélis' synthesis was taken up and improved by Günzburg and Teherniac (Eng. Pat. 1148, of 1878; 1359, of 1879; 1261, of 1881), but without financial success.

In 1887, J. S. MacArthur, R. W. and W. Forrest (Eng. Pat. 14174, Oct. 19, 1887; 10223, of 1888) patented their process for the extraction of gold and silver from their ores by means of a dilute solution of a cyanide. The process was carried out by allowing a solution containing 0.25 p.c. or less of potassium cyanide to percolate through the ore, which was usually ground to pass a sieve with 40 or 60 holes to the linear inch. The gold is dissolved in the form of potassium aurocyanide, and is recovered from the solution by passing it through a mass of zinc shavings. The process was first put into practice at Karangahake, New Zealand, in 1889, and near Johannesburg, Transvaal, in 1890. The success of these installations led to a very rapid adoption of the process in all the gold-producing countries of the world.

Prior to the introduction of this process, the cyanide industry was quite a small one. The world's consumption of potassium cyanide (produced exclusively from ferrocyanide by the Rodgers process) (F. Roessler, V. Internationaler Kongress für Angewandte Chemie, Berlin, 1903, 1, 638) did not exceed 50-70 tons per annum (G. Beilby, J. Soc. Chem. Ind. 1898, 134) and that of yellow prussiate was probably under rather than over 5000 tons (worth together about 325,000/).

Ten years later, just before the Transvaal War, the European production of potassium cyanide was estimated by Beilby (V. Inter. Kongress Angew. Chem. Berlin, 1903, 1, 630) as 5500 tons, adding the American production of about 1000 tons (U.S. Census Bulletin, No. 210, 31, 1902), we arrive at a total production of 6500 tons. Since then the world's output of cyanide has continued to increase, although at a relatively slower rate. The production of ferrocyanides, on the other hand, has remained comparatively stationary, the outlets for these substances in paint making, dyeing and calico printing, not permitting any great expansion.

The increased quantities of potassium cyanide required by the gold-mines were at first supplied by fusing potassium ferrocyanide with potassium carbonate, and very soon afterwards by E. Erlenmeyer's process (Ber. 1876, 1840), in which dry prussiate and metallic sodium are used: $K_4Fe(CN)_6 + 2Na = 2NaCN + 4KCN + Fe$. Synthetic processes producing cyanide direct without the intervention of prussiate, were also introduced, no less than 104 patents connected with cyanides being applied for during 1889-1898, and 129 from 1899-1908. The processes which have worked with some measure of success are tabulated below:—

Process	Where worked	Began production in
Siepermann . . .	Stassfurt	1892
Beilby . . .	Glasgow	1892
Castner . . .	Great Britain, Germany, U.S.A.	1900
Raschen . . .	Runcorn	1898
Readman . . .	Leven (Scotland)	1899-1906 ¹
Bueb ('Schlempe') . . .	Dessau	1902

These processes are described fully below.

¹ Ceased producing.

Potassium cyanide, as used in electroplating, was a material having the appearance of unglazed porcelain, and containing from 30 to 70 p.c. of KCN, together with large quantities of carbonate and cyanate. The material supplied to the gold-mines in the early days of the gold-extracting process was a black mass containing some 75 p.c. of KCN, and all the iron and carbon liberated by the decomposition of the ferrocyanide. This was replaced by the pure white crystalline product of the Erlenmeyer process, which contained about 2 molecules of KCN to 1 molecule of NaCN, the cyanogen content being about 40 p.c., equivalent to 98-100 p.c. of KCN. Shortly after the introduction of the Castner process, in 1900, solid cakes of pure white crystalline sodium cyanide, containing 97 p.c. to 98 p.c. of NaCN (equivalent to 129-130 p.c. of KCN), became an article of commerce, and this is at present the form in which the greater part of the cyanide employed in gold-extracting is used.

The time-honoured yellow prussiate of potash has also been replaced to a very large extent by the sodium salt which is quite easily prepared by the more recent methods of extracting the hydrocyanic acid from coal gas by special cyanogen washers (*see* p. 185).

The application of hydrocyanic acid as an insecticide, which was introduced in California in 1903, promises to become of some importance. Fruit trees (especially orange trees) are covered with a tent under which hydrocyanic acid is produced by mixing sodium cyanide and sulphuric acid (W. F. Reid, *Journ. of Gas Lighting*, 1904; *also* *J. Soc. Chem. Ind.* 1903, 22, 1330).

Another possible application which may be mentioned is in case-hardening iron; immersion in fused cyanide produces a very hard skin on mild steel, and ferrocyanides have long been used for this purpose in ordinary workshop practice.

Potassium ferrocyanide $K_4Fe(CN)_6 \cdot 3H_2O$ (Yellow prussiate of potash, Ger. *Blutlaugen-salz*).

The method of manufacture from nitrogenous organic matter is now only of historical interest.

The sources of nitrogen were horn, dried blood, hair, waste wool, and feathers (15-17 p.c. N), woollen rags (10-16 p.c. N), pigs' bristles (9-10 p.c. N), and old leather (4.5-7 p.c. N). These materials were sometimes charred before use, about 80 p.c. of the nitrogen being driven off in the form of ammonia, hydrocyanic acid, and a complicated mixture of nitriles and organic bases.

The process was carried out at first in pear-shaped, cast-iron muffles, which were replaced later by reverberatory furnaces, the beds of which were formed of cast-iron pans, 5 feet long, 3 feet wide, 4 inches deep, and about 2 inches thick. A charge of 2 cwt. of potash (usually made up of 2 parts of the 'blue salt' recovered in a later stage of the process, and 1 part of fresh potash) was put into the pan and fused with 18-20 lbs. of iron turnings; 2 cwt. of the dry nitrogenous materials were then stirred in gradually (2.5 to 3 cwt. of charred material could be added without making the mass too pasty). The temperature was then raised in order to complete the reaction, and the melt

laddled out into iron moulds. After solidification, it was broken up and digested for 24 hours with water at 50°-60°, and finally extracted completely with boiling water. The solution obtained contained potassium ferrocyanide, sulphocyanide, carbonate and sulphide. It was evaporated to sp.gr. 1.28, and allowed to crystallise. Further evaporation yielded a second crop of impure crystals, the mother liquor of which was evaporated to dryness, leaving a mixture of potassium carbonate and sulphide, known as 'blue salt' which was returned to the fusion pan.

The black insoluble residue left from the extraction of the 'metal,' as the product of the fusion was called, contained considerable quantities of potassium, mainly in the form of potassium ferrous sulphide and of double potassium, calcium, and aluminium silicates.

The quantity of 'metal' produced was very little greater than the weight of potash used, and 4 charges were put through in 24 hours, but practice varied considerably: C. Karmrodt (*Wagner's Jahresber.* 1857, 3, 139) speaks of 6 charges of 500 lbs. each as the normal output of a pan in 24 hours.

The yield of ferrocyanide was seldom more than 20 p.c. of the quantity theoretically obtainable from the nitrogen in the materials used when they were not previously charred. Using charred materials, as much as 57 p.c. of the remaining nitrogen was converted into ferrocyanide, corresponding with a yield of about 12 p.c. on the nitrogen originally present.

The quantity and composition of the black residues varied greatly with the kind of organic matter used. The main constituents were carbon (4-9 p.c.), ferrous sulphide, iron, and inorganic substances derived from the ash of the animal matters and adhering dirt, the principal being silica, lime, alumina, and phosphoric acid. The quantity of potassium combined with these substances in an insoluble form was considerable. According to Karmrodt (*Wagner's Jahresber.* 1857, 3, 139), 100 parts of 'metal' made (1) from horn gave 18.7 p.c. of dry residue, containing 12.2 p.c. of K_2O ; (2) from rags, 28.3 p.c. of residues, with 16.7 p.c. K_2O ; (3) from leather, 35.1 p.c. of residue, with 10.2 p.c. K_2O . These quantities represent about $4\frac{1}{2}$, 9, and 7 p.c. of the potassium contained in the original charge, and since only some 10 p.c. of this is converted into ferrocyanide at each operation (R. Brunquell, *Wagner's Jahresber.* 2, 102, 1856), the loss of potash in the residues appears to have been from 45 to 90 p.c. of that usefully employed. Potash was also carried away with the flue gases. The iron pans survived several hundred operations.

The theory of the process was first given by Liebig (*Annalen*, 1841, 38, 20). Scheele (*Chemical Essays*, London, 1786; reprinted 1901) had already shown that *livivium sanguinis* is essentially a solution of potassium cyanide and that the addition of a ferrous compound is necessary to convert it into prussiate. Liebig confirmed this by extracting the 'metal' with alcohol, which dissolves out potassium cyanide, leaving a residue from which no ferrocyanide can be obtained. He attributed the formation of the cyanide partly to the action of ammonia (formed by destructive distillation of the organic matter)

on carbon, $C + NH_3 = HCN + H_2$, and partly to the action of potassium on the nitrogenous residue of carbon. It may be remarked that the temperature of the fusion could not have exceeded 1000° , since cast iron melts about 1100° , and the pans withstood some hundreds of fusions. The temperature, too, was lowered by the addition of the organic matter, occasionally sufficiently to cause the charge to solidify, so that the reaction between ammonia and carbon, which requires a temperature of about 1000° , could not have occurred to any great extent. The direct action of ammonia on potassium carbonate (p. 193) would, however, take place, although, the ammonia being evolved on the surface of the mass, the conditions were not favourable to it. As to the second of Liebig's reactions, the writer has found that potassium is not formed from a mixture of charcoal and potassium carbonate below about 1200° , certainly not at 1000° , so that the greater part of the cyanide must have been formed by the action of potassium carbonate itself on the nitrogenous charcoal. The rôle of sulphur in the process was explained by Liebig thus: potassium sulphate, which is always present in the potash, is reduced by carbon to sulphide, carbonate, and polysulphide. The latter dissolves iron, forming a double sulphide of iron and potassium which, when the product is lixiviated, dissolves in the potassium cyanide solution thus:

If insufficient iron is present in the fusion, the polysulphide is not entirely decomposed, and potassium sulphocyanide is also formed. R. Hoffmann (Annalen, 1860, 113, 81) investigated the behaviour of the sulphur compounds in the process in some detail, and found that the sulphur of potassium sulphide is rapidly and completely removed by iron alone in the fusion process, and that the same is true of potassium sulphate in presence of carbon. When organic matters are added to the sulphur-free melt, however, sulphocyanide is produced in proportion to the quantity added. Hoffmann, therefore, attributes its formation to the organic sulphur.

The behaviour of potassium sulphocyanide in the fusion is not clearly understood. Hoffmann found that it is completely decomposed by fusion with excess of potassium carbonate, yielding cyanate and sulphide;¹ but if the mixture is again heated with carbon, the sulphocyanide is regenerated. It appears, therefore, that, under the conditions of the process, sulphocyanide is not decomposed.

A part of the sulphide of iron formed is present in the form of a potassium ferrous sulphide, $FeS \cdot 2K_2S$, which dissolves in hot water to a dark-green, colloidal solution which is coagulated by cooling or by adding excess of potassium carbonate. Another part is probably present in the form of the crystalline potassium ferric sulphide $K_2S \cdot Fe_2S_3$, obtained by K. Preis (J. pr. Chem. 1869, 107, 10), by fusing together finely divided iron, potassium

carbonate, and sulphur. He found that the crystalline sulphide was formed at very high temperatures, and the amorphous one, yielding the green solutions, at lower temperatures.

The reaction between potassium cyanide and ferric sulphide

would give a ratio of cyanogen in the form of sulphocyanide to cyanogen in the form of ferrocyanide of 1:12, whilst Hoffmann, in 10 experiments, found ratios varying from 1:5 to 1:18.

The improvements in the process which were proposed, aimed at saving the ammonia evolved in the early stages by distilling the organic matters separately and passing the ammonia through a red-hot mixture of potash and charcoal (Brunquell, Wagner's Jahresber, 1856, 2, 102), or a similar mixture with iron added (Karmrodt, *ibid.* 1857, 3, 139), or over red-hot charcoal forming hydrocyanic acid which was to be absorbed, together with the unchanged ammonia, in a solution of ferrous sulphate (Brunquell). These proposals, unfruitful at the time, are interesting as foreshadowing processes which came into successful operation nearly half a century later.

The commonly accepted view that cyanogen compounds are more easily produced from potash than from soda, is not entirely in accordance with the older experimental evidence. The truth appears to be that equally good results can be obtained with sodium carbonate under suitable conditions, but the conditions are not so easily realised.

L. Possoz (Compt. rend. 1858, 47, 209) obtained, under manufacturing conditions, 5 parts of sodium prussiate, instead of 25 parts of the potassium salt, from 100 parts of horn. R. Hoffmann (Annalen, 1860, 113, 81), using a very high temperature and sodium carbonate, got the equivalent of 11 parts of potassium ferrocyanide from 100 parts of woollen rags, against 10 to 14 parts with potash, and S. Tanatar (Dingl. poly. J. 1880, 237, 234) obtained the results tabulated below, as the means of 3 to 5 experiments:—

Blood charcoal	K_2CO_3	Na_2CO_3	NaCl	$CaCO_3$	Prussiate obtained
10	25	—	—	—	2·15
10	—	25	—	—	0·2
10	—	5	25	—	2·17
10	—	5	25	3	2·3

Ferrocyanides from coal gas. The coal used in the manufacture of illuminating gas may be taken to contain from 1 to 1·9 p.c. of nitrogen (Drehschmidt, Journ. für Gasbeleuchtung, 1904, 677). When the coal is distilled, a part of this nitrogen passes into the gas in the form of ammonia, hydrocyanic acid and free nitrogen, a small part is found in the tar, and the remainder in the coke. The relative quantities of the nitrogen in these products vary between wide limits, being influenced by the nature of the coal, the amount of moisture in it, the temperature of distillation, and the kind of retort used. In order to give an approximate idea of the order of magnitude of the quantities involved, it may be stated that under average conditions about 15 p.c. of the nitrogen is found as ammonia, 2·5 p.c. as hydrocyanic acid, and 48 p.c. in the coke (Drehschmidt, Journ. für Gasbeleuchtung,

¹ I can confirm the accuracy of this observation. Equal molecules of potassium carbonate and sulphocyanide were fused together in a closed aluminium crucible at 500° – 580° for $\frac{1}{2}$ hours, a little more than half of the materials had reacted in accordance with the equation $KSCN + K_2CO_3 = KCNO + K_2S + CO_2$.—T. E.

1904, 677; Vivian Lewes, quoted from Chief Inspector of Alkali Works, 43rd Rep. 1906, 58); this gives a yield of 1.6 lbs. of hydrocyanic acid or 4.6 lbs. of sodium ferrocyanide crystals per ton of coal distilled. When the gas is purified by means of ammonia scrubbers and iron oxide purifiers, about one-third of the hydrocyanic acid is condensed along with the ammonia in English works (Chief Inspector of Alkali Works, 43rd Rep. 1906, 61), but less in many German works, where less water is used in the scrubbers (W. Bertelsmann, *Technologie der Cyanverbindungen*, 171), and from 50 to 70 p.c. in the iron oxide purifiers, the remainder passing away in the gas, where it is a source of damage to meters and gas holders. When lime is used for purification, the cyanide is mainly caught as sulphocyanide, and in such small quantity (the lime being only used once) that the spent lime is worthless as a raw material for cyanide making.

The gas, as it leaves the retorts, contains the whole of its cyanogen in the form of hydrocyanic acid (Chief Inspector of Alkali Works, 43rd Rep. 1906, 33), which is formed by the action of ammonia on red-hot carbon, thus: $\text{NH}_3 + \text{C} = \text{HCN} + \text{H}_2$. The hydrocyanic acid is reconverted by water vapour at high temperatures into ammonia (Carpenter and Linder, *J. Soc. Chem. Ind.* 1905, 24, 63): $\text{HCN} + \text{H}_2\text{O} = \text{NH}_3 + \text{CO}$, so that moisture in the coal diminishes the yield of hydrocyanic acid. This is doubtless the reason that much smaller quantities of hydrocyanic acid are found in the gases of coke ovens, where the coal is distilled in a much wetter condition.

The treatment of gas liquor is discussed under the heading *Sulphocyanides* (p. 200).

Spent oxide. The hydrated oxide of iron first used in gas purification was made by mixing ferrous sulphate and slaked lime, sawdust being added to increase the porosity (Laming, *Eng. Pat.* 11944, of 1847), natural iron ores were introduced by Howitz in 1870. Sulphuretted hydrogen is absorbed, yielding a mixture of ferrous and ferric sulphides which is regenerated by exposure to air and moisture, free sulphur and ferrous and ferric hydroxide being produced. Ferrocyanide is formed from the ferrous hydroxide and hydrocyanic acid, and then converted into Prussian blue by interaction with the ferric iron. Sulphocyanides are also formed in very variable amount, doubtless by the interaction of hydrocyanic acid and ammonium polysulphide. Since ammonia, sulphuretted hydrogen, and free sulphur are always present in the purifiers, it is obvious that polysulphides of ammonium can always be formed; it appears to be generally allowed, however, that sulphocyanide is only produced in large amount when the mixture becomes warm, as, for example, when the regeneration proceeds rapidly in a large mass of material. The spent oxide finally contains 30 to 40 p.c. of sulphur (or more), soluble ammonium salts and Prussian blue, in addition to tar and iron oxides. Good material contains 11 to 12 p.c. of Prussian blue, calculated on the air-dried substance, whilst ammonium sulphocyanide varies from traces to 10 p.c.

As already mentioned, prussiates were first produced from spent oxide by Gautier-Bouchard about 1860. Ammonium salts were first re-

moved by washing with water; the residue was then mixed intimately with sufficient lime to convert the Prussian blue into calcium ferrocyanide and the mixture submitted to systematic lixiviation with cold water. This operation must be done in the cold, because otherwise calcium polysulphide is produced from the lime and free sulphur, and this converts the ferrocyanide into sulphocyanide. The calcium ferrocyanide was converted into the potassium salt by means of potassium carbonate, and the sulphur in the extracted residue burned to sulphur dioxide and converted into sulphuric acid (A. W. Hofmann, *Reports by the Juries*, *Inter. Exhib.* of 1862, 59-63). This process contains the essential features of all those which have since been worked successfully.

T. L. G. Bell (*Eng. Pat.* 257, of 1868) proposed to extract the sulphur with carbon disulphide, and, after removing soluble ammonium salts with water, to boil the residue with lime. In order to obtain a pure product, the solution was then acidified and precipitated by the addition of ferric chloride, the Prussian blue being then converted into potassium ferrocyanide. The preliminary extraction of the sulphur has occasionally been carried out, but it is difficult to separate the sulphur from the tar which is extracted along with it. In spite of the great difficulty of filtering and washing Prussian blue, this method of purification appears to have been fairly generally used up to the year 1883, when Kunheim and Zimmermann (*Eng. Pat.* 3342, of 1883) described two new methods.

In the first, the ammonia is only partially removed from the spent oxide by the preliminary washing, enough being left behind to produce the double salt $\text{Ca}(\text{NH}_4)_2\text{Fe}(\text{CN})_6$. The extraction with lime then yields an ammoniacal solution of calcium ferrocyanide, which, when neutralised with hydrochloric acid and heated to 80°, deposits the very sparingly soluble calcium ammonium ferrocyanide, which is comparatively easily filtered and washed.

By the second method, the solution of calcium ferrocyanide, obtained by following Gautier-Bouchard's original procedure, is treated with a solution of potassium chloride, which precipitates the double salt $\text{CaK}_2\text{Fe}(\text{CN})_6$ in minute crystals, which are very readily washed and are then converted into potassium ferrocyanide by boiling with potassium carbonate. By this means one half of the potassium carbonate is replaced by the cheaper chloride, and a very pure product is obtained (Franz Bössner, *Die Verwertung der Ausgebrauchten Gasreinigungsmassen*, 1902). From the calcium ammonium salt, sodium prussiate is readily obtained.

During the decade 1885 to 1895, the spent oxide of the gas works was the principal source of prussiates; its importance, however, has been diminished by the introduction of the more efficient wet methods of recovering the hydrocyanic acid.

The first practicable proposal of this kind was made by O. Knublauch (*Eng. Pat.* 15164, of 1887). Coal gas was to be scrubbed with a solution of the oxide, hydroxide, carbonate, or sulphide of ammonium, or of an alkali or alkaline-earth metal containing the hydroxide or

carbonate of iron, zinc, or manganese in suspension. The process did not succeed at the time, probably for commercial reasons. The very similar process of Foulis (Eng. Pat. 9474, of 1892; Foulis and Holmes, Eng. Pat. 15168, of 1895), has since been introduced at several gas works with satisfactory results. In this process, the reagent required is prepared by precipitating a ferrous salt with sodium carbonate. The washed precipitate (a partially oxidised mixture of ferrous carbonate and hydroxide) is suspended in a solution of sodium carbonate and the gas passed through it in a rotary scrubber. Foulis wished to obtain the whole of the ferrocyanide in solution in the form of the sodium salt, and therefore placed the cyanogen washer after the ammonia scrubbers because, in presence of ammonia, a double ammonium ferrous ferrocyanide is formed which is only decomposed by sodium hydroxide, but not by the carbonate. At the Hague gas works, however, this order was reversed in order to catch the hydrocyanic acid which is otherwise condensed along with the ammonia (Rutten, Journ. of Gas Lighting, 1902, 80, 879; Jorissen and Rutten, Journ. für Gasbeleuchtung, 1903, 716). The saturated liquor from the cyanide washer contains Prussian blue and potassium and ammonium ferrous ferrocyanides in suspension and potassium ferrocyanide and ammonia in solution (potassium carbonate is used instead of the sodium salt). This mixture is filter-pressed and the solution distilled to separate the ammonia and then evaporated *in vacuo* and crystallised. The press cake is boiled with caustic potash and the ammonia collected, the residual iron oxide returning to the cyanide washer, and the solution of ferrocyanide going to the evaporating plant.

In another set of proposals, the use of an alkali other than the ammonia of the gas is dispensed with, the crude coal gas being simply washed with a solution of ferrous sulphate. Since ammonia and sulphuretted hydrogen are present in much larger quantities than hydrocyanic acid, the ferrous sulphate is soon converted into a suspension of ferrous sulphide in a solution of ammonium sulphate, and the subsequent changes may be regarded as due to the action of a solution of ammonium cyanide on ferrous sulphide. If a large excess of the latter is present, the main product is ferrous ferrocyanide $\text{Fe}_2[\text{Fe}(\text{CN})_6]$; as the ferrous sulphide is used up, ammonium ferrous ferrocyanide $(\text{NH}_4)_2\text{Fe}[\text{Fe}(\text{CN})_6]$ is formed in increasing quantities, and finally, when but little FeS remains, ammonium ferrocyanide is found in solution (Feld, Journ. für Gasbeleuchtung, 1904, 132).

The earlier patentees of processes based on these reactions attempted to obtain the ferrocyanide in a soluble form by using a dilute solution of a ferrous salt, and so having a large excess of ammonia present (Rowland, Eng. Pat. 22347, of 1891; Lewis and Cripps, Eng. Pat. 20883, of 1896; Schröder, Eng. Pat. 19849, of 1898; Teichmann, Eng. Pat. 12485, of 1899), but since insoluble compounds are always formed to some extent, it appears to be easier to obtain all the ferrocyanide (or the greater part of it) in the insoluble form by using a saturated solution of ferrous sulphate, and so having a large excess of iron present as first proposed by Bueb (Eng.

Pat. 9075, of 1898). Bueb's process has been adopted by a considerable number of gas works. It is said to absorb 98 p.c. of the hydrocyanic acid in the gas, yielding a mud containing 6-7 p.c. of ammonia and cyanogen compounds, equivalent to 18-20 p.c. of yellow prussiate of potash. A small part of the ferrocyanide is in solution. This is precipitated by boiling the mixture with ferrous sulphate; the precipitate is then filtered off and treated with lime, the subsequent operations being the same as those already described when dealing with spent oxide.

MANUFACTURE OF PRUSSIANES FROM SULPHO-CYANIDES.

A. Gélis (Eng. Pat. 1816, of 1860) was the first to manufacture potassium ferrocyanide by heating potassium sulphocyanide with iron. He heated dry potassium sulphocyanide with iron, made by reducing the oxide, at a dull-red heat in a closed vessel. He states that too high a temperature leads to considerable loss. The fusion process yields a mixture of potassium cyanide and ferrous sulphide which gives potassium ferrocyanide, when treated with water in the same way as the 'metal' of the old process (A. W. Hofmann, Reports by the Juries, Inter. Exhib. of 1862, 59-63). Mr. G. Beilby has informed the writer that he made considerable quantities of potassium ferrocyanide by this process about the year 1880. Potassium sulphocyanide was heated with iron turnings in air-tight iron retorts and, after cooling sufficiently, the product was extracted with water in the retort itself, without coming in contact with air. In this way the only serious difficulty of the process, which is due to the extreme proneness to oxidation of the fusion product, is avoided and satisfactory yields obtained.

The process was taken up again in 1878 by Günzburg and Tcherniac (Eng. Pat. 1148, of 1878; 1359, of 1879; 1261, of 1881). They dried the sulphocyanide by fusing it at 300°, and then mixed it intimately with the oxide-free iron by grinding them together. The mixture was heated in iron boxes with closely fitting covers at 445°, the vapour of boiling sulphur being used to obtain a constant temperature. After working for two or three years, the process was given up, but it was revived for the third time in 1894 by the United Alkali Co., Ltd. (Hetherington and Muspratt, Eng. Pat. 5830, of 1894), and by the British Cyanides Co., Ltd. (Crowther, Rossiter, Hood and Albright, Eng. Pat. 8305, of 1894). The patent specifications of Hetherington and of Crowther add but little to the information given above. In both cases, some 20 to 30 p.c. excess of iron is used, and the temperature is almost the same as that recommended by Günzburg and Tcherniac. Crowther says that mere fusion is insufficient to dry the sulphocyanide: a current of an indifferent gas must be passed through it for some time. Conroy (J. Soc. Chem. Ind. 1896, 15, 12) was able in a small scale experiment, to convert 76.8 p.c. of the sulphocyanide used into ferrocyanide (leaving 18.2 p.c. unchanged) by means of Hetherington's method. The process has been worked by the British Cyanides Co. at Oldbury since 1894 (Brussels Exhib. 1910, Catalogue of British Chem. Section, 15b).

The conversion of sulphocyanides into ferrocyanides is also possible in aqueous solution. Sternberg (D. R. P. 32892, of 1882), found that by heating a solution of potassium sulphocyanide with double the theoretical quantities of iron filings and ferrous hydroxide under pressure at 110°-120°, about 80 p.c. of the material could be converted into ferrocyanide in accordance with the equation

G. R. Bower (Eng. Pat. 361, 1896) succeeded in removing the sulphur from ferrous sulphocyanide by means of copper in a similar way: $\text{Fe}(\text{CNS})_2 + \text{Cu} = 2\text{CuS} + \text{Fe}(\text{CN})_2$. Conroy (Conroy, Hurter, and Brock, Eng. Pat. 3867, of 1896; J. T. Conroy, J. Soc. Chem. Ind. 1898, 17, 98) then found that a mixture of a soluble sulphocyanide and a ferric or ferrous salt would do as well as pure ferrous sulphocyanide, and also that the sulphur is more rapidly removed by finely divided iron than it is by copper. Using very finely divided iron, the reaction takes place quantitatively in 5 to 6 hours at a temperature of 135°-140° and a pressure of 50 to 60 lbs. per square inch, in accordance with the empirical equation $\text{Fe}(\text{CNS})_2 + 2\text{Fe} = \text{Fe}(\text{CN})_2 + 2\text{FeS}$. (Sodium or potassium sulphocyanide is acted on by iron under similar conditions very slowly and incompletely.) The black mud produced is either boiled with caustic alkali to decompose the ferrous ferrocyanide, or the ferrous sulphide is first dissolved in hydrochloric acid. The latter course is to be preferred, owing to the fact that ferrous sulphide combines with the alkalis, each 3 or 4 equivalents of it rendering 1 equivalent of either caustic soda or potash insoluble.

PROPERTIES OF THE FERROCYNANIDES.

Potassium ferrocyanide crystallises from aqueous solutions in large, well-formed, orange-yellow tetragonal pyramids of the composition $\text{K}_4\text{Fe}(\text{CN})_6 \cdot 3\text{H}_2\text{O}$; sp.gr. 1.86. The crystals do not change when exposed to the air at ordinary temperatures. They begin to lose water at 60°, and the finely powdered salt may be completely dehydrated at 100°, leaving a white powder which decomposes, in absence of oxygen, slightly below a red heat to a mixture of potassium cyanide, carbon and iron, nitrogen escaping. The powder takes fire at a considerably lower temperature when heated in contact with air. It is insoluble in alcohol. According to Étard (Ann. Chim. phys. 1894 [7] 2, 546), the solubility, expressed in grams of anhydrous salt dissolved by 100 grams of water, is 14.5 at 0°, 24.5 at 20°, 36 at 40°, 49.5 at 60°, 64 at 75°, 70 at 80°, 72 at 89°, 74 at 98°, and 88 at 157°. The salt is much less soluble in solutions of potassium salts. The specific gravity of the aqueous solutions is given below (Schiff, Annalen, 1860, 113, 199):—

Grs. $\text{K}_4\text{Fe}(\text{CN})_6 \cdot 3\text{H}_2\text{O}$ per 100 grs. of solution	1	5	10	15	20
Sp.gr. at 15°	1.0058	1.0295	1.0605	1.0932	1.1275

Sodium ferrocyanide crystallises in large lemon-yellow monoclinic prisms or rhombohedra of the composition $\text{Na}_4\text{Fe}(\text{CN})_6 \cdot 10\text{H}_2\text{O}$ (Conroy, J. Soc. Chem. Ind. 1898, 17, 103), which are permanent when exposed to the air at the ordinary temperature, but are completely dehydrated at a little above 100°. The

behaviour of the dry salt, when heated, resembles that of the potassium compound. The solubility in water (Conroy, J. Soc. Chem. Ind. 1898, 17, 103): grams anhydrous salt dissolved by 100 grams of water, is at 20°, 17.9; at 30°, 23.5; at 40°, 29; at 50°, 35.5; at 60°, 42.5; at 70°, 51.5; at 80°, 59.2; at 90°, 61; and at 100°, 63.

Calcium ferrocyanide $\text{Ca}_2\text{Fe}(\text{CN})_6 \cdot 12\text{H}_2\text{O}$ is extremely soluble in water; highly concentrated solutions are very viscous and crystallise with difficulty, yielding small yellow triclinic crystals of sp.gr. 1.68, which effloresce when exposed to the air and lose $11\frac{1}{2}$ molecules of water at 40°. H. G. Colman (Journ. of Gas Lighting, 1910, 583) finds that the whole of the water is removed by heating the salt in a current of air. The dry salt begins to decompose (in absence of oxygen) at 500° yielding calcium cyanamide thus

(unpublished experiments made by the writer).

Calcium potassium ferrocyanide $\text{K}_2\text{CaFe}(\text{CN})_6$ is a white powder consisting of small quadratic prisms which becomes slightly cream-coloured on exposure to light. It contains no water of crystallisation and, at 15°-17°, 100 grams of water dissolve 0.41 gram of it (J. Campbell Brown, Chem. Soc. Trans. 1907, 91, 1826).

Calcium ammonium ferrocyanide

is a white, minutely crystalline powder, which becomes coloured on exposure to light; it is anhydrous; 100 grams of water, at 15°-17° dissolve 0.258 gram of the salt (J. Campbell Brown, *ibid.* 1907, 91, 1826).

Hydroferrocyanic acid $\text{H}_4\text{Fe}(\text{CN})_6$ is prepared by adding concentrated hydrochloric acid to a saturated solution of potassium ferrocyanide (both should be free from dissolved oxygen) and then enough ether to saturate the solution. The acid crystallises out in colourless scales which are washed with water saturated with ether (A. Joannis, Ann. Chim. Phys. 1882 [5] 26, 484), and dried over sulphuric acid. A solution of the acid, saturated at 14°, contains 150 grams per litre. The solution is readily oxidised by atmospheric oxygen, especially at higher temperatures, forming a blue substance which is usually assumed to be Prussian blue. This reaction is utilised in calico printing for the production of blue patterns.

Hydrogen ferrous ferrocyanide

is formed when a solution of the acid is boiled:

Potassium ferrous ferrocyanide (Everitt's salt) $\text{K}_2\text{Fe}[\text{Fe}(\text{CN})_6]$ is formed in a similar way if potassium salts are present, as, for example, in the preparation of hydrocyanic acid by distilling a mixture of potassium ferrocyanide and dilute sulphuric acid. Everitt's salt is a pale-yellow crystalline powder which is not identical with the white precipitate obtained by mixing solutions of potassium ferrocyanide and ferrous chloride, although this precipitate has the same composition.

Molecular constitution.—The soluble ferrocyanides all yield the complex ferrocyanogen ion, $\text{Fe}(\text{CN})_6^{4-}$; their aqueous solutions do not, therefore, exhibit the ordinary reactions of

ferrous or of cyanogen ions. The solutions are, however, not entirely devoid of these ions, we must rather consider them as being present in extremely small quantities in equilibrium with ferrocyanogen ion $\text{Fe}(\text{CN})_6''' \rightleftharpoons \text{Fe}'' + 6\text{CN}'$. The increased quantity of silver nitrate required to produce opalescence in a solution of a cyanide when a ferrocyanide is added to it (Clennel, Chem. News, 1895, 72, 227; Conroy, J. Soc. Chem. Ind. 1896, 15, 12), is possibly due to this. The decomposition of ferrocyanides by mercuric salts is explained similarly, for the concentration of cyanogen ions which can exist in equilibrium with mercuric ion is even smaller than that in equilibrium with the ferrocyanogen ion. Hence the addition of mercuric ion to the solution removes cyanogen ion in the form of undissociated mercuric cyanide and so causes fresh quantities of the ferrocyanogen ion to dissociate. The dissociation of the ferrocyanogen ion is increased by exposure to light, so that in the light, alkaline sulphides produce a precipitate of ferrous sulphide and oxygen precipitates ferric hydroxide (from alkaline solutions), reactions of which do not occur in the dark (Haber, Zeitsch. Elektrochem. 1905, 11, 846).

Very accurate measurements of the osmotic pressure and electrical conductivity of solutions of the ferrocyanides of calcium, strontium, and potassium have been made by the Earl of Berkeley, Hartley and others (Phil. Trans. 1909, 209 A, 177 and 319), which are best interpreted by assuming the salts to consist of double molecules which dissociate into 6 ions (or 10 in the case of the potassium salt). A complex structure of this kind would not be surprising in view of the great number and diversity of the ferrocyanides, especially those of iron.

Potassium ferricyanide, red prussiate of potash, $\text{K}_3\text{Fe}(\text{CN})_6$ was discovered by Leopold Gmelin in 1822. He prepared it by passing chlorine into a solution of potassium ferrocyanide until it no longer gave a blue colour with a ferric salt:

The salt is always manufactured by this reaction, the ferrocyanide is sometimes used in the form of a dry powder, in which case a mixture containing potassium chloride is obtained. Most commonly, a cold 10 p.c. solution of potassium ferrocyanide is treated with chlorine until conversion is just complete. A little Prussian green is always formed by the action of chlorine on the ferricyanide, and as this passes through any filter it spoils the appearance of the product. The difficulty may be avoided by evaporating the solution to crystallisation and then adding a little caustic potash which decomposes the green into ferric hydroxide, which is easily removed by filtration, and potassium ferrocyanide, which is apt to crystallise out along with the ferricyanide. The yield of ferricyanide, in this process, is 85 to 90 p.c. of the theoretical quantity.

A. W. Williamson (Annalen, 1846, 57, 225) found that potassium ferric ferrocyanide (Williamson's blue), when boiled with potassium ferrocyanide, gives potassium ferricyanide and Everitt's salt,

Since Everitt's salt is readily oxidised to Williamson's blue by warming with dilute nitric acid, the process might (as Dittmar suggested) be utilised to complete the conversion of ferro- into ferricyanide, chlorine being used up to the point at which Prussian green begins to be formed.

Many other oxidising agents have been suggested in place of chlorine, such as bromine, lead peroxide, calcium plumbate, potassium permanganate and persulphate, and electrolytic oxidation (*see* Bertelsmann, Technologie der Cyanverbindungen).

Potassium ferricyanide crystallises from water in magnificent, deep-red, monoclinic prisms which may be very large. It is anhydrous; sp.gr. 1.845. The aqueous solution has an intense yellow colour. The solubility (grams of anhydrous salt dissolved by 100 grams of water) is 33 at 4.4°, 36 at 10°, 40.8 at 15.5°, 58.8 at 37.8°, 77.5 at 100°, and 82.6 at 104.4° (Wallace, Dingl. poly. J. 1856, 142, 52). Specific gravity of the solutions at 15° (Schiff, Annalen, 1860, 113, 199):—

Per cent. $\text{K}_3\text{Fe}(\text{CN})_6$	1	5	10	15	20	25	30
Sp.gr.	1.0051	1.0261	1.0538	1.0831	1.1139	1.1462	1.1802

The aqueous solution is decomposed by light, potassium ferrocyanide being formed. The caustic alkaline solution is a strong oxidising agent which decolourises indigo instantaneously.

Prussian blue. The blue compounds of iron and cyanogen are all amorphous substances, some of which yield colloidal solutions in pure water. It is therefore extremely difficult to prepare them in a pure condition. Owing to the well-known tendency of colloids to absorb other substances from solutions, the precipitates require very prolonged washing to free them from adhering salts, and during this process their composition may, and very often does, change, owing to atmospheric oxidation or to hydrolysis. On the other hand, the method of determining the composition of a precipitate by mixing known quantities of the reagents and estimating the excess left in the supernatant liquid, is open, in this case, to the objection that the precipitate is not a pure substance because it has absorbed some of the salts in the solution in contact with it. The composition of the precipitates obtained by mixing the same substances depends, too, on the order of mixing and on the temperature and degree of acidity of the solutions, so that contradictory results have often been recorded by different observers. The whole subject has been reinvestigated recently by K. A. Hofmann (K. A. Hofmann, O. Heine, and F. Höchtlen, Annalen, 1904, 337, 1; K. A. Hofmann and F. Resenscheck, *ibid.* 1905, 340, 267; 1905, 342, 364) and his co-workers, and the following account of the different 'blues' is based mainly on this work.

The freshly prepared blue precipitates contain indefinite quantities of water, but the whole of it cannot be removed by drying *in vacuo* over phosphorus pentoxide until a constant weight is attained (which usually requires from 2 to 5 months). This residual water must be regarded as constitutional, because when the substances are heated to temperatures a little above 100°, they lose cyanogen, but not water. The formulæ of the substances given in what follows refer to

the very thoroughly washed substances after complete drying over P_2O_5 in the way mentioned above.

When cold neutral solutions of one molecule of a ferric salt and one molecule of potassium ferrocyanide are mixed together, a precipitate of ordinary soluble Prussian blue is formed. The dry substance has the composition

The same compound is obtained by mixing equal molecular quantities of a ferrous salt and potassium ferricyanide. This was first proved by Skraup (Annalen, 186, 371, 1877).

When a cold solution of potassium ferrocyanide is added gradually to a cold neutral (or $\frac{1}{2}$ p.c. hydrochloric acid) solution containing an excess of a ferric or of a ferrous salt, or when soluble Prussian blue is digested with a solution of ferric chloride, precipitates are formed which, after the prolonged exposure to air involved in washing them completely, are identical in composition and properties. The dry substance is normal ferric ferrocyanide

usually referred to as Prussian blue. Turnbull's blue, obtained by precipitating a solution of potassium ferricyanide with an excess of a ferrous salt, is identical with ordinary Prussian blue.

The precipitates obtained from hot acid solutions differ more or less from these in their properties, and appear to be mixtures of different substances.

Both the soluble and insoluble Prussian blue, just described, are ferric ferrocyanides, and not ferrous ferricyanides. This is proved by the fact that they can be made by the action of hydrogen peroxide on a solution containing a ferric salt and potassium ferricyanide in suitable quantities. As Schönbein (J. pr. Chem. 1866, 98, 65) showed, hydrogen peroxide reduces ferricyanide to ferrocyanide, but has no action on a ferric salt, so that ferrous ferricyanide could not be produced by this reaction.

Blue compounds, which are not identical with those described above, are also obtained by the oxidation of ferrous ferrocyanides.

(a) By adding a cold neutral solution of 1 molecule of a ferrous salt to a solution of 1 molecule of potassium ferrocyanide, and then oxidising the white precipitate by means of atmospheric oxygen, which is greedily absorbed (or better by hydrogen peroxide), a blue compound of the composition $KFe^{III}(Fe^{II}Cy_6) + H_2O$ is obtained. This differs from ordinary soluble blue in being insoluble in oxalic acid solution. It is referred to in the table of the properties of the blues as K. A. Hofmann's blue.

(b) By proceeding exactly as in (a), except that the solutions contain 1 p.c. of sulphuric acid, a white precipitate is obtained, $Fe^{III}K_2(Fe^{II}Cy_6)$, which is rather less readily oxidised to a blue of the same composition as before:

but possessing rather different properties. Like ordinary soluble Prussian blue, it is soluble in water and oxalic acid, but it differs from it in being much more stable to ammonia solution. This compound is referred to as 'stable soluble blue.'

(c) When a solution of potassium ferrocyanide, containing about 10 p.c. of sulphuric acid, is heated in an atmosphere devoid of oxygen, one half of the hydrocyanic acid is evolved and a pale-yellow crystalline powder of Everitt's salt $K_2Fe^{II}(Fe^{II}Cy_6)$ remains behind. This salt is very much less readily oxidised than the precipitate obtained by mixing solutions of potassium ferrocyanide and a ferrous salt, it is not completely oxidised by several weeks' exposure to the air. As already mentioned, it is readily oxidised by warm dilute nitric acid, but a homogeneous product is prepared most certainly by suspending it in 1 p.c. sulphuric acid and adding about 10 times the theoretical quantity of hydrogen peroxide. The substance thus obtained is Williamson's blue (sometimes called violet), and it also has the composition $KFe^{III}(Fe^{II}Cy_6) + H_2O$. Its properties are, however, totally different from those of the isomeric substances already described.

For comparison, the distinguishing properties of the different blues are tabulated below. The isomerism of these substances may be due to differences in the linking of the atoms—of the kind familiar in organic chemistry—or it may be due to differences in the size of the molecules; the data available do not appear to be sufficient to decide these questions with any degree of certainty.

It is of interest that precipitation from hot acid solutions always tends to produce substances (or mixtures) of a more stable type, approaching Williamson's blue more or less closely in properties, and also that all the blue iron cyanogen compounds contain both ferrous and ferric iron. The compounds which contain only ferrous or only ferric iron are colourless or (compared with the blues) feebly coloured. Solid pieces of ordinary Prussian blue assume a coppery lustre when rubbed on a smooth, hard surface. The blue solution in oxalic acid was formerly used as an ink. Chlorine turns a suspension of Prussian blue in water green; the solution contains ferric chloride: the blue colour is restored by washing with water. Concentrated sulphuric acid unites with Prussian blue to a white paste from which the original blue is obtained by diluting with water. It is slowly decomposed by concentrated aqueous hydrochloric acid, but dissolves to a colourless solution in alcoholic hydrochloric acid; the solubility increases with the molecular weight of the alcohol used. Water precipitates unchanged Prussian blue from these solutions. Potassium, sodium, and calcium hydroxides decompose Prussian blue into ferric hydroxide and a ferrocyanide; alkali carbonates act more slowly. Tissues dyed with Prussian blue gradually lose their colour in sunlight, but regain it in the dark. When heated to about 170° in the air, it burns like tinder leaving a brown ash.

Commercial blues are usually mixtures of the compounds already described. J. G. Gentile (Lehrbuch der Farbenfabrikation, 2nd ed. 1880) says that the best blues are obtained by precipitating a ferrous salt with yellow prussiate and then oxidising the precipitate. *Paris blue* (the finest quality of commercial Prussian blue) is made as follows: 50 kilos. of yellow prussiate are dissolved in 250 kilos. of

PROPERTIES OF THE BLUE IRON-CYANOGEN COMPOUNDS.

Reagent	Ordinary soluble Prussian blue (Turnbull's soluble blue)	Insoluble Prussian blue (Turnbull's blue)	K. A. Hofmann's blue	Stable soluble blue	Williamson's blue or violet
Pure water	Soluble, reddish-blue solution	Insoluble	Soluble, greenish-blue solution	Soluble	Insoluble, turbid greenish-blue suspension Insoluble
10 p.c. oxalic acid	Soluble, blue solution	Soluble, blue solution	Insoluble	Soluble	
4 p.c. ammonia yields red-brown ferric hydroxide	In a few seconds	In 10 seconds	In a few seconds	In 6 to 7 minutes	After some hours
Ferric chloride	Precipitates insoluble Prussian blue	No change	(?)	Gradually coagulated in unchanged condition	No change
1 to 1½ p.c. H ₂ SO ₄	Slowly precipitated, moist precipitate soluble in water	No action	Quickly precipitated; insoluble in water	Precipitated, insoluble in water	No action
Appearance of dry solids	Deep-blue with coppery lustre	Deep-blue purple lustre	—	—	Purple-red

boiling water; 42.5 to 45 kilos. of green vitriol are dissolved in about the same quantity of water, preferably in the presence of scrap iron to prevent formation of ferric salt. The clear solutions are then run simultaneously into 250 kilos. of water. The almost white precipitate is allowed to settle and then drained on a cloth filter. The oldest method of 'blueing' the paste was to heat it to boiling in a basin, transfer it to a wooden tub, and add 25.5 kilos. of nitric acid (sp.gr. 1.23) and 18 kilos. of sulphuric acid (1.84 sp.gr.). Sometimes, red fumes were evolved only after some hours, but in presence of excess of green vitriol, they were always evolved at once and this gave the best colour. After standing for 24 hours, the mixture was suspended in a large quantity of cold water and allowed to settle. The washing by decantation was continued until the blue was free from sulphuric acid. It was then collected on linen filters, pressed into thin cakes, and cut up into cubes which were dried in the air and finally at 30°-40°. The yield was 39 to 39.5 kilos. of finished blue.

Another method was to treat the heated paste of ferrous ferrocyanides with ferric chloride, instead of with nitric acid, until the solution contained ferric in addition to ferrous salts, but according to Gentele, the cheapest and best method is to acidify the paste slightly with hydrochloric acid and pass chlorine gas into it until the solution shows a distinct 'ferric' reaction with ferrocyanide.

From these descriptions it is clear that commercial Paris blue must contain, in addition to ordinary insoluble Prussian blue, one or more of the potassium ferric ferrocyanides. In the commercial pigments, Paris blue is diluted with starch, heavy spar, gypsum, or burned and finely ground kaolin. The white admixture, after having been ground very finely by itself, is added to the Paris blue paste, and along with

it passed through a colour mill. Very low qualities of blue are faced by rotating the dry cubes in a cask with the fine dust of pure Paris blue.

Hydrocyanic acid. Prussic acid (Ger. *Blau-säure*). HCN.

This substance was discovered by Scheele in 1782 (Chemical Essays, London, 1786; reprinted 1901). He observed that *Lixivium sanguinis* loses its power of forming Prussian blue when it is exposed to the air, and traced this effect to the atmospheric carbon dioxide. Other acids also produced it, and the blue-forming principle was found in the vapour given off. By distilling the *lixivium* with sulphuric acid, he obtained an aqueous solution of hydrocyanic acid. A more convenient method of preparation was to heat potassium ferrocyanide with dilute sulphuric acid. In doing this, he obtained a blue residue (oxidised Everitt's salt or Williamson's blue). Finally, he prepared mercuric cyanide by boiling Prussian blue with mercuric oxide; by treating this with iron and sulphuric acid, he decomposed it into mercury and hydrocyanic acid which he distilled off. In 1783, Scheele found that hydrocyanic acid is inflammable, its combustion yielding carbon dioxide. He also proved that it contains nitrogen by synthesising it from ammonia. Equal parts of charcoal and potassium carbonate were heated to redness, but not sufficiently to melt the potash, in a crucible and then some ammonium chloride stirred in (for 2 minutes only); the mass was then thrown into water and a solution obtained which gave 'a great quantity of Prussian blue,' whereas a similar experiment without the sal-ammoniac yielded none.

The exact quantitative composition of prussic acid was ascertained by Gay-Lussac (Annales de Chimie, 1815, 95, 156). He showed that it is similar in constitution to hydrochloric and hydriodic acids, except that the

hydrogen is united with a compound radicle, CN, which he called 'cyanogène,' which plays the part of an element in so far as it passes through many transformations unchanged.

Hydrocyanic acid itself is formo-nitrile $H-C\equiv N$. Like the nitriles, it is hydrolysed rapidly by boiling alkalis and slowly by mineral acids, whereas the isomeric isocyanides are unaffected by alkalis but violently decomposed by acids. Anhydrous liquid hydrocyanic acid, and also the nitriles, do not dissolve silver cyanide, whilst isocyanides dissolve it very readily. Isocyanides are changed when heated into the corresponding nitriles, but pure hydrocyanic acid, which undergoes no change at the ordinary temperature, is converted at 100° , or in the cold in presence of potassium cyanide, into a black amorphous mass which contains a termolecular polymeride, aminomalononitrile $NH_2CH(CN)_2$. The physical properties of hydrocyanic acid also resemble those of the nitriles, especially its high dielectric constant of 95.

The metallic cyanides, however, appear to have the isocyanide structure, $M-N\equiv C$ (Wade, Chem. Soc. Trans. 1902, 1613; Gautier, Ann. Chim. Phys. [4] 17, 103, 1869; Nef, Annalen, 270, 329, 1892; 287, 325, 1895).

Hydrocyanic acid is found in many plants, usually in the form of a glucoside. Of these, amygdalin, found in bitter almonds, laurel leaves, &c., is the best known; it is a compound of benzaldehyde, hydrocyanic acid, and maltose. The great millet (*Sorghum vulgare*), which is cultivated in most tropical countries for food, also contains, in the immature plants, a glucoside, dhurrin, which is a compound of *p*-hydroxybenzaldehyde, hydrocyanic acid and dextrose (Dunstan and Henry, Proc. Roy. Soc., 1902, 70, 153). Several cases of cattle being poisoned by the green plant have been recorded (Leather, Agric. Journ. of India, 1, 220, 1906).

Preparation of hydrocyanic acid.—A 2 p.c. solution used in pharmacy is made by distilling a mixture of 2 parts of strong sulphuric acid diluted with 6 parts of water and 3 parts of yellow prussiate almost to dryness, and diluting the distillate to the strength required.

The most convenient method, however, is to run a solution of commercial sodium cyanide (97-98 p.c. NaCN) in about twice its weight of water into a small excess of cold 60 p.c. sulphuric acid. The hydrocyanic acid can be produced in this way at any desired rate; it is almost anhydrous, and the yield is practically quantitative. The sulphuric acid must not be added to the cyanide solution, because a part of the hydrocyanic acid produced in contact with the cyanide is polymerised and the solution becomes dark brown. The vapour may be dried by calcium chloride, kept at a temperature of about 30° and then condensed in a vessel cooled by ice, although the greater part of it is quite readily liquefied in an ordinary Liebig's condenser cooled by cold water.

Synthesis of hydrocyanic acid.—The earliest synthesis of hydrocyanic acid was effected by Clouet (Ann. de Chim. 1791, 11, 30), by passing dry ammonia over wood charcoal heated to bright redness in a porcelain tube. This reaction has been studied quantitatively

by E. Bergmann (Journ. für Gasbel. 1896, 39, 117), D. Lance (Compt. rend. 1897, 124, 819), and G. A. Voerkelius (Dissertation, Hannover, 1909). The formation of hydrocyanic acid begins at about 700° , and the best yields, calculated on the ammonia used, are obtained at temperatures between 1000° and 1100° . The reaction $NH_3 + C \rightleftharpoons HCN + H_2$ is reversible, and should lead to an equilibrium between ammonia, hydrocyanic acid, and hydrogen; the equilibrium, however, cannot be realised, because both ammonia and hydrocyanic acid are unstable at the temperatures required. The final result depends, therefore, on the rates of decomposition of ammonia and hydrocyanic acid and on the rate of reaction between ammonia and charcoal. Even at 1000° , the rate of decomposition of hydrocyanic acid in presence of charcoal is small, but in presence of other substances it may be large. Voerkelius, for example, passed a mixture of hydrocyanic acid and hydrogen through an unglazed porcelain tube at 1000° , and found that over 70 p.c. of it was decomposed, but after a layer of carbon had been deposited on the tube the decomposition fell to 19 p.c. The rate of decomposition of the ammonia is even more variable; for example, at 720° , 28 p.c. of the ammonia survived 6 minutes' contact with fresh finely ground wood charcoal, whilst 82 p.c. were unchanged when the charcoal was in the form of lumps which had been already used. The rate of decomposition of the ammonia is diminished by diluting it with an indifferent gas.

In the 66 experiments recorded by Voerkelius, the ammonia (diluted with hydrogen) was in contact with the charcoal for from 16 to 360 seconds; within these limits, the ratio between the numbers of molecules of ammonia and of hydrocyanic acid in the product is roughly independent of the time of reaction, but the quantity of ammonia decomposed into its elements increases with the time of contact. The following table is calculated from the figures given by Voerkelius. The figures show the influence of the quality of the charcoal on the result:—

Temperature		P.c. NH_3 in gas used	Mols. NN_3	Mols. HCN in product	mean
720°	charcoal A	50	6.7-13.4	9.80	
	" B	50	29-45	37.7	
	sugar charcoal	50	71	71	
1020°	charcoal C	13-15	0.64-0.92	0.76	
	" D	13-15	0.90-1.80	1.40	
	" C	43-47	0.50-0.90	0.61	
1120°	" D	13.4	0.44-0.48	0.46	

Nernst's thermodynamic theorem (Applications of Thermodynamics to Chemistry, London, 1907, and Theoretische Chemie, 5th and 6th ed.) has been applied to this reaction by v. Wartenberg (Zeitsch. anorg. Chem. 1907, 52, 299). Since the reaction $NH_3 + C = HCN + H_2$ absorbs 39,500 cal. per molecule, the equilibrium must lead to the formation of more hydrocyanic acid at higher temperatures, the calculation indicates that the ratio of the partial pressures (in atmospheres) of the gases in equilibrium should have the following values:—

Temperature	$\frac{P_{NH_3}}{P_{HCN} \times P_{H_2}}$
500°	632
800°	0.27
1100°	0.003
1400°	0.0002

In the experiments tabulated above, the final mixture of gases usually contained nearly 95 p.c. of hydrogen, the partial pressure of which was therefore almost 1 atmosphere. The molecular ratio of ammonia to hydrocyanic acid is, therefore, almost the same as the ratio of the partial pressures. A comparison of the experimental values with those calculated shows that equilibrium is never even approximately attained. They agree in indicating 700° as the lowest temperature at which appreciable quantities of hydrocyanic acid can be formed.

This reaction has been discussed at some length, because there can be little doubt that the hydrocyanic acid in coal gas is formed by it.

That nitrogen and acetylene form hydrocyanic acid, $C_2H_2 + N_2 = 2HCN$, was discovered by Berthelot (Compt. rend. 67, 1141, 1868). He passed strong sparks from an induction coil through a mixture of acetylene, nitrogen, and hydrogen, the latter being added to prevent the decomposition of acetylene, and found that hydrocyanic acid was formed. He also showed that the reaction is reversible, a mixture of hydrocyanic acid and hydrogen, when sparked, yielding acetylene and nitrogen. Since Berthelot had already discovered that acetylene is formed from carbon and hydrogen at the temperature of the electric arc, and also that hydrocarbons, in general, yield variable quantities of acetylene at high temperatures, it followed that hydrocyanic acid must be formed in the carbon arc in an atmosphere of hydrogen and nitrogen, and also when sparks are passed through mixtures of nitrogen and hydrocarbons.

Hutton and Smith (Eng. Pat. 23835, of 1906, and Trans. Amer. Electrochem. Soc. 13, 359, 1908) showed that the temperature of the arc is not necessary, hydrocyanic acid being formed when a carbon rod is heated in a mixture of hydrogen and nitrogen to 1700°; and H. v. Wartenberg (Zeitsch. anorg. Chem. 52, 299, 1907) carried out quantitative measurements with the following results (using a mixture of equal volumes of hydrogen and nitrogen):—

Temperature	P.c. HCN in the gas in equilibrium
1635°	1.95
1752°	3.10
1875°	4.70

Wallis (Annalen, 1906, 345, 353), by passing the same mixture through the electric arc at varying rates obtained a maximum of 33.5 p.c. of HCN in the gas. The estimated temperature of the arc is about 3250°.

Several modifications of this synthesis have been investigated, in which the carbon is derived from hydrocarbons or carbon monoxide and the nitrogen from ammonia, but none of them has attained any practical importance.

The oxidation of organic compounds by nitric acid often yields hydrocyanic acid in greater or smaller amount, and it has been proposed to manufacture hydrocyanic acid in this way. The interesting reaction described by Hunting-

don (Eng. Pat. 14855, 1895) may be mentioned here. A mixture of acetylene and nitric oxide is readily exploded by a spark, yielding very considerable quantities of hydrocyanic acid in accordance with the equation

When ammonium formate is distilled, water is first given off together with a little ammonia and formic acid; at 180° formamide begins to distil over, and, as the temperature gradually rises to 220°, this is accompanied by increasing quantities of carbon monoxide, but only traces of hydrocyanic acid are produced. In order to obtain a good yield of hydrocyanic acid, the vapour must be heated to much higher temperatures, and the result is greatly influenced by the nature of the substance with which it is in contact. According to unpublished experiments by the writer, the principal changes which occur are:—

The ammonia and hydrocyanic acid in the product usually accounted for more than 95 p.c. of the nitrogen in the ammonium formate or formamide used. Under similar conditions, the yield of hydrocyanic acid obtained from formamide is much greater than that obtained from ammonium formate. For each contact substance there is a certain temperature at which the yield is a maximum. The following table contains the best temperatures and corresponding yields for several contact substances:—

Contact substance	Ammonium formate		Formamide	
	Yield of HCN p.c. of theoretical	Temperature	Yield of HCN p.c. of theoretical	Temperature
Porcelain chips	41.5	700°	75	800°
Copper gauze	43.0	just below 500°	78	600°
Iron wire	39.0	just below 500°	—	—
Charcoal	21.0	420°	55	400°

With finely divided nickel, no hydrocyanic acid was obtained in any circumstances; at 273°, 92½ p.c. of the nitrogen was recovered as ammonia, but much less at higher temperatures.

Ammonia and carbon monoxide were said to yield hydrocyanic when passed over heated spongy platinum (Kuhlmann, Annalen, 38, 62, 1841), $CO + NH_3 = HCN + H_2O$, and this apparently simple reaction has attracted several inventors. A careful investigation by Jackson and Laurie (Chem. Soc. Trans. 1905, 87, 433) has shown that a dry mixture of the two gases, when sparked, treated by the silent discharge or heated in presence of platinum (an electrically heated spiral of platinum wire gives the best result) yields ammonium cyanate thus:

and Kuhlmann's reaction does not take place.

The reverse change, $\text{HCN} + \text{H}_2\text{O} = \text{CO} + \text{NH}_3$, however, does occur very readily, even at 200° , when a mixture of steam and hydrocyanic acid is passed over broken brick as contact material, and at 600° it is practically quantitative. With iron oxide as contact substance, the conversion into ammonia is complete at 285° , and with Weldon mud at 200° (Carpenter and Linder, J. Soc. Chem. Ind. 24, 63, 1905).

Properties of hydrocyanic acid.—A colourless liquid possessing a characteristic smell (or rather taste), which produces a choking sensation in the larynx. It is one of the most poisonous substances known. Dogs are killed by a dose of about $\frac{1}{10000}$ part of the weight of their blood; the fatal dose for a man is about 0.05 gram. The poisonous properties of the cyanides are probably due to the liberation of hydrocyanic acid by the acids of the stomach. The simplest and most effective antidote is prepared by mixing solutions of ferrous sulphate and sodium carbonate (suitable quantities are 50 c.c. each of solutions containing 150 grams of $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ and 57 grams of Na_2CO_3 per litre). Stimulants, such as ammonia, are also helpful. The writer has seen a dog, which had swallowed some potassium cyanide, and was already partially paralysed in its hind quarters, recover in a few seconds when dosed with the above mixture which had been made up hastily from ferrous ammonium sulphate. Subcutaneous injection of hydrogen peroxide, which converts hydrocyanic acid into oxamide, has also been recommended.

The sp.gr. of the liquid acid is 0.7058 at 7° and 0.6969 at 18° (Gay-Lussac). Freezing-point, -15° (Gay-Lussac), -13.4° (Tammann). The freezing-point is raised by pressure; it is -2.88° under 500 kilos. per sq. cm., and $+50.1^\circ$ under 4000 kilos. per sq. cm. pressure. The boiling-point under atmospheric pressure is 26.5° , and the vapour pressure is $\frac{1}{2}$ atmo. at 4.5° (Gay-Lussac). The heat of evaporation is exceptionally large, 210.7 cal. per gram. The acid is miscible with water, ether, and alcohol in all proportions, almost insoluble in light petroleum. It is one of the weakest acids; its dissociation constant at 18° , 1.3×10^{-9} , is 44 times smaller than that of sulphuretted hydrogen, and 230 times smaller than that of carbonic acid (Walker and Cormack, Chem. Soc. Trans. 77, 16, 1900). In a 0.1*N*-solution, only 0.011 p.c. of the acid is dissociated into its ions, consequently it does not behave as an acid to indicators, and its salts are more or less completely decomposed by water; thus for example, $\text{KCN} + \text{H}_2\text{O} \rightleftharpoons \text{KOH} + \text{HCN}$. In 0.1*N*-solutions of the sodium or potassium salts, 1.1 p.c. is dissociated in this way; in *N*-solutions, only 0.3 p.c. at 24.2° (Shields, Zeitsch. physikal. Chem. 12, 167, 1893). This is of importance when it is required to concentrate an aqueous solution of a cyanide; the free hydrocyanic acid escapes until sufficient excess of the base has accumulated to reduce the hydrolysis to negligible proportions. In the case of weaker bases, the result is a considerable loss of hydrocyanic acid; with calcium cyanide, for example, the quantity of lime formed is greater than can be retained in solution, consequently equilibrium is never attained, and when such a solution is evaporated, the whole of the hydrocyanic acid escapes, leaving a residue of pure lime.

All the soluble cyanides are dissociated

electrolytically in aqueous solution, except the mercury salt, which, as already mentioned, exists almost wholly in the form of undissociated molecules. Cyanogen ion has a great tendency to form complex anions by uniting with neutral molecules, the most important of these are $\text{Ag}(\text{CN})_2^-$, $\text{Au}(\text{CN})_2^-$, $\text{Fe}(\text{CN})_6^{4-}$ and $\text{Fe}(\text{CN})_6^{3-}$.

Cyanogen (Ger. *Cyan*) C_2N_2 was discovered by Gay-Lussac. It is prepared by heating perfectly dry mercuric cyanide at a dull red heat, $\text{Hg}(\text{CN})_2 = \text{Hg} + \text{C}_2\text{N}_2$. A part of the cyanogen is always polymerised to dark-brown, non-volatile paracyanogen. Cyanogen itself is a gas which burns with a peach-blossom-coloured flame. Liquid cyanogen boils at -20.7° under atmospheric pressure and freezes at -34.4° . Its heat of formation from graphite and nitrogen is $-70,000$ cal. per molecule. Water dissolves 4.95 times its volume of the gas at 0° . At 18° the dissolved cyanogen is hydrolysed to hydrocyanic and cyanic acids, the latter yielding ammonia and carbon dioxide so that no definite solubility is observed (Naumann, Zeitsch. Elektrochem. 16, 772, 1910). After some time the solution deposits dark brown azulmic acid and contains also oxalic acid and urea. Cyanogen dissolves in caustic alkalis, yielding cyanide and cyanate: $2\text{KOH} + \text{C}_2\text{N}_2 = \text{KCNO} + \text{KCN} + \text{H}_2\text{O}$. Silver nitrate solution has no action on it; by means of these two reactions, it may be separated from hydrocyanic acid and estimated quantitatively in mixtures of the two gases (Wallis, Annalen, 345, 353, 1906). Cyanogen is very poisonous.

A knowledge of the exact conditions under which cyanogen can be formed from its elements is of interest in the theory of several technical processes for the manufacture of cyanides.

Wallis (Annalen, 345, 353, 1906) has shown that the electric arc burning between electrodes of very pure carbon in an atmosphere of nitrogen, produces no cyanogen at all. H. v. Wartenberg (Zeitsch. anorg. Chem. 52, 299, 1907) pointed out, however, that a very intense cyanogen spectrum is seen, and that carbon is deposited at some distance from the arc. Nernst's theorem indicates that very considerable quantities of cyanogen should exist in equilibrium with carbon and nitrogen at the temperature of the arc:

Temperature	Per cent. C_2N_2 in the gas calculated from Nernst's theorem
2000°	0.01
2500°	0.9
3000°	17.0
3250°	45.0

The probable explanation is that cyanogen is essentially unstable at low temperatures; that it can exist at all is due to an excessively slow rate of decomposition. Berthelot (Forces des Matières Explosives, Paris, 1883, 113) has shown that it can be detonated by mercury fulminate, and, when heated, its rate of decomposition becomes measurable at 1200° . v. Wartenberg supposes, therefore, that cyanogen is really formed at the high temperature, but that it decomposes again completely before it can cool to temperatures at which it can continue to exist. It is obvious from the figures given above that the direct union of carbon and nitrogen to cyanogen can play no part in the formation of cyanides in processes which are carried out at ordinary furnace temperatures.

Potassium and sodium cyanides. The methods of manufacture of these salts are most conveniently described together, since most of the processes used may equally well be applied in making either salt. The most important technical processes have already been mentioned in the introduction to this article.

Manufacture from yellow prussiate.—Potassium cyanide was first prepared by Berzelius's method, which consists in heating dry potassium ferrocyanide to redness, when it decomposes thus: $K_4Fe(CN)_6 = 4KCN + Fe + 2C + N_2$. The loss of cyanogen, which occurs in this way, is partly avoided by fusing the ferrocyanide with potassium carbonate, as first described by F. and E. Rodgers (Phil. Mag. 1834, [3] 4, 91). Liebig showed that the product contains cyanate, formed thus:

$$K_4Fe(CN)_6 + K_2CO_3 = 5KCN + KCNO + Fe + CO_2$$

The fused salt is allowed to stand until the iron and carbon have settled out, and is then poured off into moulds. The comparatively small quantities of cyanide, which were used in electroplating and for other purposes up to about 1890, were made by this process. The product was sold in white, porcelain-like cakes, containing from 30 to 70 p.c. of KCN.

In 1876, E. Erlenmeyer (Ber. 1876, 9, 1840) pointed out that a very pure product, containing on the average 40 p.c. of CN (equivalent to 100 p.c. KCN), was obtained by fusing dry prussiate with metallic sodium in the proportions required by the equation

This process was taken up first by the Deutsche Gold and Silber Scheide-Anstalt (F. Roessler, V. Inter. Kongress für Angewandte Chemie, Berlin, 1903, 1, 638) in Frankfurt-on-Maine, in 1890; they obtained a practically quantitative yield by filtering off the spongy iron from the fused cyanide and pressing the iron while red hot. The cyanide so obtained is cast in cakes and forms a pure white crystalline mass. Since about 1905, sodium ferrocyanide has been used in this process in place of the potassium salt, and the product now made is almost pure sodium cyanide. The excess of the gas works cyanogen over that required in the colour industries is converted into sodium cyanide in this way.

The processes of Siepermann and Beilby were the first synthetic processes to produce cyanide in large quantities; they are most conveniently considered together because, although they differ widely in the methods adopted in carrying them out, they are both based on the same chemical reaction which, curiously enough, was also used by Scheele in the first synthesis of a cyanide which was ever made.

In Siepermann's process (D. R. P. 38012, March 10, 1886; Eng. Pat. 13697 of 1889; 9350 and 9351 of 1900) a dry mixture of about 2 parts of charcoal and 1 part of potassium carbonate—that is, a sufficient excess of charcoal to keep the mixture in the form of a dry unfused mass throughout the process—is heated in the upper part of a vertical iron tube to a dark-red heat and treated with dry ammonia gas, which is taken up, forming potassium cyanate. The product is then allowed to fall into the lower end of the tube, which is heated to bright redness. At the higher temperature the cyanate

is converted into cyanide, the carbon monoxide evolved escaping through the upper part of the tube along with the hydrogen formed from the ammonia, without taking any part in the reaction. The finished material is drawn off into air-tight receptacles where it is allowed to cool completely, after which it is systematically lixiviated with water. Potassium cyanide may be precipitated from the solution obtained (sp.gr. about 1.4) by adding excess of potassium carbonate, but according to the later patents it is preferable to evaporate it almost to dryness and extract the unchanged potassium carbonate with small quantities of water at 66°. The residue of potassium cyanide and cyanate is then treated with water between -18° and +5°, which dissolves the cyanide and any residue of carbonate, leaving almost pure potassium cyanate. The product of this process was first put on the market in 1892 (G. Beilby, V. Int. Kongress angew. Chem. Berlin, 1903, 1, 630), but as the substance was in the form of a damp deliquescent mass, it could not be exported for use at the mines by itself but had to be fused with the product of the ferrocyanide process.

In the Beilby process (Eng. Pat. 4820, of 1891), which began to produce in the same year, the quantity of charcoal used is very much smaller, very little more being employed than is necessary to convert the potassium carbonate into cyanide thus:

The charcoal is added gradually during the progress of the operation, so that the material is always in the form of a fused liquid through which the ammonia gas is forced under some pressure. This is continued until a sample shows the conversion to be sufficiently complete; it is then only necessary to separate the small excess of charcoal by filtration in order to have a pure white saleable product. Since the melting-point of pure potassium carbonate (890°) is inconveniently high, previously made cyanide was mixed with it in starting the process, or the more readily fusible mixture of sodium and potassium carbonates was used, so that the cyanide made by the process was very similar in composition to that produced by the Erlenmeyer process from potassium ferrocyanide.

It is difficult to obtain a satisfactory yield on the ammonia in these processes, owing to the rapidity with which it decomposes into its elements at temperatures above 500° and in contact with metals, especially iron (Ramsay and Young, Chem. Soc. Trans. 1884, 88; Beilby and Henderson, *ibid.* 1901, 1245). For this reason it is necessary to work at the lowest possible temperature. Siepermann, for example, obtained a yield of 86 p.c. on the ammonia when it was absorbed at a dark-red heat, but only 58 p.c. at a bright cherry-red heat. Readman (J. Soc. Chem. Ind. 8, 757, 1889) showed that almost theoretical efficiencies can be obtained at the low temperatures attainable in an ordinary organic combustion furnace; whilst Conroy (*ibid.* 15, 12, 1896), working at very high temperatures (1000°–1200°), could not get more than 30 to 33 p.c. of the ammonia in the form of cyanide.

The chemistry of the reaction has been investigated by J. Pflieger (F. Roessler, V. Int.

Kongress angew. Chem. Berlin, 1903, 1, 638). Ammonia and potassium carbonate react, yielding potassium cyanate and hydroxide, a carbamate being most probably formed as an intermediate product:

When pure potassium cyanate is heated at 800°–900°, it decomposes, cyanide and carbonate being formed and nitrogen, carbon dioxide, and carbon monoxide evolved. The mechanism of this change is probably as follows: Drechsel has observed that the cyanates of the alkaline earth metals decompose, when heated, into carbon dioxide and the corresponding cyanamide salts. Assuming that the alkali cyanates behave similarly, the first change will be

Potassium cyanamide, however, decomposes completely at lower temperatures than 800° into cyanide, potassium, and nitrogen:

The carbonate and carbon monoxide observed are thus due to the reaction between the metallic potassium and carbon dioxide which are formed simultaneously. In presence of charcoal in excess, the greater part of the cyanamide follows Drechsel's reaction (J. pr. Chem. 1880[2] 21, 77), $\text{K}_2\text{CN}_2 + \text{C} = 2\text{KCN}$ instead of decomposing; so that the apparent reduction of cyanate by carbon probably takes place in the two stages:

The reactions occurring in the Beilby process are the same, except that, the whole process being carried on at the higher temperature, the formation of cyanate and its conversion into cyanide take place simultaneously instead of being more or less sharply separated as they are in Siepermann's process.

In the Siepermann process, it is easier to use the ammonia efficiently, owing to the lower temperature employed, but this is counterbalanced by the greater difficulty of working up the product into a marketable form.

The Castner process.—In 1894 H. Y. Castner (Eng. Pat. 12219, of 1894) patented a process in which sodium was fed in at the upper end of a column of red-hot charcoal through which a current of dry ammonia gas was passed from below, the reaction being expressed by the simple equation:

In a second patent (H. Y. Castner, Eng. Pat. 21732, 1894) it is shown that better results are obtained by first allowing the sodium and ammonia to react at a low temperature (300° to 400°), forming sodium amide NaNH_2 , and then running the amide on to an excess of red-hot charcoal with which it reacts thus:

Working in this way, it happened on one occasion that an excess of amide was accidentally run into the vessel containing the charcoal, and a product of unusual appearance was obtained, in which the writer found a large quantity of sodium cyanamide. The reaction,

therefore, takes place in three stages, in which the nitrogen enters successively into more and more stable combinations. First sodium amide is produced, a compound which begins to decompose rapidly into its elements at 500° (Titherley, Chem. Soc. Trans. 1894, 504); this reacts either with carbon

or, as Pfeleger found, with sodium cyanide

forming sodium cyanamide, a compound which only decomposes slowly at 600°, and finally this takes up carbon, forming sodium cyanide which is quite stable at any temperature attained in the process.

Like the Beilby process, this process yields a fused product containing very small quantities of solid impurities which are easily removed by filtration. After being cast in iron moulds, the cyanide is obtained in the form of pure white cakes with crystalline fracture, containing 97½ to 98 p.c. of NaCN (equivalent to 129–130 p.c. of KCN).

'Schlempe' process.—The juice of the sugar beet contains both inorganic and organic substances other than sugar, and these substances accumulate in the molasses. In Germany, rather more than half of the molasses made are treated with strontia, which combines with the sugar to an insoluble sucrate; the residue left after removing this, the concentrated essence of the impurities of the original juice, is known as 'schlempe.' After concentration to sp. gr. 1.4, it contains 75 p.c. of dry substances, 30 p.c. of which are inorganic (mainly potassium) salts and the remainder organic substances. The 'schlempe' contains about 4 p.c. of nitrogen in the form of betaine

and decomposition products of the vegetable proteins. Of the molasses not treated by the strontia process, a large part is consumed as cattle food and a small part fermented to alcohol.

The first attempt to utilize the nitrogen of 'schlempe' was made by Vincent in 1877–1880. He distilled the 'schlempe' in horizontal iron retorts at a red heat, ammonia, a mixture of methylamines, methyl alcohol, and combustible gases were evolved, and potassium carbonate mixed with some carbon remained behind (H. Ost, Zeitsch. angew. Chem. 19, 609, 1906). In 1879 Ortlieb and Müller devised a process for converting Vincent's methylamines into hydrocyanic acid, which was worked by the Société Anonyme de Croix (Eng. Pat. 3844, of 1879). The vapour of the methylamines was passed through a red-hot retort, yielding ammonia, hydrocyanic acid, methane and hydrogen. The ammonia was absorbed by sulphuric acid, and the hydrocyanic acid by a suspension of ferrous hydroxide in caustic potash. The manufacture of the methylamines was abandoned in 1881 for want of a market, and with it the production of cyanides.

The problem was again attacked by Bueb (Reichardt and Bueb, Eng. Pat. 1717, of 1895; Bueb, Eng. Pat. 26259, of 1898). Instead of separating the products of distillation of the 'schlempe,' he passed them directly, after condensing some tar, into a series of firebrick

channels which were heated to bright redness. The ammonia and hydrocyanic acid were absorbed together in a solution of ferrous sulphate, and the product worked up in the way described on p. 185. The narrow flues were soon stopped up by deposits of carbon, so that they were replaced by chambers filled with fire-brick checker-work, which is heated up to 1000° by firing directly with producer gas; during this process, the deposit of carbon is burned. Two such chambers are used alternately, the one being heated up whilst the gases from the retorts are passing through the other. The gases leaving the decomposing chambers contain 7 p.c. HCN; 7 p.c. NH₃; 8 p.c. (mainly) CH₄; 12 p.c. H₂; 18 p.c. CO; 24 p.c. CO₂, and 24 p.c. N₂. In passing through the decomposing chamber, the methylamines disappear and hydrocyanic acid is formed, the ammonia undergoing but little change. The ammonia is now removed from the gas by absorption in sulphuric acid, and the hydrocyanic acid absorbed in caustic soda, but the exact method employed to separate it from the large quantity of carbon dioxide which accompanies it has never been published. The solution of sodium cyanide is evaporated to crystallisation, the crystals dried, and briquetted by compressing them into blocks which are dried at 70° *in vacuo* (Eng. Pat. 18096, of 1907), and then contain sodium cyanide equivalent to 120 p.c. of KCN.

Of the nitrogen in the 'schlempe,' about one-half is converted into nitrogen gas and so lost; a quarter is obtained as sodium cyanide and the remainder as ammonium sulphate.

The decomposition of di- and tri-methylamine, when passed through a heated porcelain tube filled with fragments of porcelain, fire-brick, or charcoal, has been studied by Voerkelius (Dissertation, Hannover, 1909). At temperatures lying between 800° and 1000°, as much as 98 p.c. of the trimethylamine decomposes into hydrocyanic acid and methane $N(CH_3)_3 = HCN + 2CH_4$, the remaining 2 p.c. yielding ammonia $N(CH_3)_3 + 3H_2 = NH_3 + 3CH_4$. This result was obtained when the gaseous contents of the tube were changed once in 7½ seconds; with a slower current of gas and also with a contact material of large surface (fireclay or charcoal) or with iron, a part of the hydrocyanic acid is decomposed into its elements. The rate of decomposition at 1000°, however, is small. At 720° the yield of hydrocyanic acid was only 78 p.c., and at 600° none was produced.

The formation of hydrocyanic acid from dimethylamine also begins between 600° and 700°, from 800° to 1100° the change takes place quantitatively in accordance with the equation $NH(CH_3)_2 = HCN + CH_4 + H_2$. If hydrogen is present, however, a second change occurs, $NH(CH_3)_2 + 2H_2 = NH_3 + 2CH_4$. Using equal volumes of hydrogen and dimethylamine, this reaction is of no importance, but as the hydrogen present increases more and more of the dimethylamine is converted into ammonia until, with a mixture of 97 parts of hydrogen to 3 parts of dimethylamine, ammonia is the sole product.

The behaviour of monomethylamine is probably analogous to that of dimethylamine. Wurtz found that considerable quantities of ammonia are formed by its decomposition.

In practice, therefore, the losses of hydro-

cyanic acid and ammonia by decomposition will depend on the rate of passage of the gases and on the nature of the contact material—the deposit of carbon on the porous bricks diminishing the decomposition of hydrocyanic acid.

Cyanides direct from sulphocyanides. Several processes for the direct conversion of sulphocyanides into cyanides, without passing through ferrocyanide, have been carried out on a manufacturing scale, although they have not been able to take a leading place in the production of cyanide.

The earliest of these was D. J. Playfair's process (Eng. Pat. 7764 of 1890). Playfair found that certain metals, lead and zinc especially, when fused with potassium sulphocyanide, abstract the sulphur, leaving potassium cyanide, which may be separated from the metallic sulphide by extraction with water. The fusion is carried out at 400°, and 70–80 p.c. of the sulphocyanide is converted into cyanide (D. J. Playfair, J. Soc. Chem. Ind. 11, 14, 1892; Conroy, *ibid.* 15, 8, 1896). The reaction is slower with lead, owing to the small surface offered by the fused metal, whilst with zinc the product is apt to be contaminated by the double cyanide of zinc and potassium. The process was worked about 1894 by the British Cyanides Co. at Oldbury (Brussels Exhib. 1910, Catalogue of British Chem. Section, p. 63).

Raschen's process (Eng. Pats. 10476, 10956 and 21678 of 1895; 19767 of 1898; 12180 of 1900) is based on the oxidation of sulphocyanic acid to hydrocyanic and sulphuric acids which was first observed by E. A. Hadow (Annalen, 1858, 108, 380). Hadow found that permanganate, lead peroxide, manganese dioxide, and nitric acid bring about the same reaction. Raschen found that it takes place quantitatively in acid solutions only when an excess of the oxidising agent is present. If the oxidising agent is added to the sulphocyanide, solid yellow compounds are produced of variable composition, one of which, 'canarin' (*q.v.*), has been used as a yellow dye.

The Raschen process (J. T. Conroy, J. Soc. Chem. Ind. 1899, 18, 432) was carried out by allowing a solution containing about 15 p.c. of sodium sulphocyanide to flow into dilute nitric acid kept at the boiling-point by means of live steam. The reaction:

took place. From 3 to 5 p.c. of the nitric acid was less completely reduced, N₂O₃ being formed, so that the gases leaving the decomposer were first scrubbed with a little water. The resulting solution of nitric, nitrous, and hydrocyanic acids was returned to the decomposer. The gas, which now contained about 1 volume of hydrocyanic acid to 2 volumes of nitric oxide, was passed through a solution of caustic soda (sp.gr. 1.37), which absorbed the hydrocyanic acid. It was found necessary to avoid saturating this solution completely with hydrocyanic acid because of the brown decomposition products which are formed from the free acid in presence of a cyanide. The nitric oxide was then mixed with air and passed upwards through towers packed with flints down which water trickled; in this way it was reconverted into nitric acid (sp.gr. 1.12) which was returned to the decomposer. The solution of

sodium cyanide was evaporated to dryness in vacuum pans without appreciable loss.

The reduction of sulphocyanides by hydrogen was studied by Playfair (J. Soc. Chem. Ind. 11, 14, 1892). He found that hydrogen acts on potassium sulphocyanide at a dull-red heat, forming potassium cyanide and sulphide and sulphuretted hydrogen.

Conroy, Heslop, and Shores (J. Soc. Chem. Ind. 1901, 20, 320) showed that the reaction takes place slowly at 500°, and fairly fast at 600°. Their results indicate that two reactions occur simultaneously:

and

A little ammonia is also evolved, probably owing to the difficulty of drying the sulphocyanide completely. About 70 p.c. of the nitrogen is obtained in the form of cyanide and 20 p.c. as hydrocyanic acid. With barium and cuprous sulphocyanides, the reaction is similar to that represented by the second of the above equations, the principal nitrogenous product being hydrocyanic acid. With the cuprous salt, the reaction begins below 300°.

Rossiter, Crowther, and Albright (Eng. Pat. 4403 and 6226, of 1901) have patented a process based on the behaviour of the cuprous salt. It is mixed with finely divided copper and heated at temperatures rising from 150° to 650° in a current of hydrogen. Hydrocyanic acid is evolved and cuprous sulphide remains behind.

Production of cyanides from atmospheric nitrogen. In every process at present used for the manufacture of cyanides, the nitrogen is derived from coal more or less directly. The production of cyanides from atmospheric nitrogen is a problem on which both money and chemical and engineering skill have been lavished without leading to any financially successful solution. An account of the cyanide industry would be incomplete without some description of these very interesting and instructive experiments.

The reaction of potassium cyanide by the action of nitrogen on carbon and potassium carbonate, was observed by Desfosse (Ann. Chim. Phys. 1828, 38, 158), but the quantities formed either in laboratory experiments or in the blast furnace were so small compared with the quantities of materials used, that even as late as 1842 the source of the nitrogen in the cyanide was doubtful, some chemists holding that it was derived from the coal or charcoal employed. The first industrial application of the reaction was made by Possoz and Boissière (Eng. Pat. 9985, of 1843). Their process was worked by the inventors at Grenelle in France, in 1843, and from 1844 to 1847 at the works of Bramwell & Co. in Newcastle-on-Tyne. An account of these very interesting experiments was given by F. R. Hughes (Graham, Reports of Juries, Exhib. of 1851, 1, 95), who was concerned in carrying them out.

Wood charcoal was soaked in a solution of ordinary potash and dried; this yielded a mixture containing about 20 p.c. of K_2O . This was at first heated in vertical fireclay retorts of small diameter, which were fired externally. Owing to the bad conductivity of the retort and of the charcoal, the heat penetrated the mass

very slowly, and the output of a tube was very small. After a number of alterations, retorts were adopted which were built of ordinary firebricks: they were 2 feet in internal diameter, and were heated to a temperature sufficient to produce cyanide for a length of 6 to 8 feet. In an upper prolongation, the wet charcoal was dried and preheated, and in a lower, unheated extension, made of cast iron, the product was cooled down and then discharged, by means of an arrangement which permitted a periodical withdrawal of a part of the charge, into a solution of a ferrous salt, into which the lower end of the cast-iron tube dipped. A ring of small slots was left in the brick retort at every third or fourth course of bricks, through which the hot mixture of nitrogen and carbon dioxide in the furnace was drawn into the retort. In this way the difficulty of heating the mass to its centre was overcome. The highest temperature in the furnace was sufficient to soften a Stourbridge fireclay brick throughout its substance. The hot gases passed upwards through the retort, drying and preheating the fresh charge in its upper part. As much as one-half of the alkali in the cyanised charcoal produced was found to be in the form of cyanide, and 7 or 8 retorts of the dimensions given yielded 36 to 40 cwts. of prussiate of potash per week, under favourable circumstances. About one-half of the charcoal used was consumed, and three parts of potash were used for one part of prussiate made. About one-third of the potash was accounted for by the prussiate; one-third remained in the refuse charcoal, which could not be profitably lixiviated; and the remainder combined with the bricks of the retort or volatilised up the chimney. The financial failure of the process was due to the losses of potash and to the short life of the retorts.

Hughes suggested that potassium carbide may be the first product, and that the cyanide may be produced by its combination with nitrogen, an explanation of the process which was also given by Berthelot 17 years later. Although this process has attracted many subsequent inventors, no success has attended their efforts. The difficulties due to the high temperature required appear to be insuperable. Bunsen and Lyon Playfair (British Assoc. Reports, 1845, 185) showed, in 1845, that cyanide is only formed at temperatures sufficient for the production of metallic potassium. A few temperature measurements which the writer made with a platinum-rhodium thermocouple showed that potassium vapour is first evolved from a mixture of charcoal and potassium carbonate at about 1350°, and that the formation of cyanide takes place very slowly at this temperature, the potassium cyanide volatilising for the most part.

In 1860 Margueritte and De Sourdeval (Eng. Pat. 1171, of 1860) discovered that a mixture of barium oxide and carbon absorbs nitrogen at a much lower temperature than that required when potash is used. Ludwig Mond (Eng. Pat. 433, of 1882; J. Soc. Chem. Ind. 1889, 8, 505) experimented with this process in 1882. He found that a temperature of 1200° was required for the formation of cyanide, and that the reaction goes best about 1400°. The barium compounds fuse readily at these temperatures

and attack the fireclay retorts. To avoid this he briquetted them with an excess of carbon and pitch. The apparatus used was similar to that of Possoz and Boissière, and 40 p.c. of the barium used was readily cyanised. The object of Mond's experiments was the production of ammonia, and he abandoned this process in favour of the more promising method of acting on coal with air and steam in large excess (see AMMONIA).

In 1894 J. B. Readman (Eng. Pat. 6621, 1894) made a very considerable step in advance by introducing electrical heating. His process was worked by the Scottish Cyanides Co. at Leven in Fifeshire, between the years 1899 and 1907. Considerable quantities of sodium cyanide of excellent quality were produced, but the financial results were unfavourable. The following account of the process in its final form is believed to be substantially accurate.

Barium carbonate, produced in a later stage of the process, was intimately mixed with ground coal to a thick paste, which was dried and coked in ordinary gas retorts. The granular mixture of barium oxide and coke so produced was then fed into an electric furnace, consisting of a vertical shaft of magnesia bricks. A ring of carbon blocks in the wall of the shaft near its lower end formed one electrode, a carbon cylinder suspended in the mouth of the shaft formed the other. The alternating current passed between these electrodes through the granular mass of coke and barium oxide, heating it to a high temperature. A current of producer gas with about 70 p.c. of nitrogen, passed upwards through the mass, which was constantly fed downwards into a cooling chamber by means of a plate and rotating arm which closed the lower end of the shaft. The cooled product was lixiviated with water, and the resulting solution, containing barium cyanide and hydroxide, treated with sodium bicarbonate. After filtering off the barium carbonate, the solution of sodium cyanide was concentrated *in vacuo* and then passed over cooling coils depositing crystals of the hydrate $\text{NaCN}\cdot 2\text{H}_2\text{O}$. These were separated from the mother liquor in a centrifugal machine, and then dehydrated by heat and the powder briquetted.

The chemistry of this process is far from simple. Barium carbonate itself (as Finkelstein (Ber. 1906, 39, 1585) has shown) does not melt at 1350°, but when heated alone or with carbon, it is partially converted into barium oxide, which yields readily fusible mixtures with the carbonate. Le Chatelier found, for example, that partially decomposed barium carbonate melts at 795°. The fusibility of the mixtures is increased by the formation of barium cyanide (which melts about 600°), so that in practice the material undergoing treatment is a liquid mixture of the oxide, carbonate, and cyanide of barium absorbed in carbon. Nitrogen begins (Kühling and Berkhöld, Ber. 41, 28, 1908) to react with barium oxide and carbon at 925°, but the reaction is reversible (writer's unpublished experiments), and may be expressed by the equation $\text{BaO} + 3\text{C} + \text{N}_2 \rightleftharpoons \text{Ba}(\text{CN})_2 + \text{CO}$. The pressure of carbon monoxide required to decompose barium cyanide, diminishes rapidly as the concentration of the latter increases, reaching extremely small values at temperatures below

1200°, when some 40 p.c. of the barium has combined with nitrogen. For this reason, a moderately complete conversion of the barium oxide into cyanide can only be effected at low temperatures by using an enormous excess of pure nitrogen, which is fatal to the economy of the process. This difficulty is avoided by resorting to higher temperatures (1400° to 1500°), at which the fixation of nitrogen will proceed in presence of considerable quantities of carbon monoxide, so permitting the use of producer gas in place of pure nitrogen. Unfortunately, however, a large part of the nitrogen fixed at the higher temperatures is in the form of barium cyanamide, which, when treated with water, yields barium hydroxide and free cyanamide.

While Readman's process was being worked out, the problem was attacked in a different way by Frank and Caro (Eng. Pat. 15066, of 1895) and by T. L. Willson (Eng. Pat. 21997, of 1895), who discovered independently, in 1895, that the carbides of the alkaline earths combine with nitrogen. Frank and Caro at first attempted to apply their discovery to the manufacture of cyanides.

Finely ground barium carbide, made in the electric furnace, was heated at about 700° in presence of pure nitrogen. The product contained about 11 p.c. of nitrogen, 30 p.c. of which was in the form of barium cyanide, the remainder being barium cyanamide. In order to convert the cyanamide into cyanide, the material was heated with dry sodium carbonate and carbon. The sodium carbonate probably converts the barium cyanamide into the sodium salt, which then takes up carbon in the way discovered by Dreschel,

By extracting the product with water, converting the sodium cyanide into ferrocyanide, and then fusing it with sodium, about 86 p.c. of the nitrogen fixed was obtained in the form of marketable sodium cyanide (G. Erlwein, V. Int. Kongress angew. Chem. Berlin, 1903, 1, 646). The process, however, even in this form, did not pay, and the cheaper calcium carbide was therefore tried. Commercial calcium carbide absorbs nitrogen at about 1100°, yielding a product containing from 20 to 23.5 p.c. of nitrogen, which is wholly in the form of calcium cyanamide (Frank and Caro, Eng. Pat. 25476, of 1898), $\text{CaC}_2 + \text{N}_2 = \text{CaCN}_2 + \text{C}$. By heating this product with sodium chloride, from 90 to 95 p.c. of the cyanamide is converted into sodium cyanide. The hydrocyanic acid may be set free by means of an acid, and then absorbed in caustic soda solution (G. Erlwein, V. Int. Kongress angew. Chem. Berlin, 1903, 1, 646).

Cyanides from nitrides. At high temperatures, nitrogen combines directly with several elements to form nitrides, and these, when fused with sodium carbonate and carbon, produce sodium cyanide. This has been shown to be the case with the nitrides of boron, calcium, magnesium, titanium, silicon, and aluminium, and with phosphorus PNH_2 . Since none of these processes has emerged as yet from the experimental stage, it is sufficient to mention the possibility of producing cyanides in this way.

THE PRINCIPAL CYANIDES.

Potassium cyanide KCN crystallises in anhydrous, colourless octahedra from aqueous solutions, or in cubes when the fused salt solidifies; sp.gr. 1.52. It melts at a dull-red heat, and volatilises without decomposition at high temperatures. It is readily soluble in water; the saturated solution contains 122.2 grams of KCN to 100 grams of water at its boiling-point (103.3°). At 19.5°, 100 grams of absolute alcohol dissolve 0.88 gram (Landolt, Börnstein and Meyerhoffer, Tabellen, Berlin, 1905). It deliquesces in moist air.

Sodium cyanide NaCN crystallises from the fused liquid in apparently cubic crystals; from aqueous solutions below 35° large colourless plates of the hydrate NaCN.2H₂O are deposited. Joannis (Ann. Chim. Phys. 1882, [5] 26, 484) obtained a hydrate NaCN.3H₂O from cold 85 p.c. alcohol. F. Roessler (Eng. Pat. 279, 1899) showed that the hydrate NaCN.2H₂O decomposes at 33° (34.7° according to the writer's measurements) into the anhydrous salt and a saturated solution, about 40 p.c. of the sodium cyanide separating in the anhydrous state. The solubility of the hydrate (in grams of NaCN to 100 grams of water) is, 35.4 at -20°; 43.4 at 0°; 58.3 at 20° and 82 at 34.7°. The solubility of the anhydrous salt is almost independent of the temperature (82 grams per 100 grams of water). The sp.gr. of aqueous solutions of sodium cyanide at 25° is given by the expression $1 + 0.00534p$, where p is the percentage of NaCN. Sodium cyanide (96 p.c.) melts at 540°. The pure salt, when heated in a glass tube so as to be out of contact with metals, in a current of dry air free from carbon dioxide, remains entirely unchanged at temperatures up to 370°; if, however, it is in contact with iron or nickel, or if traces of the oxides of these metals are added to it, oxidation proceeds rapidly, cyanate and carbonate being formed and carbon dioxide evolved. The carbonate is formed by the oxidation of the cyanate, which is the primary product. Sodium cyanate behaves towards oxygen in exactly the same way as the cyanide; it is quite unaffected by dry air (free from CO₂) even at 400°, but when mixed with 1 p.c. of nickel oxide it oxidises rapidly; thus:

(writer's unpublished experiments).

Sodium cyanide absorbs moisture with great avidity from ordinary moist air. The writer has found that it takes up water from purified air saturated with aqueous vapour at 20° at all temperatures below 44°, but not at higher temperatures. This is of importance in sampling and analysing the salt.

Dilute solutions of potassium or sodium cyanide decompose very slowly in contact with the atmosphere, the loss being almost wholly due to absorption of carbon dioxide.

Liebig's statement that metallic iron is dissolved by solutions of potassium or sodium cyanide with evolution of hydrogen is true of the finely divided metal, but iron vessels may be used for years for boiling concentrated solutions of cyanides without requiring repair, and iron tanks are regularly used in the treatment of gold ores with cyanide solutions.

With the exceptions of lead and platinum, all

ordinary metals are dissolved by cyanide solutions in presence of oxygen.

Zinc is slowly dissolved without oxygen, but if a piece of zinc is half immersed in a cyanide solution, it is eaten through at the surface of the liquid before any appreciable action has taken place on the submerged portion.

Alkali cyanides yield ammonia and a formate when boiled with water or treated with strong sulphuric acid, in the latter case the formic acid produced is at once decomposed into carbon monoxide and water.

Mercuric cyanide Hg(CN)₂ was first prepared by Scheele, in 1782, by boiling Prussian blue with mercuric oxide, and, in 1783, by dissolving mercuric oxide in hydrocyanic acid and evaporating to crystallisation. He also found that mercurous salts, when treated with soluble cyanides, yield mercuric cyanide and metallic mercury. The decomposition of the ferrocyanides, as already mentioned (p. 187), depends on the extremely small electrolytic dissociation of mercuric cyanide in aqueous solution. For the same reason, it is not decomposed by caustic alkalis, and hydrocyanic acid can only be expelled from it by boiling with a strong acid. The concentration of the mercury ions is, however, sufficient to permit of the precipitation of the extremely insoluble mercuric sulphide by sulphuretted hydrogen.

Mercuric cyanide crystallises in anhydrous, colourless crystals of sp.gr. 4.0. The saturated solution contains 93 grams per litre at 20°, 111 grams per litre at 25°; 100 grams of absolute alcohol dissolve 10.1 grams of it at 19.5°, and 100 grams of absolute methyl alcohol take up 44.2 grams at 19.5°.

Small quantities of mercuric cyanide are sometimes used in addition to alkali cyanide in the treatment of ores containing silver sulphide (Clennel, Cyanide Handbook, London, 1910, 297), the dissolution of which is accelerated, probably owing to the formation of mercuric sulphide

Calcium cyanide has never been prepared. An aqueous solution of lime in hydrocyanic acid decomposes completely into its constituents when boiled (Scheele). By evaporating such a solution *in vacuo*, Joannis obtained a crystalline compound, 3CaO.Ca(CN)₂.15H₂O, which decomposed completely in a vacuum, leaving nothing but lime. Dry reactions, at high temperatures, yield calcium cyanamide, but no cyanide.

Barium cyanide Ba(CN)₂. When a concentrated solution, made by adding hydrocyanic acid to baryta in theoretical quantities, is evaporated *in vacuo*, crystals of the hydrate Ba(CN)₂.2H₂O are deposited (A. Joannis, Ann. Chim. Phys. [5] 26, 484, 1882). This is a very deliquescent substance which, when dried *in vacuo* over sulphuric acid, yields an amorphous monohydrate which can be completely dehydrated by heating it very gradually to 100° in a good vacuum. The writer has failed to obtain a pure product in this way. Some 7 or 8 p.c. of the hydrocyanic acid escapes during evaporation, and the product contains a corresponding quantity of barium hydroxide. By drying pure Ba(OH)₂.8H₂O in a good vacuum at 100°, a very finely divided powder of Ba(OH)₂ is obtained,

which is suspended in dry light petroleum and treated with a small excess of dry hydrocyanic acid also mixed with light petroleum. In this way, the solid hydrated barium cyanide is obtained without evaporation :

When dehydrated *in vacuo*, it still contains a little hydroxide, but by shaking it with a little hydrocyanic acid and light petroleum and again drying, practically pure anhydrous barium cyanide is fairly easily obtained.

By saturating a solution of baryta in methyl alcohol with hydrocyanic acid, a compound $\text{Ba(CN)(OCH}_3\text{)} + \text{CH}_3\text{OH}$ is obtained, which, when heated, first loses methyl alcohol and then methyl ether, leaving $\text{BaO} + \text{Ba(CN)}_2$ (Drechsel, J. pr. Chem. [2] 21, 77, 1880).

Dry methods of preparation yield mixtures of cyanide and cyanamide. When barium ferrocyanide is heated it begins to decompose about 500°, yielding a mixture of barium cyanide and cyanamide (with carbon and iron) in which nearly 60 p.c. of the nitrogen is in the form of cyanamide, practically the same product as that obtained by the action of nitrogen on barium carbide. Even the action of cyanogen on barium amalgam yields a mixture (Drechsel), the reason being that barium cyanide decomposes into barium cyanamide and carbon, thus; $\text{Ba(CN)}_2 = \text{BaCN}_2 + \text{C}$. The change is very slow at 500° to 600°, but it is accelerated by iron (writer's unpublished experiments).

Barium cyanide is colourless; 100 grams of cold water dissolve about 80 grams of it (Joannis). It melts about 600°. It is distinctly volatile, even at its melting-point, but when mixed with barium oxide it is much less so.

Silver cyanide AgCN . The precipitate obtained by adding excess of silver nitrate to a solution of potassium cyanide is probably the silver salt of the complex acid $\text{H[Ag(CN)}_2\text{]}$. The solubility of silver cyanide in pure water lies between those of the chloride and sulphocyanide, as the following table shows :—

	Solubility at 25° in gram-mols. per litre
AgI	0.01×10^{-6}
AgBr	0.81×10^{-6}
AgSCN	1.08×10^{-6}
AgCN	4.40×10^{-6}
AgCl	14.10×10^{-6}

It is hardly attacked by cold dilute nitric acid, but is decomposed quantitatively on boiling (Plimmer, Chem. Soc. Proc. 1903, 285). It is slightly soluble in a solution of hydrocyanic acid, forming the unstable acid HAg(CN)_2 . It dissolves very readily in alkali cyanides to salts such as KAg(CN)_3 , in which the silver is contained in the complex anion Ag(CN)_2^- . Owing to the excessively small dissociation of this anion, all silver salts except the sulphide are dissolved by cyanide solutions, and in presence of oxygen, metallic silver and the sulphide are also dissolved.

Gold cyanides. Aurous cyanide and the soluble aurocyanides are of technical importance. The former, AuCN , a yellow crystalline powder, insoluble in water and acids, is formed by the action of hydrocyanic acid on auric hydroxide. It is readily soluble in solutions of alkali or alkaline-earth cyanides,

yielding aurocyanides such as KAu(CN)_2 . A solution of the potassium salt, which is used for electroplating with gold, is readily obtained by precipitating a solution of gold chloride with ammonia and dissolving the fulminating gold in a solution of potassium cyanide, or by precipitating gold chloride with magnesia, dissolving out the excess of magnesia in the precipitate with nitric acid, and then dissolving the auric hydroxide in potassium cyanide as before.

Potassium aurocyanide is also formed when gold is dissolved in a solution of potassium cyanide in presence of oxygen or other oxidising agent :

The dissolution of metallic gold is primarily due to the great stability of the aurocyanogen ion Au(CN)_2^- . Metals, like all other substances, have a tendency to dissolve in water. In contact with its aqueous solution, a salt will dissolve if the solution is unsaturated, or crystallise out if it is supersaturated. Metals behave similarly, with the important difference that they dissolve in the form of positively charged ions, so that when a metal is placed in contact with a solution containing fewer of its ions than correspond with equilibrium, it gives out positively charged atoms, becoming itself negatively charged, until the electrical attraction stops further change, and *vice versa*. In this way, a definite potential difference always arises between a metal and a solution of it, the sign and magnitude of which depend on the nature of the metal and on the concentration of the positively charged ions of the metal in the solution.

In order for a metal to dissolve at all, therefore, it is necessary that the solution shall contain less than the saturation quantity of positive ions; and for the dissolution to continue, the positive charges of the ions and the negative charge of the metal must be got rid of in some way.

These conditions are fulfilled in the case of the dissolution of gold in a cyanide solution containing oxygen, because the dissociation of the complex ion, $\text{Au(CN)}_2^- \rightleftharpoons \text{Au} + 2\text{CN}^-$ is extremely small, and solutions of it therefore contain infinitesimal quantities of gold ion, and further the electrical charges produced by the dissolution of the gold are removed by the reactions :

The potential difference between a metal like zinc (which has a greater tendency to dissolve than gold) and a cyanide solution is much greater than the natural potential difference between gold and the solution; hence gold ions are drawn out of the solutions to the zinc, where their positive charges are neutralised by the negative change of the zinc. This disturbs the equilibrium between zinc and the solution and also between aurocyanogen ions and gold ions, causing fresh quantities of zinc to dissolve and of aurocyanogen ions to dissociate, processes

which continue until the whole of the gold is precipitated.

As W. Skey (Trans. and Proc. New Zealand Inst. 8, 334, 1876) first showed, gold in cyanide solutions is electro-positive to silver and silver to mercury, so that gold will precipitate silver and mercury for their solutions in cyanides. This has been confirmed by Bodländer (Ber. 1903, 36, 3933). This reversal of the usual order is, as will be understood from the above explanation, due to the increasing stability of the mercury, silver, and gold complex cyanogen ions.

It is of interest to note that most of the minerals which accompany gold in its ores are electro-negative to gold in cyanide solutions, and therefore accelerate its dissolution in the way which is familiar in the solution of zinc in sulphuric acid in presence of copper or platinum.

Copper cyanides. When potassium cyanide is added to the solution of a cupric salt, a brownish precipitate of cupric cyanide $\text{Cu}(\text{CN})_2$ is produced, which gradually evolves cyanogen, changing into green cupric cuprous cyanide. When heated, this loses a further quantity of cyanogen and yields white cuprous cyanide CuCN .

Cuprous cyanide is soluble in solutions of potassium cyanide, about $2\frac{1}{2}$ molecules of KCN being required to dissolve 1 molecule of CuCN ; the solutions contain the complex anions $\text{Cu}(\text{CN})_3^-$ and $\text{Cu}(\text{CN})_4^{2-}$ (Kunschert, Zeitsch. anorg. Chem. 41, 359, 1904). These anions are so little dissociated into copper ions that sulphuretted hydrogen will not produce a precipitate in the solutions, and therefore copper itself (in presence of oxygen) and all its compounds dissolve readily in cyanide solutions.

Zinc cyanide $\text{Zn}(\text{CN})_2$ is a white substance, insoluble in water, but soluble in acids and in cyanide solutions. It is not easily prepared in a perfectly pure condition, because water decomposes it partially. When dry it is very stable, decomposing only at a bright-red heat.

The complex salt potassium zinc cyanide $\text{K}_2\text{Zn}(\text{CN})_4$ crystallises in large well-formed octahedra from aqueous solutions; 100 grams of water at 20° dissolve 11 grams of it. It is anhydrous, and may be fused at a red heat without decomposition. The sodium salt $\text{NaZn}(\text{CN})_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$ is very readily soluble in water. The complex zinc cyanogen ions are much less stable than those containing copper, gold, silver, and mercury; a small excess of an alkali sulphide precipitates the zinc completely.

Cyanogen bromide CNBr . A solution containing cyanogen bromide in addition to a cyanide dissolves gold more rapidly than one containing cyanide alone (Sulman and Teed, Eng. Pat. 18592, of 1894; and J. Soc. Chem. Ind. 1897, 961). Cyanogen bromide is therefore used in the treatment of a few refractory ores, the West Australian tellurides especially. The final result of the reaction is expressed by the equation: $2\text{Au} + 3\text{KCN} + \text{BrCN} = 2\text{KAu}(\text{CN})_2 + \text{KBr}$.

Cyanogen bromide is formed by the action of bromine on a cyanide or on hydrocyanic acid. Owing to the difficulty of transporting either bromine or cyanogen bromide, it is always prepared at the place where it is to be used by liberating bromine from a mixture of a bromide and a suitable oxidising agent by the addition of

sulphuric acid, and then adding a concentrated solution of an alkali cyanide. By the use of a suitable quantity of the oxidising agent, the whole of the bromine is utilised; with sodium bromate, for example, the reaction is (C. Göpner, Zeitsch. angew. Chem. 1901, 14, 355):

Cyanogen bromide is a colourless, crystalline substance which melts at 52° and boils at 61° ; 100 grams of water dissolve from 5 to 6 grams of it at the ordinary temperature. It has an intensely irritating effect on the mucous membranes and eyes, and is said to be very poisonous. The perfectly pure substance can be kept without change, but traces of bromine (or hydrobromic acid) cause it to polymerise rapidly to cyanuric bromide, partial decomposition always occurring. It is very slowly decomposed by water: $\text{CNBr} + \text{H}_2\text{O} = \text{HCNO} + \text{HBr}$, the cyanic acid decomposing further to ammonia and carbon dioxide. Caustic alkalis bring about the same change instantaneously, alkali carbonates much more slowly, and bicarbonates have no action at all. Cyanogen bromide and potassium cyanide react in aqueous solution, yielding cyanogen; thus:

(private communication from Mr. C. J. Ellis). In solutions containing 0.2 to 0.8 p.c. of potassium cyanide and 0.1 to 0.2 p.c. of cyanogen bromide, the latter is completely decomposed in from 3 to 6 hours at the ordinary temperature.

Sulphocyanides or Thiocyanates. (Ger. *Rhodanide* or *Schwefelcyanide*.)

At the present time, sulphocyanides are obtained exclusively from the hydrocyanic acid of coal gas, but a modification of Gélis' synthetic process was working as recently as five years ago.

A. W. Hofmann (Reports by the Juries, Inter. Exhib. of 1862, 59-63), writing in 1862, said that ammonium sulphocyanide obtained by washing the spent oxide of gas works was only treated to recover its ammonia, the sulphocyanide being thrown away. In 1863 P. Spence (Eng. Pat. 2364, of 1863 (provisional only)) proposed to separate the sulphocyanides in gas liquor (after distilling off the ammonia) in the form of cuprous sulphocyanide by adding copper and ferrous sulphates, and the idea has been revived in various forms since that time, but it does not appear to have become of any importance. Gas liquor is really a very dilute solution of sulphocyanide, as the following figures, calculated from Linder's analyses of various English gas liquors (Chief Inspector of Alkali Works, 42nd Rep. 1905, 35), show:—

	Grams per litre				
	1	2	3	4	5
HCN as ferrocyanide	0.068	0	0.576	0.460	0
HCN as sulphocyanide	1.683	4.457	1.238	1.029	1.042
HCN as hydrocyanic acid	0.680	0	0.030	0.050	0.355

These liquors had all been stored for some time: perfectly fresh gas liquor contains ammonium sulphide and cyanide. By the action of the air, the former is oxidised to ammonium polysulphides, which convert the cyanide into sulphocyanide; thus:

The recovery of the whole of the hydrocyanic acid of coal gas in the form of a concentrated

solution of ammonium sulphocyanide is possible by applying this reaction in a suitable way. In 1877 W. Marriott (Eng. Pat. 3311, of 1877) proposed to scrub gas with a solution of sodium polysulphides, and in 1888 Campbell and Boyd (Eng. Pat. 10186, of 1888) proposed the use of manganese dioxide suspended in water. This liberates sulphur from a part of the sulphuretted hydrogen in the gas, and this free sulphur combines with ammonium sulphide to form polysulphide, which converts the cyanide into sulphocyanide. The final step, which led to a successful and economical process, was made by H. Wood Smith (H. Wood Smith, Gidden, Salomon, and Albright, Eng. Pat. 13658, of 1901) by simply scrubbing the gas through a suspension of sulphur, whereby the hydrocyanic acid is removed quantitatively, and a solution containing as much as 200 grams of ammonium sulphocyanide per litre may be obtained. This process is in use at several gas works, and yields practically the whole of the sulphocyanides made at present.

Synthesis of sulphocyanides from ammonia and carbon disulphide.—In Gélis' original process (A. W. Hofmann, Reports by the Juries, Inter. Exhib. of 1862, 59-63; A. Gélis, Eng. Pat. 1816, of 1860), a concentrated solution of ammonia and ammonium sulphide was agitated with carbon disulphide, yielding a solution of ammonium sulphocarbonate

which was then heated to 90°-100° with potassium sulphide

A very large amount of sulphuretted hydrogen is produced in this way, the disposal of which would occasion much trouble and expense. Günzburg and Teheriac (Eng. Pat. 1148, of 1878; 1359, of 1879; 1261, of 1881) heated a 20 p.c. solution of ammonia with carbon disulphide in autoclaves provided with stirrers at 100° until a pressure of 15 atmos. was reached, which indicated the end of the reaction. As Conroy (J. Soc. Chem. Ind. 1896, 15, 8) has shown, ammonium sulphocyanide is formed quantitatively under these conditions, the large pressure developed being due to the formation of the volatile ammonium sulphide $4\text{NH}_3 + \text{CS}_2 = \text{NH}_4\text{SCN} + (\text{NH}_4)_2\text{S}$.

Subsequent improvements were all in the direction of diminishing the quantity of ammonia required and reducing the pressure in the autoclaves. The simplest and most effective way of doing this is to add lime to the charge (Crowther and Rossiter, Eng. Pat. 17846, of 1893; Brock, Hetherington, Hurter, and Raschen, Eng. Pat. 21451, of 1893), the reaction then taking place in accordance with the equation:

A certain excess of ammonia over the quantity required by the equation must be used to prevent the formation of calcium sulphocarbonate. The excess of ammonia is distilled off, the residual mixture treated with carbon dioxide to remove sulphuretted hydrogen (in the way used in the treatment of Leblanc alkali waste), and the calcium carbonate filtered off. The clear solution of calcium sulphocyanide is easily converted into other salts.

THE PRINCIPAL SULPHOCYANIDES.

Potassium sulphocyanide KSCN crystallises in anhydrous, striated prisms or needles of sp.gr. 1.9, which melt at 172.3°. It resembles salt-petre in appearance and taste. It is deliquescent and very soluble in water, 100 grams of which dissolve 177.2 grams at 0°, 217 grams at 20°, and 239 grams at 25°. It is also soluble in many organic liquids. The solubilities (in grams per 100 grams of solvent) are:

Acetone, 20.8 at 22°; 20.4 at 58°.

Ethyl acetate, 0.44 at 0°; 0.4 at 14°; 0.2 at 79°.

Amyl alcohol, 0.18 at 13°; 2.14 at 100°.

Pyridine, 6.75 at 0°; 4.97 at 58°, and 3.21 at 115°.

The fused salt becomes deep blue at 430°; the colour is said to be due to the liberation of sulphur. The sulphocyanides are plant poisons.

Ammonium sulphocyanide NH_4SCN crystallises in anhydrous, colourless leaflets of sp.gr. 1.3, which melt at 159°; 100 grams of water dissolve 122 grams at 0° and 162 grams at 20°; it is readily soluble in alcohol. When heated a little above its melting-point, it is partly converted into the isomeric thiourea. At 220° decomposition takes place, ammonia, sulphuretted hydrogen, and carbon disulphide being evolved, and guanidine sulphocyanide remaining behind.

ANALYSIS OF CYANIDES.

The methods of analysis described here are those commonly employed in technical laboratories. It is believed that they will be found to be sufficient for most ordinary purposes.

Alkali cyanides. Owing to the hygroscopic nature of sodium and potassium cyanides when cold, samples, taken from different parts of a cake, should be transferred at once and without touching them with the hands to a hot iron mortar, broken up coarsely, and transferred to a hot perfectly dry bottle. If the sample has to be kept for any length of time before it is analysed, it is preferable to use glass-stoppered bottles and to grease the stopper with a little vaseline. Errors due to absorption of moisture in sampling are more common and more serious than those due to inaccuracies in testing.

Estimation of cyanogen.—5 grams of the sample are weighed out and made up to 500 c.c.; 25 c.c. of the solution are diluted to 200-300 c.c. and titrated with a solution of pure silver nitrate until the faintest visible turbidity results. The silver nitrate must be neutral and free from lead and zinc especially. A convenient strength of solution is obtained by dissolving 13.1 grams of silver nitrate in 1 litre of distilled water: 1 c.c. of this solution is equivalent to 0.01 gram of KCN. The solution is standardised by means of a solution of pure sodium chloride (dried by heating to redness before weighing) containing 4.487 grams per litre; 1 c.c. of the silver solution should exactly precipitate 1 c.c. of the sodium chloride solution using pure potassium chromate as indicator. In impure solutions of cyanides, the end point is often more easily observed if a little caustic soda (or a few drops of ammonia) and a crystal of potassium iodide are added before running in the silver nitrate solution. Sulphides interfere with the test, but they are easily removed by

shaking the solution with a little lead carbonate and filtering it.

Estimation of sulphide.—10 grams of the finely powdered sample are dissolved in 15 c.c. of ordinary water and a solution of lead nitrate (2.4 grams per litre) run in gradually. The mixture is stirred until the colloidal lead sulphide at first formed has coagulated into brown flocks; a drop of the solution is then placed on blotting paper beside a drop of the lead nitrate solution, and the two allowed to run together. When no difference can be detected between the colour of the paper where the drops have mixed and where they have not, the titration is considered to be at an end: 1 c.c. of the lead solution = 0.001 gram of K_2S (T. Ewan, J. Soc. Chem. Ind. 28, 10, 1909; Rossiter, *ibid.* 30, 583, 1911).

Carbonate is conveniently estimated by precipitating a suitable portion of the solution with barium chloride in the cold (to avoid decomposition of cyanate). The precipitate is washed and titrated, together with the paper, with normal hydrochloric acid and methyl orange.

Chloride. The solution is neutralised with dilute nitric acid, and methyl orange, and boiled for about 1 hour (in a draught cupboard, of course) to drive off the hydrocyanic acid and decompose cyanate. The chloride remaining Richards and Singer, Amer. Chem. J. 27, 205, 1902) is then precipitated by a known excess of standard silver nitrate solution, the silver chloride filtered off and the excess of silver titrated with ammonium sulphocyanide and iron alum in the usual way.

If ferrocyanide is present, it may be precipitated with excess of silver nitrate in ammoniacal solution; by acidifying the filtrate with nitric acid, silver chloride is precipitated and may be weighed.

Cyanamide in presence of alkali cyanides is easily estimated by exactly neutralising the solution of 1 gram of the substance in 100 to 150 c.c. of water with *nitric acid*, and then boiling for 20 minutes to expel hydrocyanic acid. After cooling, 2 or 3 drops of ammonia are added, and then excess of silver nitrate. The canary-yellow precipitate of silver cyanamide Ag_2CN_2 is filtered off and dissolved in cold dilute nitric acid (which usually leaves a small residue of undissolved silver cyanide). The silver in the solution is then titrated by means of ammonium sulphocyanide, using ferric alum as indicator. The method is applicable to most substances containing cyanamide, the boiling with acid being, of course, omitted when little or no cyanide is present.

Cyanate. The solution is acidified with nitric acid and boiled for 20 minutes at least to expel hydrocyanic acid, and convert the cyanate into ammonium nitrate and carbon dioxide. The ammonia is then distilled off, after adding excess of caustic soda, and estimated by titration with *N*-hydrochloric acid as usual. In presence of cyanamide, the method is not available, because some ammonia is formed from the cyanamide when it is boiled with caustic soda. In this (rather uncommon) case, the cyanate must be estimated by collecting the carbon dioxide evolved when the sample is boiled with acid (Ewan, J. Soc. Chem. Ind. 1904, 23, 244).

Ferrocyanide is most conveniently estimated,

either alone or in presence of cyanides, by titration with a standard solution of zinc sulphate until a drop of the solution no longer gives a blue colour when brought in contact with a drop of ferric solution on paper. A zinc alkali ferrocyanide of somewhat indefinite composition is precipitated, and H. G. Colman (Analyst, 33, 261, 1908; and J. Soc. Chem. Ind. 27, 806, 1908) has shown that the quantity of zinc solution required to precipitate a given quantity of ferrocyanide depends, to some extent, on the nature of the metal in the ferrocyanide used. This effect can be eliminated almost entirely by adding an excess of potassium sulphate. The method is carried out as follows: a solution containing 10.2 grams of $ZnSO_4 \cdot 7H_2O$ and 10 c.c. of concentrated sulphuric acid per litre is standardised against pure potassium ferrocyanide; 25 c.c. of a solution of 10 grams of yellow prussiate per litre, mixed with 25 c.c. of a saturated solution of potassium sulphate, 25 c.c. of water, and 10 c.c. of 1:10 sulphuric acid, are convenient quantities. Subsequent titrations should be made as nearly as possible under the same conditions.

A more accurate method is that of W. Feld (Journ. für Gasbeleuchtung, 47, 565, 1903). Ferrocyanide, equivalent to 0.3 to 0.5 gram of yellow prussiate is boiled for 5 minutes with 10 c.c. of *N*-NaOH and 15 c.c. of 3 (molecular) *N*-MgCl₂. If cyanide is present, the boiling is continued for 10 minutes and the hydrocyanic acid may be distilled into caustic soda and titrated with silver nitrate with potassium iodide as indicator. 100 c.c. of boiling 0.1*N*-HgCl₂ are now run in, and the boiling continued for 10 minutes to convert ferrocyanide into mercuric cyanide. This is then distilled with 30 c.c. of 3*N*-sulphuric acid for 20–30 minutes, and the hydrocyanic acid collected in caustic soda and titrated as before.

The estimation of the valuable constituents of gasworks products (cyanide and ferrocyanide) is performed by triturating 30 to 40 grams of the material in a mortar with excess of a cold solution of caustic soda for several hours. A little ferrous sulphate may be added to convert cyanide into ferrocyanide. The filtrate is treated with 4 to 5 times its volume of methylated spirit. Carbonyl ferrocyanide (from 2 to 5 p.c. of the cyanogen is usually present in this form, but exceptionally as much as 20 p.c. may be present), sulphocyanide, sulphide, and excess of caustic soda remain in solution, whilst the whole of the sodium ferrocyanide is precipitated. The precipitate is then treated by one of the methods described above (H. G. Colman, Analyst, 33, 261, 1908; and J. Soc. Chem. Ind. 27, 806, 1908; F. W. Skirrow, *ibid.* 29, 319, 1910).

Sulphocyanide. Ferrocyanide, if present, is first removed from the solution by adding iron alum after acidifying slightly. The filtrate is treated with acid sodium sulphite in excess and then with copper sulphate and boiled for 1 or 2 minutes. The precipitate of cuprous sulphocyanide, which may be mixed with copper sulphide, is filtered off and washed with boiling water. It is then digested with excess of caustic soda which gives cuprous hydroxide and a solution of sodium sulphocyanide. This is separated by filtration, acidified with nitric acid,

and titrated with silver nitrate, using a ferric salt as indicator (Linder, 43rd Alkali Report, 1906, 39).

Alkali metals in commercial cyanides. 1 gram of the substance is evaporated to dryness with excess of hydrochloric acid. Traces of iron and calcium are removed by re-dissolving, adding a drop of ammonium carbonate, and filtering. The solution is again evaporated to dryness, and the residue is gently fused and weighed. The mixture of alkaline chlorides is dissolved in water and an aliquot portion titrated with silver nitrate, using chromate as indicator. If n gram of cyanide has yielded a gram of the pure mixed chlorides containing b gram of chlorine, the percentage of potassium in the cyanide is given by the formula

$$\left(\frac{2.431a - 4.012b}{n}\right) 100.$$

This method is sufficiently accurate for most purposes, but the gravimetric estimation of the potassium as potassium platinichloride must be resorted to if a greater degree of accuracy is required.

T. E.

CYANINE and CYANINE DYESTUFFS *v.*

CYANOLINE COLOURING MATTERS.

CYANOMACLURIN *v.* JAKWOOD.**CYANOSINE** *v.* TRIPHENYLMETHANE COLOURING MATTERS.**ISO-CYANURIC ACID** *v.* FULMINURIC ACID.

CYCLOFORM. The trade name of *isobutyl* ester of *p*-amino benzoic acid used as a local anæsthetic. A white crystalline powder, m.p. 65°. Sparingly soluble in water (0.022 p.c.), readily soluble in alcohol and ether.

CYMENES. *Cymols.* The name *cymene* was first applied to the hydrocarbon isolated by Gerhardt and Cahours (Ann. Chim. Phys. [3] 1, 102 and 372) from Roman oil of cumin, which is the ethereal oil of *Cuminum cyminum*. Until 1891 this hydrocarbon was wrongly called *p*-methylpropylbenzene, but in that year Widman (Ber. 1891, 439, 970, 1362) proved it to be the *isopropyl*-compound (see also Fileti, J. pr. Chem. [2] 44, 150). Frequently, however, the various benzene hydrocarbons of the formula $C_{10}H_{14}$ are grouped together under the collective name of *cymenes*. No fewer than 22 of these are theoretically possible, of which 18 have been prepared; but only the most important, namely, *cymene* proper (*p*-methylisopropylbenzene) and the tetramethylbenzenes are described here.

***p*-Methylisopropylbenzene** (*Cymene*)

occurs in Roman oil of cumin (Gerhardt and Cahours, *l.c.*; Brühl, Ber. 1892, 149; Wolpian, Chem. Soc. Abstr. 1897, i. 357); in the volatile oil from the seeds of the water-hemlock (*Cicuta virosa*) (Trapp, Annalen, 108, 386); in the oil from *Ptychotis ajowan* (H. Müller, Ber. 2, 130); in oil of thyme (Lallemand, Annalen, 102, 119; Labbé, Bull. Soc. chim. 1898, [iii.] 1009) along with thymol $C_{10}H_{14}O$ and thymene $C_{10}H_{16}$; in eucalyptus oil (from *Eucalyptus Globulus*) (Faust and Homeyer, Ber. 7, 1429); in oil of caraway (Wolpian, Chem. Soc. Abstr. 1897, i. 17); in bitter fennel oil (Tardy, J. Pharm. Chim. 1897, 98); in oil of lemon grass (Barbier and Bouveault, Compt. rend. 121, 1159; Stiehl, J. pr. Chem. 1898, 51); in oil of origanum (Gilder-

meister, Arch. Pharm. 1895, 174); in geraniol (Semmler, Ber. 1891, 205); and in American petroleum (Mabery, Amer. Chem. J. 19, 419). May be obtained from camphor by abstracting from it the elements of water

by heating it either with phosphorus pentoxide (Dumas, Ann. Chim. Phys. 50, 226; Delalande, *ibid.* [3] 1, 368) or with phosphorus pentasulphide (Pott, Ber. 2, 121), or with phosphorus pentachloride (Lippmann and Louguinine, Bull. Soc. chim. [2] 7, 374; see also Brühl, *l.c.*; Tiemann, Ber. 1895, 1089). Various isomerides of camphor yield *cymene* by the same treatment. The terpenes $C_{10}H_{16}$ may be converted into *cymene* by withdrawing two atoms of hydrogen: this may be effected in the case of oil of turpentine, for example, by distilling it with bromine (Oppenheim, Ber. 5, 94 and 628), or better, with iodine (Kekulé, *ibid.* 6, 437). Old turpentine generally contains *cymene* (Wallach, Chem. Zentr. 1898, i. 572; Kondakow and Schindelmeyer, Chem. Zeit. 30, 722). It has been obtained synthetically from *p*-bromisopropylbenzene by means of methyl iodide and sodium (Widman, *l.c.*). To prepare *cymene*, camphor is warmed with an equal weight of phosphorus pentoxide, the *cymene* is poured off, treated again twice with a little phosphorus pentoxide, and finally rectified from sodium. The yield varies from 50 to 80 p.c. (Fittig, Annalen, 172, 307). It can also be prepared from *isopropyl*iodide, and *p*-bromotoluene (Reuter, Chem. Zentr. 1892, i. 625; Brühl, *l.c.*) or from *isopropyl*chloride, toluene and aluminium chloride (Silva, Bull. Soc. chim. [ii.] 43, 321).—Liquid boiling at 177°–177.5° (corr.); sp.gr. 0.8670 at 7.9°/4° (Perkin, Chem. Soc. Trans. 1896, 1125; 1900, 267). With chromic acid it yields paratoluic acid ($CH_3 \cdot C_6H_4 \cdot CO_2H$) and terephthalic acid

with potassium permanganate, hydroxyisopropylbenzoic acid,

Taken internally, it appears in the urine as cumic (*p*-isopropylbenzoic) acid

The preparation of *cumene* (*q.v.*) from propylbromide, benzene, and aluminium chloride, and that of *cymene* from *p*-bromotoluene, normal propylbromide, and sodium (Fittig, Schäffer, and König, Annalen, 149, 331) were for a long time the cause of great confusion in ascertaining the constitution of members of the *cumene* and *cymene* groups, as it was not realised that in each case the propyl-group changed into the *isopropyl*-group owing to the temperature of the reaction not being regulated.

Tetramethylbenzenes:

1. *Consecutive tetramethylbenzene* (*Prehnitene*) $C_6H_2(CH_3)_4$ (1, 2, 3, 4). When sodium durene-sulphonate

$C_6H(CH_3)_3SO_3Na$ (CH_3 -groups 1, 2, 4, 5, *v. infra*) is dissolved in concentrated sulphuric acid and allowed to stand for 12 hours, prehnitene-sulphonic acid is formed. The mixture is diluted with water, saturated with barium carbonate, the barium salts converted into sodium salts, and these, by treatment with phosphorus

same temperature as the active isomeride, is three times as soluble in water, and can be resolved into the active components by the action of *Aspergillus niger*, the *l*-compound being consumed.

Cystine is readily reduced to *cystein* (α -amino- β -thiolpropionic acid) $\text{HS}\cdot\text{CH}_2\cdot\text{CH}(\text{NH}_2)\cdot\text{CO}_2\text{H}$ (Baumann, Zeitsch. physiol. Chem. 1882, 8, 300; Mauthner, Zeit. Biol. 1901, 42, 176), which can be converted by the action of bromine water into *cysteic acid* (α -amino- β -sulphopropionic acid) $\text{HO}_2\text{S}\cdot\text{CH}_2\cdot\text{CH}(\text{NH}_2)\cdot\text{CO}_2\text{H}$, and from this, by loss of carbon dioxide, *taurine* $\text{NH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{SO}_3\text{H}$ is obtained (Friedmann, Beitr. Chem. Physiol. Path. 1902, 2, 433). According to Von Bergmann (*ibid.* 1903, 4, 92), the normal taurine in the bile originates from the cystin groups contained in the ingested protein. Cystein yields cystine on oxidation, the change occurring spontaneously in alkaline solution, although the rate is increased by the addition of a mixture of ferric chloride and potassium cyanide (Mathews and Walker, J. Biol. Chem. 1909, 6, 289).

When cystine is given with food, it is completely oxidised to sulphate and excreted as such (Rothera, J. Physiol. 1905, 32, 175). Baumann and Preusse (Zeitsch. physiol. Chem. 1881, 5, 309; Ber. 18, 258) found that when bromobenzene was administered to animals, it was excreted as *bromophenylcystein*

a compound crystallising in glittering needles

or plates; m.p. 180° – 182° , and yielding a blue crystalline copper salt $(\text{C}_6\text{H}_9\text{BrSNO}_2)_2\text{Cu}$.

Derivatives.—Cystine forms sparingly soluble salts with copper, $\text{C}_6\text{H}_{10}\text{O}_4\text{N}_2\text{S}_2\text{Cu}$; or mercury,

Benzoylcystine $\text{C}_6\text{H}_{10}\text{O}_4\text{N}_2\text{S}_2\text{Bz}_2$, m.p. 156° – 158° , crystallises in needles and forms a sparingly soluble sodium salt (Goldmann and Baumann, Zeitsch. physiol. Chem. 1888, 12, 254). *Cystinophenylhydantoin* is a well-defined crystalline compound, and is used for identifying cystine.

Cystine ethyl ester hydrochloride

forms colourless needles, m.p. 185° , with decomposition (Friedmann, Beitr. Chem. Physiol. Path. 1902, 3, 1). Numerous *acyl*-derivatives of cystine have been described by Fischer and Suzuki (Zeitsch. physiol. Chem. 1905, 45, 405; Fischer and Gerngross, Ber. 1909, 42, 1485). Of these *di-l-leucyl-l-cystine*

is a granular powder, turns yellow at 200° , and decomposes at a higher temperature, has $[\alpha]_D^{20} - 136.6^\circ$, or, when obtained in a crystalline form, has $[\alpha]_D^{20} - 141.4^\circ$; it gives a reddish-violet colour with copper sulphate; is precipitated by ammonium sulphate, and may be termed an *albumose*.

CYTISINE v. VEGETO-ALKALOIDS.

D

DAGUERREOTYPE v. PHOTOGRAPHY.

DAHLIA. Syn. *Hofmann's violet*, *Primula* (v. TRIPHENYLMETHANE COLOURING MATTERS).

DAHMENITE v. EXPLOSIVES.

DAMASCENINE v. VEGETO-ALKALOIDS.

DAMMAR RESIN, **DAMMARYL**, **DAMMARYLIC ACID** v. RESINS.

DANDELION ROOT. *Taraxaci radix*. (*Pissenlit*, Fr.; *Löwenzahmwurzel*, Ger.) The root of the common dandelion, *Taraxacum officinale* (Weber) (Bentl. a. Trim. 159), is used in medicine for its mild laxative and tonic properties. It is administered either in the form of expressed juice or weak spirituous extract. The roots employed should be collected in the autumn. (For a summary of the earlier chemical examinations of the root, see Pereira, Mat. Med. 1853, [2] 1574.) According to Kromayer (Arch. Pharm. 105, 6), there separates from the milky juice on standing a coagulum, 'leontodonium,' from which hot water dissolves a bitter substance. The bitter compound is removed from the solution by animal charcoal, from which it is extracted by alcohol, and after further purification constitutes the *taraxacin* of Kromayer. A similar taraxacin in warty crystals had been previously described by Pölex (Arch. Pharm. 19, 50). From that part of the coagulum left undissolved by the water, alcohol extracts crystalline *taraxacerin* $\text{C}_8\text{H}_{16}\text{O}$ (Kromayer).

Among the other constituents of the root are *inulin* (Frickinger, Rep. Pharm. 23, 45; Widemann, *ibid.* 43, 281; Overbeck, Arch. Pharm. 23, 240) and *levulin* (Dragendorff, Sachsse's Farbstoffe, 125). Mannite, which had been often found in the juice, was shown by T. and H. Smith not to pre-exist in the root, but to be a product of fermentation (Pharm. J. 8, 480). In the root collected in October Dragendorff found 24 p.c. of inulin, while that collected in March contained only 1.7 p.c. associated, however, with 17 p.c. of uncrystallisable sugar and 19 p.c. of levulin. The last-mentioned compound is an isomeride of inulin, being distinguished by its solubility in cold water, the sweetness of the solution, and by the absence of any action on polarised light.

The leaves and stalks, but not the root of the dandelion, contains *inosite* (Marmé, Annalen, 129, 222).

A. S.

DAPHNETIN. Daphnetin is present in the form of its glucoside daphnin in the bark of the *Daphne alpina* (Linn.) and *D. mezereum* (Linn.).

The alcoholic extract is digested with boiling water, filtered, and treated with lead acetate solution. The precipitate is removed, basic lead acetate added to the filtrate, the lead compound of the glucoside decomposed with sulphuretted hydrogen, and the solution evaporated (Zwenger, Annalen, 115, 8).

Daphnin $C_{15}H_{16}O_9 \cdot 2H_2O$ crystallises in prisms, melting at 200° , and dissolves in alkaline solutions, with a yellow colour. It is hydrolysed by boiling dilute acids with formation of daphnetin and glucose:

Daphnetin $C_9H_6O_4$ forms pale-yellow needles, is soluble in alkalis, with a yellow colour, and gives a yellow precipitate with lead acetate solution. On acetylation, a *diacetyl*-derivative $C_9H_4O_4(C_2H_3O)_2$ is obtained, and by means of ethyl iodide a *diethyl ether* $C_9H_4O_2(OEt)_2$ is produced. When daphnetin diethyl ether is boiled with caustic soda solution, the diethyl ether of daphnetinic acid

is probably produced in the form of its sodium salt, which when ethylated gives the triethyl derivative:

By oxidising daphnetinic acid triethyl ether *trithoxybenzaldehyde*, is formed, which is readily converted into triethoxybenzoic acid. The silver salt of this acid, when destructively distilled, gives pyrogallol triethyl ether. Daphnetin is accordingly a dihydroxycoumarin, and has the following constitution:—

(Will and Yung, Ber. 1884, 17, 1081).

It has been synthetically prepared by heating pyrogallol with malic acid in the presence of sulphuric acid (Pechmann, Ber. 17, 933):

$C_4H_6O_5 + C_6H_3(OH)_3 = C_9H_6O_4 + CO_2 + 2H_2O + H_2$
and by the condensation of pyrogallic aldehyde with sodium acetate (Gattermann and Koebner, Ber. 1899, 32, 287):

$C_6H_2(OH)_3 \cdot CHO + CH_3 \cdot COOH = C_9H_6O_4 + 2H_2O.$

Daphnetin is a yellow colouring matter, and gives with mordanted woollen cloth the following shades:—

Chromium	Aluminium	Tin	Iron
Olive yellow	Pale olive yellow	Very pale yellow	Olive black

(Perkin and Wilson, Chem. Soc. Trans. 1903, 83, 134) (v. LACTONES). A. G. P.

DAPICHO or **ZASPIS**. The South American name for the caoutchouc which exudes from the roots of *Hevea guianensis* (Aubl.).

DARWINITE v. **DOMEYKITE**.

DATE. The fruit of the date palm, *Phoenix dactylifera*. A palm of the tropics of Africa and the East Indies. It furnishes food to a large population in Egypt and Arabia.

The fruit grows in bunches of from 15 to 20 lbs. weight, and a tree usually produces about 20 bunches annually. The date palm also yields a sweet sap, which flows, when incisions are made in the trunk, almost continuously from November to March; the sap is clarified and boiled down, when a brown sugar, known as jaggery, is obtained (Bied. Zentr. 1884, 284).

Analyses of the flesh of dates give:

Water	Protein	Fat	Sol. carbohydrates	Fibre	Ash
28.8	1.9	trace	63.1	2.7	1.6

Dried dates, according to König, have the mean composition:

Water	Protein	Fat	Sugar	Free Other carbohydrates	Fibre	Ash
18.5	1.9	0.6	67.2	1.3	4.3	3.8
						1.8

Among the 'soluble carbohydrates' is included about 3 p.c. of pentosans, while the date stone contains about 2.7 p.c. of the same substances (Wittmann, Zeitsch. landw. Versuchs. Oesterreich. 1901, 4, 131).

König gives, as the composition of the date stone:

Water	Protein	Fat	Nitrogen free extract	Fibre	Ash
7.7	5.2	9.0	53.0	24.0	1.1

Dates are sometimes used as coffee substitutes, the whole fruit being occasionally employed, but more usually the stones only.

König gives as the composition of 'date-coffee':

Water	Protein	Fat	Sugar	Other carbohydrates	Fibre	Ash
6.6	5.5	7.9	2.2	48.7	27.8	1.3

yielding about 14 p.c. of its weight to water. H. I.

DATHOLITE v. DATOLITE.

DATISCA CANNABINA (Linn.). This is a tall, erect herb, resembling hemp, belonging to the *Datisceæ*, and met with in the temperate and sub-tropical Western Himalayas from Kashmir to Nepal. The root, known as *Akalbir*, is extensively used in Kashmir and throughout the Himalayas as a yellow dyestuff chiefly on alum-mordanted silk; but the colouring matter appears to be present in the whole plant, for the leaves and twigs can also be employed for the same purpose.

The leaves of the *Datisca cannabina* were first examined by Braconnot (Ann. Chim. Phys. [2] iii. 277), who isolated from them a crystalline substance which he named datiscin. Somewhat later it was shown by Stenhouse (Annalen, 1856, 98, 167) that this compound is a glucoside, and when hydrolysed is converted into a sugar, together with a yellow colouring matter, *datiscetin* $C_{15}H_{10}O_6$.

Schunck and Marchlewski (Annalen, 278, 261), however, considered that the formula $C_{15}H_{12}O_6$ was preferable, and showed that, on fusion with alkali, datiscetin gives *salicylic acid*. By the action of dilute nitric acid, a *nitro-salicylic acid* was produced, whereas with strong nitric acid, picric acid, as already indicated by Stenhouse, was formed. Datiscetin appeared to contain methoxyl groups, and was at that time considered by the authors to be most probably a xanthone derivative.

Korczynski and Marchlewski (Ann. d. Akad. Krakau, 1906, 95), have shown that pure datiscetin $C_{15}H_{10}O_6$ does not contain methoxy-groups. It consists of yellow needles, m.p. 268° – 269° , soluble in alkaline solutions, with a yellow colour, and gives, with sulphuric acid, a yellow liquid possessing a green fluorescence. When boiled with strong alkaline solutions, phenol and salicylic acid are produced.

Tetraacetyldatisectin $C_{15}H_6O_6(C_2H_3O)_4$ forms colourless needles, and melts at 138° ; and **tetra-benzoyldatisectin** $C_{15}H_6O_6(C_7H_5O)_4$ gives colourless needles, m.p. 190° – 191° . Korczynski and Marchlewski consider that datisectin is most probably a flavone derivative, isomeric with luteolin and fisetin.

Datiscin $C_{21}H_{24}O_{11}$ (S. and M.), the glucoside, crystallises in silky needles, which melt at about 190° , and dissolve in alkaline solutions with a yellow colour. Hydrolysis with dilute sulphuric acid yields datisectin and *rhamnose*, not datisectin and glucose, as stated by Stenhouse (*l.c.*).

The dyeing properties of datisca root on wool are very similar to those of old fustic. It is, however, slightly inferior in dyeing power. On cotton it dyes more like quercitron bark, in so far that the olives obtained on iron mordant are bluer in shade, as though some tannin matter were present. It appears to have about the same colouring power as quercitron bark, but gives a brighter yellow with aluminium mordant. Applied to wool, it differs from quercitron bark by giving with chromium mordant an olive-yellow, which is not of such a reddish tinge, and with tin mordant a bright yellow instead of an orange. It is an excellent dyestuff, and worthy to rank with the natural yellow mordant colouring matters at present in use (Hummel and Perkin, *J. Soc. Chem. Ind.* 1895, 14, 458).

A. G. P.

DATISCIN *v.* **DATISCA CANNABINA.**

DATISCETIN *v.* **DATISCA CANNABINA.**

DATOLITE. A native boro-silicate of calcium, discovered near Arendal, in Norway, by Esmark, in 1806. It derives its name from $\delta\alpha\tau\acute{\epsilon}\omicron\mu\alpha\iota$, 'to divide,' in allusion to its readily breaking with a granular fracture; Werner, however, incorrectly spelt it *Datholith*, whence it has been supposed that the name is connected with $\delta\acute{\alpha}\delta\omicron\varsigma$, 'turbid,' though the best-marked varieties are remarkable for their transparent vitreous character. The mineral crystallises in the monoclinic system, but occurs also massive, and a variety from Lake Superior, of opaque white colour, is so compact as to resemble unglazed porcelain. $H. = 5$ to 5.5 ; sp.gr. 2.8 to 3.4 . Analyses agree closely with the formula $HCaBSiO_5$, corresponding with SiO_2 , 37.6 p.c.; B_2O_3 , 21.8 p.c.; CaO , 35.0 p.c.; H_2O , 5.6 p.c.

Datolite is occasionally found in the trap rocks of Scotland, especially in the Kilpatrick Hills. The finest crystals are found at Bergen Hill, New Jersey, and Westfield, Massachusetts. It occurs in veins of silver ore at Andreasberg in the Harz; in granite at Baveno, near Lago Maggiore; in serpentine at Monte Catini in Tuscany, and in the Lizard district in Cornwall; and in amygdaloidal melaphyre at Theiss in Tyrol, and many other localities. A botryoidal variety, from Arendal in Norway, containing as much as 8.6 p.c. of water, is distinguished as *Botryolite*. At Haytor in Devonshire, a rare pseudomorph was formerly found, consisting of large crystals of datolite completely replaced by quartz; this mineral is known as *Haytorite*. (For an exhaustive description of datolite, with bibliography, *v.* O. Lüdecke, Ueber Datolith: eine mineralogische Monograph, Zeitschr. f. Naturwiss. Halle, [4] 7, 1888, 235–403.) F. W. R.

DATURA STRAMONIUM. *Thorn-apple.*

(*Stramoine*, Fr.; *Stechapfel*, Ger.) The seeds and leaves of *Datura stramonium* (Linn.) are employed in medicine for their sedative and narcotic properties. The former are administered in the form of tincture or solid alcoholic extract, and the latter are smoked as a remedy for asthma. According to De Candolle, the plant is indigenous to the neighbourhood of the Caspian Sea, whence it has spread throughout the temperate and warmer parts of the world (Flück. a. Hanb. 2nd ed. 459; Benth. a. Trim. 192).

Like other drugs derived from the *Solanaceae*, the physiological action of datura depends upon the presence of poisonous alkaloidal constituents. What appeared to be a single alkaloid, 'daturine,' was isolated by Geyger (Annales, 7, 272). Von Planta (*ibid.* 74, 246, and 252), and subsequently Ladenburg (*ibid.* 206, 279) and Schmidt (*ibid.* 208, 196; Arch. Pharm. [3] 22, 329), have, however, proved that 'daturine' is a mixture of *hyoscyamine*, the alkaloid of henbane, and its isomeric *atropine*, originally obtained from belladonna. In belladonna atropine was supposed to exist together with *hyoscyamine*, but it has been observed that in the extraction of the alkaloids, the relative proportion of the one to the other depends upon the mode of working. With greater care, the yield of *hyoscyamine* is increased, and that of *atropine* diminished, and it is possible to obtain the whole of the alkaloid as *hyoscyamine*. This fact has been investigated by W. Will (Ber. 21, 1719), who finds that *hyoscyamine* may be easily converted into *atropine* by the action of alcoholic solutions of alkalis or by heat alone. It is probable, therefore, that in belladonna, and possibly also in datura, *hyoscyamine* only is present in the plant, and that it is converted more or less into *atropine* during the process of extraction (*cf.* Schmidt, Ber. 21, 1829; Will and Bredig, *ibid.* 21, 2777). Ladenburg, however, questions this view (*ibid.* 21, 3065).

Scopolamine is also present in the leaves and stalks of *Datura stramonium* (Schutte, Arch. Pharm. 229, 492; Beckurts, Chem. Zentr. 1906, ii, 916).

The seeds yield about one-quarter of their weight of a bland fixed oil, from which Gérard (Compt. rend. 111, 305) has isolated *daturic acid* $C_{17}H_{34}O_2$. It consists of slender needles, which melt at 55° . Two other acids have also been isolated (Holde, Chem. Zentr. 1902, ii, 1417). (For a method of estimation of the alkaloids, *see* Schmidt, *ibid.* 1900, i, 376; Andrews, Chem. Soc. Trans. 1911, 99, 1871).

Other species of datura have been investigated by Van den Driessen Mareeuw (*ibid.* 1899, i, 539); Kucher, Arch. Pharm. 243, 309; Schmidt, *ibid.* 244, 66; Pyman and Reynolds, Chem. Soc. Trans. 93, 2077; Andrews, *l.c.*) A. S.

DATURIC ACID $C_{16}H_{33}COOH$ occurs as a glyceride in the oil from the seeds of *Datura stramonium* (Gérard, Ann. Chim. Phys. [6] 27, 555); m.p. 55° .

DATURINE *v.* **DATURA STRAMONIUM.**

DAUCINE *v.* **VEGETO-ALKALOIDS.**

DEAD DIPPING. The process of producing a pale-yellow dead surface on ornamental brasswork. The brasswork, after the final stamping, with its adhering black scale from the annealing

oven, is placed in dilute nitric acid until the scale is detached, when it is removed and washed with water. It is next plunged into stronger nitric acid, and when its surface is covered with minute gas bubbles, it is washed in a solution of argol and dried in hot saw-dust.

DEAD OIL. The higher boiling fractions of shale oil, from which the greater portion of the solid paraffin has been crystallised out.

n-DECAHEXANEDICARBOXYLIC ACID
 $\text{CO}_2\text{H}[(\text{CH}_2)_{10}\text{CO}_2\text{H}]_n$. Prepared by the electrolysis of an aqueous solution of the potassium salt of the monoethyl ester of suberic acid, and hydrolysing the diethyl ester thus formed (Brown and Walker, *Annalen*, 261, 125); m.p. 118°.

DECAMETHYLENEDICARBOXYLIC ACID
 $\text{CO}_2\text{H}(\text{CH}_2)_{10}\text{CO}_2\text{H}$. Prepared by heating the methyl ester of bromundecylic acid with alcohol and potassium cyanide, and hydrolysing the product with alcoholic potassium hydroxide (Nördlinger, *Ber.* 1890, 2357); m.p. 124.5°–125.5°.

DECATOIC ACIDS $\text{C}_{10}\text{H}_{20}\text{O}_2$.

1. *Capric acid* $\text{CH}_3(\text{CH}_2)_8\text{COOH}$ is found as a glyceride in the butter of the cow and goat, and in cocoa-nut oil, in association with caproic and caprylic acids. Many fusel oils also contain it (Fischer, *Annalen*, 118, 307; Grimm, *ibid.* 157, 264; Rowney, *ibid.* 79, 236), and it is found as isoamyl caprate in certain Hungarian wines, and is formed by the oxidation or distillation of oleic acid (Redtenbacher, *ibid.* 59, 45), and by heating octylacetacetic ester with alcoholic potash (Guthzeit, *ibid.* 264, 5). A white crystalline substance of m.p. 31.3°; b.p. 268.4° (corr.); sp.gr. 0.8858 at 40°/4°; possessing a goat-like smell; insoluble in cold water, but slightly soluble in boiling water.

2. *Diisobutylic acid*,

Obtained by heating diisobutylmalonic acid (Bentley and Perkin, *Chem. Soc. Trans.* 1898, 62); b.p. 225°–230° (730 mm.).

DECHENITE v. VANADIUM.

DECOIC ACID, CAPRIC ACID v. DECATOIC ACID.

DÉGRAS, or SOD OIL, is the waste fat obtained in the chamoising process, and is used for currying purposes, i.e. dressing bark-tanned or chrome-tanned leather. The skins which are to be converted into chamois leather, are first 'limed,' the hair is then removed and the un-haired hides are 'drenched,' i.e. placed in a 'sour bath,' in which the free lime is neutralised through an acid fermentation setting in, caused by *Bacillus furfuris*. The skins are then stretched and well rubbed with whale oil, or cod (liver) oil, in the United States with Menhaden oil, and worked in 'stocks,' so as to become thoroughly saturated with the oil. The skins are then exposed to the air, and the process of rubbing with oil and stamping in the stocks is repeated until enough oil has been absorbed. By exposure to the atmosphere, a portion of the oil becomes changed, and is most likely converted into the glycerides of 'oxidised' acids. In order to promote the oxidation of the oil, the skins are heaped together in a warm room, and covered carefully with canvas, so as to keep the generated heat in the heap whereby a large

proportion of the oil is converted into 'oxidised' oil. The bulk of the oil is expressed from the skins by pressure, the remainder of the oil retained by the skins being removed by one of the two following methods, known respectively as the English and German method, or the French method. In the English and German method, the skins are washed with alkaline lyes; the emulsion thus obtained is acidified with sulphuric acid, when the fatty matter separates and is skimmed off. This fatty substance forms the 'sod oil' of commerce. In the French method, the skins are 'stocked,' aired, and 'fermented' for a shorter period than in the English or German method, so that a large proportion of the oil can be obtained from the skins by steeping them in warm water, and wringing or pressing in hydraulic presses. The oil thus obtained is termed 'première torse moëllon.' The oil still retained by the skins is recovered by washing with alkaline lyes, as is done in the English and German method, and the fatty matter so recovered is usually added to the moëllon.

The most characteristic constituents of dégras are the oxidised fatty acids contained in it.

Dégras is largely admixed with fish oils, blubber oils, tallow of low quality, &c. According to trade custom, such products are considered as a genuine product. On the other hand, the numerous substitutes of dégras, or *artificial dégras*, which occur in commerce, consist of highly adulterated dégras, the adulterants being mineral oils, wool fat, or blown blubber oil, and rosin. J. L.

DELPHINE BLUE v. OXAZINE COLOURING MATTERS.

DELPHININE v. VEGETO-ALKALOIDS.

DELPHLEGMATOR. An apparatus used in fractional distillation. The term is also employed in distilleries for an apparatus for freeing alcohol from water (*phlegma*).

DELTAPURPURIN v. AZO-COLOURING MATTERS.

DENATURANTS. This term is applied to substances which are added to articles usually subject to revenue imposts, and primarily intended for human consumption (as spirits, tobacco, &c.) in order to render such articles unfit for human consumption, but without impairing their efficacy as raw material for use in various arts and manufactures. Articles thus 'denatured' may safely (from a revenue point of view) be released from revenue control without payment of duty.

The principles underlying the choice of suitable denaturants are mainly as follows:—

(a) They should be inexpensive, so as not to add materially to the cost of the denatured article;

(b) Their use should cause the minimum amount of inconvenience to the manufacturer, both in regard to his processes and the necessary revenue supervision involved;

(c) The denaturant should not be incompatible with the process of manufacture or the subsequent use of the denatured article;

(d) It should be of such a nauseous and repugnant character as to remove any temptation to would-be consumers of the denatured article; and

(e) The denaturant should have such a relation to the original article both in quantity and character as to preclude its removal from the mixture by any process which could be profitably carried out on a commercial scale.

In the United Kingdom the dutiable articles allowed to be denatured are *tea*, *tobacco*, *wine*, and *spirit*, the last being by far the most important, both by reason of the large amount of revenue derived from it, and the great variety and extent of its applications in the arts and manufactures.

Tea, before being admitted for consumption in the United Kingdom, is examined by the Customs under sect. 30 of the Sale of Food and Drugs Act, 1875, and, if found satisfactory, is passed on payment of duty; but if otherwise, it is refused admission as 'tea.' Since, however, it still possesses a certain commercial value as a raw product for the extraction of theine or caffeine (*v.* ALKALOIDS), the Commissioners of Customs and Excise usually permit it to be admitted for this purpose duty free, after it has been effectively denatured in such a way as to make it unsuitable for use as a beverage, but without interfering with its efficacy as a source of caffeine. The same applies to those teas which have been accidentally damaged and are voluntarily withdrawn by the importers from sale as 'tea.'

In the case of tea, the denaturing process consists in grinding and mixing the tea with lime and asafoetida in the proportions of 1 part of asafoetida and 100 parts of lime to 1000 parts of tea.

Tobacco is dutied on the whole leaf, of which certain portions, as the midribs or so-called 'stalks,' are by manufacturers treated as waste or 'offal,' and the same applies to the unused portions of manufactured tobacco, known as 'shorts' or 'smalls.' On these the duty which has been paid is returned as 'drawback' to the manufacturer on condition, either that the tobacco offal is surrendered to the Government for destruction, or (if intended for such purposes as the manufacture of nicotine, insecticides, sheep dips, &c.), that it is denatured according to certain prescribed formulæ, and under the supervision of revenue officers. Denaturing is equally necessary in the case of offal from tobacco manufactured in bond (although no duty has been paid nor drawback given), in order to prevent its fraudulent use as a substitute for duty-paid tobacco.

The following formulæ have been officially approved in the United Kingdom for denaturing certain preparations having tobacco as a basis:—

(a) *Sheep wash.* To every 100 lbs. of tobacco are added 10 lbs. of blue vitriol, 15 lbs. of common salt, 2 lbs. of oil of turpentine.

(b) *Tobacco extract* manufactured in bond may be denatured by adding 30 parts of soft soap to 70 parts of extract.

(c) *Hop powder.* To every 75 lbs. of snuff or tobacco are added 28 lbs. of sulphur, 5 lbs. of asafoetida, and 3 lbs. of sago flour.

(d) *Fumigant* for horticultural purposes. To every 100 lbs. of tobacco or snuff are added 10 lbs. of ground hellebore, 18 lbs. of saltpetre, 6 lbs. of asafoetida, 4 lbs. of cayenne, 2 lbs. of lamplack, 10 lbs. of sago flour.

VOL. II.—T.

Wine which has become unsound and sour (owing to the formation of acetic acid) so as to be no longer suitable for use as a beverage, is released from revenue custody after being denatured with a view to its conversion into wine vinegar. The denaturant used in this case is 20 p.c. of commercial vinegar, or an equivalent quantity of acetic acid.

(For methods of denaturing alcohol, *v.* *Methylated spirits* and *Industrial alcohol*, art. ALCOHOL.) J. C.

DENITRIFICATION *v.* FERMENTATION AND SOILS.

DENSIMETER *v.* SPECIFIC GRAVITY.

DERMATOL. *Bismuth subgallate* (*v.* BISMUTH, ORGANIC COMPOUNDS OF; also SYNTHETIC DRUGS).

DERMOL. *Bismuth chrysophanite.* A yellowish-brown powder, said to have the composition $\text{Bi}(\text{C}_{15}\text{H}_9\text{O}_4)_3\text{Bi}_2\text{O}_3$. According to Merck, it is a mixture of impure chrysoarabin and bismuth hydroxide (*v.* BISMUTH, ORGANIC COMPOUNDS OF; and SYNTHETIC DRUGS).

DERRIS ULIGINOSA (Benth.). The stem of this species of derris, used in the Far East as a fish poison, contains a poisonous resin (Proc. Amer. Pharm. Assoc. 1902, 50, 296).

DESCLOIZITE. A basic lead and zinc vanadate $(\text{Pb}, \text{Zn})_2(\text{OH})\text{VO}_4$, crystallising in the orthorhombic system, and isomorphous with olivenite (basic copper arsenate). A small amount of copper is sometimes present. The small crystals are deep reddish-brown in colour, and the streak is a paler yellowish-brown. It occurs in veins of lead ore in association with vanadinite, &c., and has been mined to a limited extent in New Mexico and Arizona, as a source of vanadium. Recently the mineral has been found in considerable quantities at Broken Hill in North-Western Rhodesia.

L. J. S.

DESICCATION AND DRYING. The removal of mechanically admixed water from substances. The removal of chemically combined water is usually termed *dehydration*, but it is not always possible to draw a sharp distinction between the two processes.

A substance may be termed 'dry,' even though it still contains mechanically admixed water, provided that this water is not apparent to the touch; the term 'desiccation' refers, strictly speaking, to the complete removal of admixed water.

The importance of drying and desiccating will be appreciated by a consideration of the numerous reasons for which these processes have to be employed, among which the following may be mentioned:—

1. To preserve material from undergoing physical and chemical alterations, *e.g.* leather, tobacco, fruit.

2. To remove water needed in preceding operations, *e.g.* drying coal after washing, woollen and cotton goods after dyeing, &c.

3. To facilitate accurate sampling, since substances are much more readily and uniformly mixed in the dry state than in the moist condition.

4. To diminish the weight of an unnecessary ingredient and thereby diminish cost of packing, carriage, and freight; *e.g.* timber, peat, &c.

5. To retain desirable moisture in a substance by drying its surface, thereby rendering the outer layer impervious to moisture, *e.g.* the drying of soaps and chocolates.

6. To prevent injury to health or goods, as in the case of the moisture-laden air of textile factories, evaporating rooms, &c.

7. To prevent waste of heat in vapourising water when combustibles are burnt.

A slight consideration of the various purposes served by drying processes is sufficient to bring out the wide range of degrees of dryness, and the various conditions to which the term 'dry' is applied. This vagueness arises partly from the difficulty of stating quantitatively the amount of water present in a given instance, and partly owing to the varying capacity that substances possess for absorbing moisture. Thus it is that in ordinary conversation substances are variously described as 'soaked,' 'wet,' 'moist,' 'damp,' 'dry,' 'dried,' 'desiccated' or 'dehydrated,' in order to indicate qualitatively their degrees of dryness.

The drying processes in use may be classified under the following headings, corresponding with the degrees of drying to which they lead:—

A. Gravitational drying, by draining, filtering, absorbing, and condensing.

B. Mechanical drying, by pressure and centrifugal force.

C. Drying by evaporation.

A. **Gravitational drying.** The processes included under this heading are usually only preliminary to the employment of method C above.

Drainage is a natural process occasionally used for the purpose of removing surface water, *e.g.* from washed coal. The procedure requires no special description.

Decantation is a process by which solid substances mixed with a large amount of water are separated from the greater portion of that liquid by allowing them to settle, and running off the liquid from above the sediment. In practice it is often the custom to arrange 'settling tanks' in series, stepwise, and gradually feed the mixture of liquid *plus* suspended solid into the upper vessel by means of a pipe leading to the bottom. The overflow runs into the second vessel, and so on throughout the series. Arrangements are provided for emptying each tank as required. China clay, chalk, and barytes are separated in this manner.

Filtration is a process of accelerated drainage. Thus wet pigments prepared by precipitation are drained on calico sheets stretched loosely over a skeleton framework. Filtration is greatly accelerated by partially exhausting the air from the chamber into which the liquid drains. A vacuum filter has been designed to work continuously, and consists of a hollow drum, mounted with its axis horizontal, and partly submerged in a tank containing the suspension to be filtered. The periphery is covered with filter cloth, and the water is drawn by suction, applied to the interior of the drum, through this cloth, leaving the solid matter as an outside coating. By slowly revolving the drum, a continuous coating of solid is thus formed, and, after it reaches a certain thickness, an adjustable skimmer removes the surplus. This

arrangement can be adapted to many drying operations, and consumes very little power.

Absorption is a drying process in which the material is dried by causing it to yield its moisture to other substances which are capable of annexing it. This process is not often applied on a large scale, although it is commonly employed in the laboratory. Instances are furnished, however, in the preliminary drying of large clay ware in dried plaster of Paris moulds, and in the drying of the highly water-laden atmospheres of evaporating rooms, dye houses, &c., by pumping warm, fresh air into them. Warm air having a much higher capacity for holding water vapour than cold air, the result is naturally to effect a drying of the atmosphere, besides warming up the room and fittings.

In the laboratory, substances are frequently dried by placing them in a *desiccator*. This is simply a closed glass vessel containing in a suitable receptacle some chemical compound, such as anhydrous calcium chloride, concentrated sulphuric acid, or phosphoric anhydride, which has a remarkable affinity for water, so that it will, by absorption, remove water vapour from the interior even when the tension of the aqueous vapour therein is exceedingly small. The substance to be dried being placed in the desiccator, in the interior of which the tension of aqueous vapour is almost *nil*, it gives off its moisture, and this is continuously absorbed by the desiccating agent employed. The latter must expose a large surface for rapid absorption to occur. The velocity of drying in a desiccator may be greatly increased by exhausting the air from the interior (vacuum desiccator), since the rate at which moisture can diffuse from the material to the absorbing agent is thereby largely augmented. The degree of drying attained cannot, however, be increased, since that is limited merely by the pressure of the aqueous vapour when it has reached equilibrium with the absorbing agent. The rapidity of drying is also increased by placing the material to be dried at the bottom and suitably arranging the desiccating material above it. This arises from the fact that moist air has a smaller density than dry air at the same temperature and pressure; consequently, the natural process inside the desiccator is for the moist air to rise. The error in design exhibited in most laboratory desiccators, in which the above arrangement is reversed, was pointed out by Hempel (Ber. 1890, 23, 3566), to whom the desiccator shown in Fig. 1 is due. In this desiccator, the drying agent is placed in the trough of the lid.

It is usual to evacuate laboratory desiccators by means of the water-pump, but it may be easily accomplished by simple chemical means (J. Amer. Chem. Soc. 1906, 28, 834; Amer. Chem. J. 1902, 27, 340).

Condensation.—This is employed as a means of drying materials which must be handled at low temperatures, and is a method adopted

FIG. 1.

in cold storages. The principle of the process is, briefly, that the moist air of the rooms is drawn out and passed into chambers maintained at a very low temperature, where it is made to deposit the greater part of its moisture as a liquid. The dry air is then returned to the drying rooms, either cold, when it warms itself at the expense of the materials drying, or after being previously heated. This circulation of air goes on continuously. The method adopted in order to maintain a low temperature in the cooling rooms is to allow liquid ammonia, carbon dioxide, or ether to evaporate at the requisite rate through long coils of metal pipes over the outer surfaces of which the moist air is drawn. The latent heat of the ammonia (or other) vapour is obtained at the expense of the heat of the moist air, which is thereby cooled; the vapour condenses on the pipes and the water trickles down into troughs and flows away. The ammonia (or other) gas is repeatedly used in a cycle of operations, being successively liquefied and evaporated. This process is highly efficient, but requires careful handling for economical working.

B. Mechanical drying. These methods are efficient when water forms a large proportion of the total weight, and when the solid material to be separated is porous in texture. They leave the solid damp or moist.

Drying by pressure.—There are very few cases in which direct mechanical pressure is used for removing water from substances, the most important of which is the direct squeezing of peat in specially designed machines, in order partly to remove the surplus water.

Filter presses are used for partly drying semi-solids, and leave them still containing about 20 p.c. of moisture. They are efficient in removing the large bulk of the water from granular substances in a state of thick mud. Essentially a filter press consists of a number of flat sections or chambers formed of iron plates covered with filtering cloths, and supported in a strong horizontal frame, in which they can be squeezed up tightly together. The chambers are made either round or square, and usually each has its own outlet cock, while the washing arrangement can be made reversible. The sludge to be filtered is fed in under moderate pressure, and all the outlet cocks opened. After water has ceased to flow out, the solid in the press is washed, if desirable, and the press then taken to pieces to remove the moist solid cakes from its interior. This process is used for filtering, among other things, sewage sludge, gold slimes, and precipitated pigments.

Drying by centrifugal force.—This method is largely employed for drying clothes in laundries, when the centrifugal machines are termed hydro-extractors. It is also used for drying wool, cotton yarns, piece goods, &c., after they have left the dye houses, and for separating and drying sugar, gun-cotton, and starch.

The process consists in placing the material to be dried in a basket containing numerous holes, and rotating it in a horizontal plane at a considerable speed. The water is thrown off from the material very effectually, much more effectually than when simple filtration or filtration under moderate pressure is adopted.

A centrifugal machine consists essentially of

a circular basket, rotated on a vertical central shaft and enclosed in an outer stationary casing. The circular basket is drum shaped, having an open top to introduce the material and sometimes a valve at the bottom to form an outlet for dried crystals. The periphery is perforated with holes of a suitable size. These baskets are made of steel, bronze, copper, aluminium, silver, or china, as may be suitable, and are lined with rubber, enamel, or lead when dealing with acid liquids. The outer stationary casing serves as a guard in case of accident and as a collector for the water. The successful working of a centrifugal machine depends upon the skill with which the vertical shaft is mounted and driven, since the apparatus must have sufficient freedom when running for the axis to take up the position it requires; otherwise vibrations will rapidly wreck the machine.

C. Drying by evaporation. This is by far the most efficient method of drying; indeed, several of the preceding processes are only employed as preliminary steps to the application of this more powerful method.

Drying by evaporation is a process in which the water is removed by first converting it into vapour and then conveying the vapour away. Water always has a tendency to pass into the gaseous state, and is constantly giving off vapour from its free surface. If this process occurs in a closed space, some of the vapour finds its way back into the liquid, and a state of equilibrium is set up when the rate at which vapour is leaving the surface has become equal to the rate at which it is passing back into the liquid. To the state of equilibrium at any particular temperature there corresponds a definite vapour pressure, which is a measure of the tendency of water at that temperature to pass into the gaseous state, and this vapour pressure rapidly increases with rise of temperature. When evaporation takes place in free space, no condition of equilibrium is reached, since, owing to diffusion of the vapour, the rate at which it passes back into the liquid can never equal that at which vapour leaves it. Evaporation therefore goes on until no more liquid remains. From these considerations, it follows that the two main practical principles in drying by evaporation are: (i.) to warm the material and thereby increase the tendency of its contained water to vapourise; and (ii.) to remove the vapour as it is produced from the neighbourhood of the substance, in order that the evaporation shall proceed continuously.

In applying these principles it is necessary to bear in mind that the rate of drying permissible in any given instance is restricted by (a) the physical and chemical nature of the material, which put a limit to the rate at which heat may be safely applied; and (b) by the cost of drying, since the plant mechanically most sound may not be most economical in practice. It must always be remembered that the nature of the material governs the method of drying to be employed, and must be considered before the question of mechanical efficiency.

The various methods for applying heat and for removing vapour are indicated below, and in order to explain more definitely how these methods are employed in practice, brief

descriptions follow of various types of drying installations in actual use, and of the purposes for which they are used.

Application of heat. In the majority of cases hot air is employed for conveying heat to the material, and its use is attended with many advantages. Air, although an extremely poor conductor, is an excellent absorber of heat; the increase in volume resulting from this process naturally tends to disperse this heat and to warm surrounding materials by convection. The mobility of the air enables it to come into intimate contact with the surfaces of materials, thereby supplying the heat necessary to vapourise the moisture. Most important of all, the heated air can be thus supplied in large or small amounts, at any desired rate and at uniform pressure, while any of these factors may be rapidly and easily altered at will.

Of the various *sources of heat*, the cheapest is, of course, solar heat. Owing to its unreliability so far as quantity and continuity are concerned, its direct use is attended by considerable risks. Indirectly, however, it is of great value, in being the primary cause of natural air currents. Drying directly by furnace heat obtained by fuel combustion is economical, but the method is restricted in use to drying those substances which are not sensibly affected by high temperatures. For the commonest method of drying, by means of a warm blast of air, heat is usually supplied by passing the air over the surfaces of radiators. These are simply iron vessels, built to expose as much surface as possible, and through the insides of which steam, hot water, or hot gases are passed. Heat is conducted through the iron to the outer surface, and warms the surrounding air mainly by radiation.

The *dangers* encountered in the application of heat result from the nature of the material, and the factors involved, which are briefly discussed below, naturally affect various materials to very different degrees.

(a) Rate of application of heat. Although the amount of heat required to vapourise a definite quantity of water is fixed, yet if this heat be applied at a rate faster than that to which the material can accommodate itself, injury will result, e.g. wet bricks will crack unless the greater part of their water is first driven off at a slow and uniform rate.

(b) Change in power of absorbing heat with loss of water. As a material dries, its heat capacity usually diminishes, and hence the risk of overheating increases as drying progresses.

(c) Uncertainty as to degree of dryness, which is often unavoidable.

(d) Local application of heat. This is the usual cause of distortion and cracking, since most materials shrink as they dry, and local shrinking sets up strain. This makes it advisable to keep wet material from actual contact with the source of heat, and to agitate the material to continually expose fresh surfaces, since evaporation is a purely surface phenomenon.

Methods for removal of vapour. The natural method by which vapour is removed is by means of *air currents*, and, excepting in the case of the vacuum process, this is the method upon

which all artificial processes for vapour removal are based.

The ordinary *atmospheric* process for drying utilises the natural movements of the air, e.g. by utilising the action of the wind on floors, pans, gentries, sheds, &c. It requires no motive power, but, being dependent upon varying atmospheric conditions, it is not reliable.

In the *exhaust* process the moisture-laden air is drawn away from the wet material quicker than gravity would perform the removal. For this purpose a propeller or fan is usually employed. Since the operation is carried out under slightly reduced pressure, vapourisation proceeds quicker than it otherwise would; on the other hand, the exhaust carries away the heat-bearing medium from the material to be heated, and unless proper control is exercised, this defect may more than counterbalance the increased rate of removal of vapour.

In the *vacuum* process the material is enclosed in an air-tight receptacle, from which the air may be exhausted to any desired extent. Heat is then applied, and the vapour pumped off as fast as it is produced. Considerable experience is necessary in the application of this process, which, properly applied, is highly efficient and rapid.

In the *plenum* process the vapour is removed by supplying sufficient warm air to create an augmentation in air pressure. A fan is usually employed for this purpose, and drying must, of course, take place in an enclosed room with regulated egress for the air. This process is usually the best to employ, since it can be maintained strictly under control.

Drying installations. Drying floors. *Natural floors* are not often used, since serious difficulties arise as to heating, handling the material, and removing the vapour. Haymaking affords a good instance of its employment.

Artificial floors warmed by the products of combustion from a furnace, by hot gases, or by steam passing in flues or pipes beneath, are a considerable improvement on natural floors. Advantage is taken in constructing them of any convenient sandy or porous ground floor; sand is put down if the natural ground is clayey.

These floors are used for drying china clay, calcium phosphate, barytes, chalk, cement, and calcined quartz, materials which are not readily injured by excessive or irregular heating.

Drying gentries or racks. These are employed in order that as much surface as possible may be exposed to air currents. Their construction assumes various forms. According to circumstances, they may be either skeleton shelves, or racks, or props, &c. Occasionally hot water or steam pipes are used as supporting racks, but their use is to be avoided as uneconomical, and tending to produce uneven drying and distortion.

Such substances as damp corn, peat, raw rubber, chalk, bricks, and clayware are frequently dried on open racks, while pigments in colour works are often dried in open gentries or skeleton shelves.

Drying sheds. These are merely drying floors or gentries provided with roofs to keep off rain and snow. These sheds are best constructed of light open framing in order to facilitate the removal of vapour, and the more open

it is on all sides the better, provided that the substance is not such that direct sunlight must be excluded from it, *e.g.* rubber. Such sheds are highly efficient in producing 'air-dried' materials. Bricks are often dried in sheds erected on drying floors, while Chile saltpetre is dried in sheds without the application of artificial heat, as also are china clay and ochre in the quarry state.

Drying pans and troughs. Drying pans, correctly designed and handled, are very useful appliances. The oldest commercial use of such pans is in the evaporation of salt brine, which, as usually carried out, is not at all an economical process. The pans are usually rectangular, and each stands in its own shed. They are directly heated, three or four fires being beneath each pan.

Shallow earthenware pans are of great use in the colour trade, the pigments being readily dried if the pans are carefully arranged on gantries in well-heated and ventilated chambers.

Semi-cylindrical iron pans heated from below by gas or steam give good results in drying soft materials, especially powders. They are most efficient when provided with revolving grids for mechanically stirring the wet material and with valve outlets at the bottom for automatically discharging their dried contents.

Granulated sugar is dried in a type of troughed pan, through which passes a hollow 'conveyer' carrying hollow paddles. Steam is blown through the conveyer and paddles. The trough is jacketed on one side, and through this jacket air is blown into the bottom of the trough. The sugar is fed into the hot end, and automatically carried by the heated paddles to the outlet at the cool end of the trough.

Kilns. These are buildings containing a furnace, the direct heat of which is used for drying materials by allowing the products of combustion to pass through them. For substances which may be strongly heated without damage, kiln-drying is an economical method of procedure, since the walls of the kiln are very effective in saving heat that would otherwise be lost; but care must be taken to provide proper exits for the vapour.

A primitive type of kiln is one in which calcium phosphate is dried. It consists of a plain rectangular brick building with a wooden roof. The floor is piled with wood, and the phosphate placed upon it. Flues admit air for combustion and circulation. Such a kiln will burn for from 2 to 5 days and dry from 1000 to 1200 tons of phosphate.

Kilns for drying clays, fuller's earth, barytes, and chalk are constructed upon the same principle, the fire being placed so as to prevent the ashes mixing with the material; the latter is sometimes supported within the kiln on iron racks.

A rotating bed dryer is in extensive use for drying materials which allow of direct firing. The material is placed on a circular cast-iron bed, which slowly rotates on a vertical shaft. The bed is covered by a firebrick arch, into which the exit flue leads. Heating is done directly by fires, and stationary blades fixed in the arch stir the material as it is drying. The blades are fixed at such an angle that the material is slowly moved from the centre,

above which the feed is situated, to the edge, where it is automatically discharged. This is a common type of drying kiln for ores.

Drying cylinders. This term includes those dryers in which the material to be dried is contained in a cylindrical tube, which is slowly rotated. The essential feature of their construction is that the rotation of the cylinder affords the means of moving the material along. With suitable materials and the necessary power, cylinders will automatically deliver large quantities of uniformly dried product, with the minimum of labour and fuel consumption. They are consequently extensively used, and many types of drying cylinders have been devised.

For materials that withstand high temperatures, the heating may be carried out by passing the hot gases from a furnace through the tube. The latter is constructed of steel, and is mounted nearly horizontally (slope of 1 in 12), with the furnace at the lower end. The feed is situated at the higher cold end, and the gases pass out through a flue at this end, connected with a fan or chimney. As the material gravitates down the tube it is dried, and on reaching the lower end, it drops out, quite dry, into trucks. A modification of this construction consists in enclosing the steel tube in a horizontal brickwork chamber, and heating it externally by passing the furnace gases into this brickwork chamber, whence they pass through a series of external hooded openings into the steel cylinder itself. This arrangement allows of a more gradual and systematic heating, while dust and other objectionable parts of the products of combustion may be arrested prior to the gases entering the cylinders. Besides these two arrangements, many others have been devised, each having its particular advantages.

Cylinder dryers are very suitable for heating by steam, thus meeting the requirements of such substances as sugar, salt, soda, cocoa, coffee, &c., provided they contain not more than 25-30 p.c. of moisture. The drying cylinder may be either steam-jacketed externally, or internally, or by both methods united. The exhaust is best taken by means of a fan at the feed end of the cylinder. In using such dryers for sugar, they are employed in conjunction with a conveyer trough dryer (*v. supra*), into which the sugar falls after passing through the steam-heated cylinder.

Drying rollers. These are heated rotating cylinders, with the outside periphery of which the material to be dried is brought into contact. They are made of steel, cast iron, copper, or tinned iron, and are usually heated by passing steam or hot air through their interior. Another method of heating consists in coating the cylinder externally with felt and rotating it in a polished iron bed, against the under surface of which steam is blown. The material to be dried is automatically passed between the roller and its bed, and the rollers are usually arranged in series of two to eight.

The latter method is largely employed in laundry work, and the use of drying rollers is extensive in the paper and textile trades.

Drying tunnels. These consist essentially of a stationary passage through which the material passes either continuously or intermittently as the drying proceeds. Drying in a

tunnel is progressive from one end to the other. Heat may be applied either by direct firing or by heated air, which passes into the tunnel from beneath one end and travels along to the other. The warm air current usually travels in the opposite direction to that in which the material moves, but not always, as, for instance, in the drying of wool, where the pressure of the warm blast is utilised in blowing the material forward. The vapour-laden air may be removed either by chimney, exhaust, or by pressure fan, while the material may be handled in a very large number of ways, according to circumstances. This method of drying is economical, but the initial cost of plant is often considerable.

In drying timber, the material is carried on special trucks running on a tram track. The air is heated by means of a heater coil fed with steam and situated under the track at the discharging end. The air ascends, dries the timber, thereby becoming cooler and denser, and then, pressed forward by the incoming air, it gravitates into a large space beneath the feeding end of the tunnel and passes up the flue. Wool is dried in a tubular tunnel, being blown along by the warm air. Soap is dried by passing it on trolleys through narrow tunnels, usually arranged in fours, through which warm air is driven by means of a propeller. In particular, bricks and clayware are dried by passing them through drying tunnels, for which purpose a very large number of types of plant have been devised.

Drying rooms. These are enclosed spaces, which are warmed by means of hot air, and into which the loader or discharger has to enter. When not constructed of brick or stone, the material of the walls should be chosen for its insulating qualities.

The expense attached to drying by this method is due largely to the manual labour required in handling the material, which arises, in most cases, from the fact that the peculiar properties of the material render it impossible to utilise mechanical methods. Since manual labour in a heavily moisture-laden atmosphere is unhealthy, desiccation in drying rooms is restricted in practice to those materials for which the process is unavoidable. Such products as hops, confectionery, leather, paper, textile fabrics, pottery, and rubber are dealt with by this method.

The materials are supported in the most convenient manner within the chambers, and warm air circulated either through or over them. The warming of the air may be accomplished either within or without the compartment, by means of radiators, and, if desired, the same air can be used continuously in a circuit (compare the condensation process, p. 210).

Drying ovens. These are entirely enclosed drying chambers; the necessary heat for the purpose is not generated within them, neither is it necessary to enter them in order to charge or remove the material to be dried. Ovens can be adapted to suit a wide range of conditions, and some of the most scientific and economical dryers are of this type.

A great variety of methods are available for the purpose of heating, since the heat is generated outside the oven. Products of combustion are

readily excluded from the material. There is no necessity for the plant to cool down before the dried product is removed, and hence heat losses are greatly minimised. Heat is applied to the material either by means of hot gases, usually hot air, or by direct conduction through metallic plates, as, for instance, in steam ovens. Vapour is usually removed mechanically, either by pressure or exhaust, but it may be pumped off, as, for instance, in all vacuum machines. Ovens are more efficient than drying rooms, since the latter are frequently used for other purposes than drying, whereas the former are designed exclusively for drying. Only a few types of drying ovens can be here described.

Laboratory ovens are rectangular boxes, constructed of copper, iron, or aluminium, which may be either steam- or air-jacketed, or in simple ovens not jacketed at all. The substances to be dried are supported on shelves inside. With air ovens heat is applied directly at the bottom of the oven or of the outer jacket. A ventilator situated at the bottom of the oven door allows air to enter, and one or more chimneys in the lid allow the warm vapour-laden air to escape. A convenient method of heating, which can be readily controlled, consists in heating electrically, by passing a current through a number of resistance coils embedded in the jacket surrounding the oven. (See also ANALYSIS, Vol. I.) Removable tray dryers are largely used for drying tea, coffee, cocoa, cinchona bark, &c. The trays are arranged in the oven in a series of rows. Each tray has a separate slide, and is independent of the others, and each column of trays has its own regulating damper for the hot air. The method of working is progressive, the wet material being first placed in the top tray of the column and passed downwards stepwise to the bottom. The heat required is supplied from a multitubular furnace, which also produces the air current which aerates the material. The hot air may be allowed to rise through the material, or be drawn down by two centrifugal fans on either side of the centre through the substance. The latter arrangement is more readily controlled, gives a larger output, and affects a considerable saving in height. A modification that gives an even larger output is that which consists in causing each horizontal line of trays, commencing with the lowest, to automatically tilt and discharge its contents into the base of the dryer. For drying other substances than those mentioned above, many other types of tray ovens have been devised.

Sliding-panel dryers are used in laundries, and can also be adapted for drying yarns, piece goods, &c. They consist of a row of vertical sliding panels, built up with hanging rods to form rigid horses for the goods. They are readily movable on runner wheels, and each panel may be withdrawn independently of the others, with the minimum loss of heat, as the back of the panel closes the outlet and thus reshuts the oven. A hot-air blast is supplied from above, and after passing through the oven it discharges into the open.

The Lennox plate-oven dryer is a type which has many advantages, is compact, and occupies a small floor space. The outer vertical cylindrical casing is built up in sections to allow for extension and renewal. A concentric cylindrical

drum slowly rotates inside. At each external section there is a horizontal metal plate within the apparatus, and each section plate contains a hole; these holes are not vertically above one another. The material to be dried is fed in at the top, falls on the first section plate, and is slowly stirred round by horizontal arms on the rotating centre drum till it reaches the hole in the plate. It then falls through on to the next plate, is slowly stirred round till it falls on to the third plate, and so on, till it is discharged at the base. Hot air is blown in at the base, and passes upwards into the central drum, from which it issues, through numerous holes in its sides, passes through the material, and thence upwards and outwards.

A horizontal steam-jacketed cylindrical oven, containing a very powerful and thorough agitating gear inside, is used for drying wet pasty materials like meat, fish, &c. The material is fed in at the top, and discharged as a dry, mealy powder through a manhole in the bottom. The vapour is removed from the interior through a large outlet duct operated either by a fan or pump according to circumstances. In vacuum ovens the removal of vapour by means of air or other gases in motion is discarded in favour of pumping away the vapour from the warmed-up material, operating in a closed space and diminishing the pressure within it to any desired extent. The oven must be strongly built, and all joints must fit tightly to maintain the diminished pressure. The material may be supported inside in any suitable manner, for instance, on steam-heated grids. The necessary accessories are a vacuum pump, a condenser for the vapour and a receiver for the condensed water. The latter is provided with a sight glass in order to tell when no more water is given off by the material in the oven. The effective working of such a plant depends largely upon the observance of various mechanical and engineering points; the chief feature of the vacuum process is the saving of time that it effects. The oven may be designed to suit either solids or liquids, and provision may also be made for effectively stirring the material during the drying process.

Desiccators. (For an account of laboratory desiccators, *v.* this article, p. 210.)

A desiccator is any type of drying machine, which, working by evaporation, carries the degree of drying to the utmost possible extent. In some of the types previously described, it is difficult to prevent thorough desiccation, and, in fact, to avoid dehydration and calcination, but a number of machines have been devised for the effective desiccation of liquids and thin pastes, which work upon a common principle that may be briefly explained. It consists in spreading the liquid in a thin film over a heated metallic surface kept in motion, and, when the water has been removed, skimming off the solid residue with a knife. By suitable arrangements, this process can be made continuous, and it is employed on a large scale for desiccating milk to a dry powder. A modified method of removing the desiccated product is to cause the liquid to spread out on the upper part of an endless horizontal metallic belt, working over two rollers contained in a heated chamber under reduced pressure. The heated liquid, being fed on to the

belt at one roller, is desiccated by the time it arrives at the other, and, on the belt passing over that roller, the dry powder falls into the delivery hopper beneath.

Literature.—Marlow's *Drying Machinery and Practice*, which contains a bibliography of the subject.

DETONATORS *v.* EXPLOSIVES.

DEXTRAN *v.* GUMS.

DEXTRINS $n(C_6H_{10}O_5)_n$. When diastase acts on starch paste (gelatinised starch), maltose is the final product, but, intermediate between the starch and maltose, various dextrans are formed as the reaction proceeds in successive stages. These dextrans are colloidal amorphous compounds, and do not form characteristic derivatives. They are soluble in water, and precipitated by alcohol. Only maltodextrin, which is possibly the simplest of them, has been prepared in anything like a state of purity, and most of the other dextrans described must be regarded as mixtures.

As diastatic hydrolysis proceeds, the optical rotatory power diminishes, and the cupric-reducing power increases. The change is rapid to a certain point, but then becomes arrested: this behaviour is interpreted as proof of an essential difference between the higher and lower dextrans. The constants of this stage of hydrolysis are $[\alpha]_D = 162.5^\circ$, K (cupric-reducing power) = 48.3, and correspond to the conversion of four-fifths of the starch into maltose. The remaining dextrin is hydrolysed with greater difficulty. According to H. Brown, it cannot have a simpler formula than $40(C_6H_{10}O_5)_4H_2O$.

The dextrin isolated from a starch conversion stopped at a stage which gives a deep brownish-red colouration with iodine, is termed *erythro-dextrin*. At a later stage iodine ceases to give a colouration, and the dextrin present is termed *achro-dextrin*. These dextrans have little or no cupric-reducing action, this point being still undecided.

Dextrans are also formed by the action of hot dilute mineral acids, or of heat alone on starch. The final product in this case is dextrose instead of maltose. These methods are used for the commercial preparation of dextrin.

Maltodextrin $6(C_6H_{10}O_5)_6H_2O$ has $[\alpha]_D +193.6^\circ$, $[\alpha]_D +181^\circ$; cupric-reducing power, 42. These figures agree with a mixture of 1 part maltose to 2 parts dextrin; but the facts (1) that it cannot be separated into maltose and dextrin by dialysis, (2) that it is not fermentable by yeasts, (3) that it is completely converted into maltose by diastase, prove maltodextrin to be a definite chemical compound. To prepare it, a starch transformation is carried out at $60^\circ-65^\circ$, until $[\alpha]_D = +198^\circ$. The solution is boiled, concentrated to a sp.gr. of 1.06, and the maltose removed by fermentation. The solution is filtered, evaporated to a syrup, and digested with alcohol first of 90 p.c., and then of 85 p.c. This last liquid is decanted hot, and the alcohol distilled off, when maltodextrin remains; it is purified by further treatment with alcohol.

On oxidation of maltodextrin with mercuric oxide, until the cupric-reducing power has disappeared, maltodextrinic acid is obtained. This behaviour proves maltodextrin to contain

an aldehyde group, but the change goes further than the oxidation of this group to carboxyl (CO_2H), since it splits up the terminal C_{12} group into a C_5 acid residue, which remains attached to the rest of the molecule, and a C_6 residue which is eliminated.

(For a full account of the decomposition products of starch, v. STARCH.)

Manufacture.—The commercial products known as solid dextrin, British gum, starch gum, &c., are mixtures containing various dextrans, together with carbohydrates (copper oxide reducing substances). They consist mainly of erythro-dextrin, and accordingly give a brown iodine colouration.

They are prepared (1) by the action of heat on dried starch; (2) by the action of heat on acidified dried starch.

The starch is first freed as much as possible from combined water by drying in suitable ovens, and then submitted to a temperature of 212° – 275° in rotating sheet-iron drums. The heat is supplied by hot oil, rape oil being pretty generally used, or by direct fire. When the oil-bath is used, the control over the temperature is greatest, and the colour of the product can be varied at will from white to dark-brown. When the drums are heated by direct fire, they are made to rotate on slightly inclined axes, the dried starch being fed in at the higher end of the revolving cylinder and the product discharged at the other. Sheet-iron ovens are also used; they are constructed singly or in sets. The heat is supplied by a furnace, the heated air from which is drawn over the top of the ovens. The material is kept continually stirred by flat iron oars. Boxes and trays are also used as converters, and, indeed, the maker has only to consider the variety and quality of product required, and to remember that the drier the starch and the lower the temperature of conversion, the whiter will be the product, and, further, that different starches yield different products, *i.e.* behave differently when submitted to the action of heat, to enable him to construct an apparatus that will suit his requirements. It must also be borne in mind that the conversion takes place more slowly at a low temperature.

The alternative method, in which less heat is required to yield a satisfactory product, is to spray or moisten the starch either with a mixture of dilute nitric and hydrochloric acids, or with each acid singly, or with dilute oxalic acid. The paste is dried and heated at 100° – 120° or to 150° , till the transformation is complete, as determined by the iodine test; it must then be arrested promptly.

Payen recommended 1000 lbs. starch to be moistened with 30 gallons water containing 2 lbs. nitric acid (sp.gr. 1.38), the mixture to be well kneaded, made up into balls, and dried in a hot-air chamber; then powdered, spread on brass trays to the depth of $1\frac{1}{2}$ –2 inches, and submitted to a temperature of from 110° – 120° in a hot-air oven.

The products thus obtained appear in commerce in the form of powders varying in colour from almost white to dark-brown, through every shade of light-yellow and brown. They are reduced to this state after roasting, by crushing in pans or passing through rollers, and then sifting

through a rotating silk screen such as is used in flour mills.

Dextrans prepared from powdered starch are used by textile manufacturers and calico printers as vehicles for colours. They are also used for all kinds of gum, paste, sizings, and in the manufacture of paper boxes, wall paper, and for a variety of other purposes.

On heating dry starch with formic or acetic acids, the starch nucleus is broken down and esters of dextrans are formed, which are soluble in cold water. The proportion of acid fixed depends on the time of treatment. After 15 hours' heating with glacial acetic acid at 90° , the product just ceases to give a blue iodine colouration, and the products of the further heating are soluble in cold water. When care is taken to exclude moisture, and the heating is continued for 2 or 3 hours only, using equal weights of starch and glacial acetic acid, an acetylated starch, known commercially as *Feculose*, is obtained. This behaves like starch towards boiling water, but the jelly does not revert on standing. It forms very clear flexible films, and is said to give better results than dextrin as a textile finish (*see* Traquair, *J. Soc. Chem. Ind.* 1909, 28, 288).

Dextrin syrups find employment in a variety of industries. They are prepared from starch by heating it with hydrochloric or sulphuric acids in precisely the manner already described for dextrose (*v.* CARBOHYDRATES), with the exception that conversion is stopped at a much earlier stage. Thus in the modern American process of manufacture of corn syrup from maize starch, less than 10 minutes' heating is required. The product evaporated to 42° – 45°B. forms a colourless viscous syrup, having the composition water, 19 p.c.; dextrose, 38.5 p.c.; dextrin, 42.0 p.c.; ash, 0.5 p.c.

In America corn syrup is used extensively in making confectionery, preserves, and table syrups, being preferable to sugar or cane syrup, as the goods are not likely to grain.

Dextrin may also be prepared by the action of malt extract on gelatinised starch.

E. F. A.

DEXTROSE *v.* CARBOHYDRATES.

DHAURA. A gum obtained from *Anogeissus latifolia* (Wall.). It is extensively used in India in calico-printing; it occurs in clean straw-coloured elongated masses, sometimes honey-coloured or even brown from impurities. As an adhesive gum, it is inferior in strength to gum arabic. In India, the reputation of this gum stands high with the calico printers, especially of Lucknow, and it is probable it possesses some specific peculiarity justifying the preference, since it is used with certain dyestuffs, such as with haldi (*Curcuma longa* [Linn.]), whilst gum arabic or 'babul' is used with madder (*Rubia cordifolia* [Linn.]) (Watts' Economic Products of India).

DHURRIN *v.* GLUCOSIDES.

DIABETIN. A trade name for a preparation of lævulose.

DIACETYL *v.* KETONES.

DIACETYLDIOXIME *v.* KETONES.

DIALKYL BARBITURIC ACIDS *v.* PYRIMIDINES.

DIALOGITE. *Manganese carbonate* (*v.* MANGANESE AND RHODOCHROSITE).

DIALURIC ACID, *Tartronylurea*

prepared by reducing alloxan with zinc and hydrochloric acid, or with sulphuretted hydrogen at the temperature of boiling water (Liebig and Wöhler, *Annalen*, 26, 276), or with ammonium sulphide, when ammonium dialurate is obtained and is readily converted into the acid by the action of hot dilute hydrochloric acid (Gregory, *Chem. Soc. Mem.* 1845, ii. 11). A mixture of potassium dialurate and oxalurate is obtained by adding potassium carbonate to a solution of alloxan containing potassium cyanide (Strecker, *Annalen*, 113, 53); it is prepared by reducing alloxantin with sodium amalgam, or dibromobarbituric acid with sulphuretted hydrogen (Baeyer, *Annalen*, 127, 12; 130, 133). Magnier de la Source showed that dialuric acid is obtained by prolonged boiling of uric acid with water (*Bull. Soc. chim.* 1875, 23, 529), and Grimaux effected its synthesis by treating tartronic acid and urea with phosphorus oxychloride (*Compt. rend.* 1879, 88, 85).

Dialuric acid forms colourless short four-sided prisms, sparingly soluble in cold, more readily so in hot water. The moist crystals or the aqueous solution rapidly absorb oxygen from the air to form alloxan, which combines with the dialuric acid, forming alloxantin. The rate at which the change takes place is illustrated by the results obtained by Hartley (*Chem. Soc. Trans.* 1905, 87, 1804), in an unsuccessful attempt to obtain the absorption spectra of dialuric acid: 0.144 gram of pure dialuric acid was dissolved by agitation and warming in 100 c.c. of water, and immediately afterwards the solution yielded the same series of absorption spectra as a solution of 0.322 gram of alloxantin, dissolved in 250 c.c. of water. Alloxantin is also formed by mixing solutions of equivalent quantities of dialuric acid and of alloxan. Dialuric acid is monobasic, and, contrary to the statements of Menschutkin (*Ber.* 1875, 8, 760; *Annalen*, 1876, 182, 70), forms only one series of salts of the type $\text{C}_4\text{H}_3\text{O}_4\text{N}_2\text{M}$. The sodium, potassium, ammonium, and barium salts are crystalline (Koech, *Annalen*, 1901, 315; Behrend and Friederich, *Annalen*, 1906, 344, 1).

crystallises in white prisms or leaflets; m.p. 210°–212°; gives a violet precipitate with barium hydroxide; forms the potassium salt $\text{C}_6\text{H}_5\text{O}_5\text{N}_2\text{K} \cdot \text{H}_2\text{O}$, and combines with alloxan to form *acetylalloxantin* $\text{C}_{10}\text{H}_8\text{O}_8\text{N}_4 \cdot \text{H}_2\text{O}$, m.p. 263°–265°; *benzoyldialuric acid* $\text{C}_{11}\text{H}_8\text{O}_5\text{N}_2$, crystallises in prisms, m.p. 209°–210°, yields with barium hydroxide a white precipitate, turning violet, and combines with alloxan to form *benzoylalloxantin* $\text{C}_{15}\text{H}_{10}\text{O}_8\text{N}_4 \cdot \text{H}_2\text{O}$ or $\frac{1}{2}\text{H}_2\text{O}$, m.p. 253°–255° (Behrend and Friederich, *Annalen*, 1906, 344, 1–18).

Substituted dialuric acids of the type

are obtained by the condensation of alloxan with (1) aromatic ketones, e.g. phenacetyldialuric acid, where $\text{R} = \text{C}_6\text{H}_5 \cdot \text{CO} \cdot \text{CH}_2 -$; (2) aromatic amines, e.g. *p*-aminophenyltartronylurea, where

(3) pyrazolone bases, e.g. phenylmethylpyrazolonetartronylurea, where $\text{R} = \begin{array}{c} \text{NPh} \cdot \text{CO} \\ \text{NMe} \cdot \text{CMe} \end{array} -$;

(4) phenols, e.g. *p*-hydroxyphenyltartronylurea, where $\text{R} = \text{OH} \cdot \text{C}_6\text{H}_4 -$. For the preparation and technical application of these compounds, see art. ALLOXAN.

Dimethyldialuric acid

obtained by reducing amalic acid (tetramethylalloxantin) with sulphuretted hydrogen (Maly and Andreasch, *Monatsh.* 1882, 3, 92), or with sodium amalgam (Tschow, *Ber.* 1894, 27, 3082), forms colourless compact crystals which become red at 100° and decompose at 170°. It forms crystalline alkali salts, and reduces cold solutions of silver and copper salts.

iso-Dialuric acid

or $\text{CO} \begin{array}{c} \diagup \text{NH} \cdot \text{CH}(\text{OH}) \\ \diagdown \text{NH} \cdot \text{CO} \end{array} \text{CO}_2 \cdot 2\text{H}_2\text{O}$, obtained by the action of bromine water on *iso*-barbituric acid

or $\text{CO} \begin{array}{c} \diagup \text{NH} \cdot \text{CH} \\ \diagdown \text{NH} \cdot \text{CO} \end{array} \text{C}(\text{OH})$ or aminouracil or hydroxyxanthine (Behrend and Roosen, *Ber.* 1888, 21, 999), crystallises in trimetric prisms sometimes a centimetre long (Weinschenk, *Annalen*, 1889, 251, 243), is readily soluble in water, less so in alcohol; it loses one molecule of water of crystallisation at 100°. The other molecule, which is regarded as water of constitution, is lost at 140°–150°, at which temperature the compound decomposes. *Isodialuric acid* is converted into dialuric acid by the action of bases (Koech, *Annalen*, 1901, 315, 246). It yields uric acid on condensation with urea, reduces solutions of silver salts, and combines with hydroxylamine to form two isomeric *oximino*-compounds. The α -oxime forms shining plates or prisms, becomes red and decomposes at 100°; the β -oxime crystallises in needles which do not become red at 110° (Behrend and Roosen, *Annalen*, 251, 244).

Methylisodialuric acid $\text{C}_7\text{H}_8\text{O}_5\text{N}_2$, prepared by oxidising methylisobarbituric acid (Lehmann, *Annalen*, 1889, 253, 80) with bromine water, crystallises in rosette-like aggregates from water, and in contradistinction to *isodialuric acid*, contains only 1 molecule of water, which is regarded as water of constitution. DIAMINOACRIDYLBENZOIC ACID v. ACRIDINE DYESTUFFS.

DIAMINOBENZENES, DIAMINOTOLUENES v. AMINES.

DIAMOND. A natural form of carbon, crystallising in the cubic system. The commonest forms are the regular octahedron, the rhombic dodecahedron and the six-faced octahedron, all others being subordinate to these, and occurring

generally in combination with them. The forms are, to some extent, characteristic of the locality: thus the octahedron is common in Cape stones, while Brazil yields rhombic dodecahedra and six-faced octahedra. It is notable that the faces of diamond crystals are often curved, and the six-faced octahedron, with its 48 rounded faces, may become almost a sphere. The curvature is in some cases due to a lamellar structure (*Schalenbildung*), the component lamellæ regularly decreasing in size towards the centre of each face. In a glazier's diamond, it is necessary that the cutting edge be cusped. The faces of diamond crystals are often striated parallel to the edges of the octahedron; they also exhibit impressions, or indentations, frequently of triangular shape, and it is noteworthy that similar impressions may be artificially developed, as shown by G. Rose, by subjecting diamonds to intense heat, without access of air (Ueber das Verhalten d. Diamants u. Graphits bei d. Erhitzung, Monatsb. Berl. Ak. 1872, 516).

The frequent occurrence of triangular depressions on Cape diamonds has been adduced as proof of their exposure to subterranean heat.

Twin crystals of diamond are not uncommon; and flat triangular hemitropes, splitting easily along the plane of union, are known to the Amsterdam workers as *Nahsteine*. (On the crystallisation of diamond, v. Sadebeck, Monatsb. Berl. Ak. 1876, 578; Hirschwald, Zeits. f. Krystal. i. 1877, 212; and Weiss, N. Jahrb. f. Min. 1880, ii. 12.)

The cleavage of the diamond is perfect and parallel to the faces of the octahedron. The cutter frequently takes advantage of this cleavage in removing portions disfigured by flaws, and in dressing rough stones to be cut as brilliants. Notwithstanding the ancient belief that a true diamond could bear the blow of a hammer, it is rather a brittle stone, not only splitting along the cleavage planes, but breaking elsewhere with a conchoidal fracture. The hardness of the diamond is indicated as 10 on the mineralogical scale, but it is so greatly superior to that of any other mineral that this is merely an arbitrary expression. Crystals from different localities vary considerably in degree of hardness: thus, lapidaries assert that Indian diamonds are harder than the Brazilian, and these, again, harder than South African stones; whilst those from New South Wales are the hardest of all. The hardness may vary on different faces of a single crystal, and even in different directions on the same face. The sp. gr. of diamond ranges from 3.509 to 3.550, the mean being about 3.514 (Schrötter). Baumhauer determined the density of a nearly colourless Cape diamond to be 3.51812.

Diamonds vary greatly in colour. The purest, or stones of the 'first water,' are practically colourless; while certain stones, known as 'blue whites,' incline to a faint bluish tint; the best example of this type being the Porter-Rhodes diamond—a stone of 150 carats, found at the Cape in 1880. Most of the 'off-coloured' stones present yellow or brown tints; the colour cannot be discharged by heat, but yellow diamonds have sometimes been fraudulently washed with dilute violet ink, whereby the tint is superficially neutralised. The dark colour of some diamonds has been doubtfully referred to

the presence of crowds of minute internal cavities, revealed by microscopic examination (Brewster).

Whole off-coloured stones are of comparatively small value, those which possess a pronounced and pleasing colour are highly prized as 'fancy stones.' A deep-red colour is the rarest. The famous 'Hope Blue' diamond of 44½ carats is of a dull slaty-blue; while the 'Dresden Green' diamond, in the Grüne Gewölbe in Dresden, presents a delicate green colour.

The index of refraction is higher in diamond than in any other transparent gem-stone. According to Des Cloizeaux, it is 2.414 for red rays, and 2.428 for green. It was the high refraction of diamond that led Newton to conjecture that it might be 'an unctuous substance coagulated.' The character of the lustre is known as adamantine. Much of the brilliancy of the faceted brilliant is due to its small critical angle (24° 24'), since a very large proportion of the rays entering the diamond must be necessarily returned by total reflection. The coefficient of dispersion is higher than in most transparent bodies; it is given by Jannettaz as 0.044. Examined in polarised light, many diamonds exhibit an anomalous behaviour, apparently due to internal strain. Brewster, who supposed that the diamond might have been originally a vegetable gum, explained the depolarising action which certain diamonds display between crossed nicols as the result of tension caused by included bodies. Chatrian has found a crystal of iron-pyrites in a Brazilian diamond.

After exposure to solar light, the diamond becomes highly phosphorescent, and different faces of the same crystal may emit rays of different colours. Submitted to molecular discharge in Crookes's exhausted tubes, the diamond glows with great brilliancy. On exposure to the heat of the electric arc, it swells up, cracks on the surface, and becomes coated with a substance resembling graphite. In its ordinary state, the diamond does not conduct electricity, but the coke-like mass obtained by exposure to the arc is a good conductor.

The study of the action of heat upon the diamond, with and without the presence of air, gave the earliest clue to its chemical composition. The famous experiment of the Florentine academicians, Averani and Targioni, made in 1694, at the instance of the Grand Duke Cosmo III., showed that it could be volatilised by heat. In 1751 the Emperor Francis I. caused a quantity of diamonds and rubies to be placed in a crucible and exposed to great heat, when it was found that the diamonds disappeared, while the rubies were fixed. Darcet afterwards showed that, though the diamonds vanished if heated in an open crucible, they remained unaltered if air were completely excluded. In 1772 Lavoisier demonstrated that the diamond is truly combustible, and yields carbon dioxide; and it was subsequently shown by Smithson Tennant that equal weights of charcoal and of diamond gave equal weights of this gas. By heating diamond with iron, Guyton de Morveau obtained steel, and thus indirectly showed the probable composition of the mineral. The experiments of Davy, in 1816, proved that the diamond was practically pure carbon: a result confirmed by

the refined investigations in determining the atomic weight of carbon by Dumas and Stas, and subsequently by Roscoe and by Friedel. The behaviour of diamonds when exposed to high temperatures in various gaseous media has been studied by M. Morren (Compt. rend. 70, 990).

On the combustion of the diamond, there remains a quantity of a colourless or reddish ash, varying from one five-hundredth to one two-thousandth of the original weight of the mineral. Microscopic examination of this delicate spongy ash led Göppert, Petzholdt, and others to believe that it shows traces of cellular tissue, suggestive of a vegetable origin.

Various hypotheses have been advanced to explain the origin of the diamond, but these have rarely been subjected to experimental verification or disproof. Liebig suggested the decomposition of liquid hydrocarbons, while Chancourtois and others have resorted to hydrocarbonaceous vapours. Carvill Lewis, basing his opinion on the occurrence of diamonds in South Africa, derived the mineral from the action of eruptive rocks on carbonaceous shales (Geol. Mag. 1887, 22). As many of the minerals associated with the diamond in Brazil have been formed artificially by the decomposition of chlorides at a high temperature, it has been suggested by A. Favre that the decomposition of chloride of carbon may have yielded the diamond. Gannal attempted to obtain it from carbon disulphide. Reviewing the geological conditions under which diamonds occur in various parts of the world, it is seen that these are so different in different localities as to suggest that the natural process of diamond-making has not been uniform. Thus, in Brazil and in India the diamond appears to be associated with acid rocks, while in South Africa it occurs in a highly basic rock, resembling an altered peridotite.

The artificial production of diamond, though many times attempted with doubtful results, was successfully accomplished by H. Moissan, in 1893, by the crystallisation of carbon from its solution in iron at a high temperature and under enormous pressure. This was effected by plunging molten iron from an electric furnace into cold water; the contracting crust so formed holding the molten interior under pressure. The largest crystal of diamond so obtained measured $\frac{1}{2}$ mm. across. Microscopic crystals have also been obtained by I. Friedländer (Geol. Mag. 1898, 226) and by R. v. Hasslinger (S. B. Ak. Wien, 1902, 111, ii. b, 619; 1903, 112, ii. b, 507), by dissolving carbon in molten olivine.

The most ancient diamond-mines are those of India, whence the precious stone has been obtained from remote antiquity. The Indian diamonds are found in river gravels, and in superficial deposits scattered over the country, while occasionally they occur in sandstones of the Vindhyan formation, but these probably do not represent the original matrix. In 1884 Chaper announced the discovery of the diamond in a pink pegmatite, at Bellary in Madras (Compt. rend. 1884, 98, 113), but this seems doubtful. Diamonds have been worked in three extensive districts in India. The mines of the most southern group are partly in the Madras Presidency and partly in the territory of the Nizam, the most famous workings having been those on

the Kistna and Godavery rivers, improperly known as the mines of Golconda. The 'Golconda' district yielded most of the great historical diamonds, such as the Koh-i-nur, the Regent, and the Great Mogul; and workings have been reopened at Partial (W. Morgans' Report, 1889). Diamonds also occur in the districts of Cuddapah, Bellary, and Karnul, but most of the mines are now abandoned. In 1881 a diamond of irregular shape, weighing 67 $\frac{3}{4}$ carats, was found near Wajra Karur, in the Bellary district, and yielded a fine brilliant of 24 $\frac{3}{4}$ carats, known as the 'Gor-do-Norr' (Mallet). Another group of diamond localities is situated in the Central Provinces: at Sambalpur on the Mahanadi river, and at Wairagarh. The mineral is also found in Chutia Nagpur in Bengal; while further to the north is a third group of mines, including those of Panna in Bundelkhand, still worked on a limited scale. (On Indian diamonds, v. Manual of the Geol. of India: vol. 3, Economic Geology, by V. Ball, 1881; and vol. 4, Mineralogy, by F. R. Mallet, 1887.)

Although the sands of many of the rivers of Brazil had been long worked for gold, it was not until 1727 that the occurrence of diamonds in association with the precious metal was observed. The distribution of the diamond is extensive, occurring locally in the states of Minas Geraes, Goyaz, Bahia, Matto Grosso, Parana, and São Paulo. The best-known locality is Diamantina, formerly calle Tejuco, in Minas Geraes. The diamond occurs in gravels mixed with clay, and forming a loose conglomerate known as *cascalho*; while if the quartz pebbles are less rolled, as in the plateau gravels, it is termed *gurgulho*. The diamond is said to have been found in a metamorphic sandstone called *itacolumite*, and it is asserted that where itacolumite is not present the neighbouring gravels never bear diamonds. In the Diamantina region, the original matrix seems to be in veins of quartz and clayey matter, carrying iron-pyrites and tourmaline, and traversing a series of hydromica-schists and itabarites, with itacolumite. In the sands and gravels, the diamond is associated with rutile, anatase, brookite, magnetite, hematite, ilmenite, &c. (On Brazilian diamonds, v. papers by Orville Derby in Amer. J. Sci. [3] 24, 1882, 34; and Gorceix in Compt. rend. 113, 1881, 981; H. Pearson, J. Soc. Arts, 58, 1909, 101.)

It appears that the occurrence of diamonds in South Africa was known as far back as the middle of the 18th century, yet it was not until 1867 that attention was recalled to this forgotten discovery. At that time, the child of a Boer farmer near Hopetown, picked up among the pebbles of the Orange river a diamond weighing 21 $\frac{3}{16}$ carats. Search in the neighbourhood soon led to other discoveries, one of the earliest being that of a stone of 83 $\frac{1}{2}$ carats, which came to be known, when cut, as the 'Star of South Africa,' or the 'Dudley' diamond. The earliest workings were 'river diggings,' in the gravels of the Vaal and some of its tributaries, especially near Pneil and Klipdrit. The largest diamond obtained from the river diggings was the 'Stewart,' a stone weighing 288 $\frac{3}{4}$ carats, found in 1872 at Waldeck's Plant, on the Vaal. On the discovery of diamonds in the soil at Du

Toit's Pan, most of the river diggings were abandoned in favour of what were called 'dry diggings.' The principal mines at present worked are those of Kimberley, De Beer's, Du Toit's Pan, Wesselton, and Bultfontein, all within a limited area around the town of Kimberley in Griqualand West. There are also several smaller isolated mines in Griqualand West and in Orange River Colony, in the latter notably the Jagersfontein and Koffyfontein mines. The largest pipe of 'blue ground' is that of the Premier mine, near Pretoria in the Transvaal, which was discovered in 1903; here, in 1905, was found the largest by far of known diamonds, the 'Cullinan,' which weighed in the rough 3025½ English carats (=621.2 grams).

The South African diamonds occur mostly in a serpentinous breccia, filling vertical pipes, which, piercing the surrounding rocks, rise to the surface, where their presence was originally marked by little hills or *kopjes*. A reddish sandy soil occupied the surface, beneath which occurred a deposit of calcareous tufa; this passed downwards into the 'yellow earth,' which finally merged into the so-called 'blue ground.' The yellowish material was simply the upper part of the blue earth more or less altered by surface agencies.

It is now generally believed that the pipes, or chimneys, are ancient volcanic ducts, through which the diamond-bearing material has been brought up from some deep-seated source. The pipes traverse black and reddish shales of the Karoo formation, believed to be of Triassic age, associated with sheets of basaltic rocks, and resting upon a granite base. The edges of the shales are slightly upturned, as if by pressure from below, but they do not show signs of fusion or other alteration suggestive of a high temperature. The walls of the chimneys are smooth, or vertically striated, and between the walls and the contents of the pipes there are occasional hollows lined with crystals of calcite, and sometimes yielding explosive gases, apparently derived from the carbonaceous shales.

The materials filling the pipes consist of fragments of the shales and other neighbouring rocks, usually sharp at the edges and not fused, cemented into a hard breccia by a greenish serpentinous material, chiefly a hydrated ferromagnesian silicate, which is probably an altered enstatite or bronzite (for analysis, *v. Maskelyne and Flight*, *Quart. Journ. Geol. Soc.* 30, 1874, 406). The embedded diamonds are associated with garnets (pyrope), sometimes known in the trade as 'Cape rubies'; with green sapphire, and a peculiar mica, named by Maskelyne *Voalite*, which appears to be an altered biotite. Ilmenite is present, and is sometimes mistaken for carbonado or black diamond. Among the other associates of the diamond are iron-pyrites, magnetite, and zircon. It is notable that the diamonds are often fragmentary, and neighbouring fragments do not correspond, thus suggesting that fracture occurred at some deep-seated point. Much discussion has arisen as to the original character of the blue rock; but most geologists now regard it as an altered volcanic product which was probably brought up in a pasty condition, not at a very high temperature, but perhaps rather like the materials of a mud volcano. Carvill Lewis described the rock as an altered

peridotite under the name of *Kimberlite*, and concluded that the matrix of the diamond in many parts of the world was probably serpentine, resulting from the alteration of an erupted peridotite (*Rep. Brit. Ass.* 1887 meeting, 720).

Until 1885 the diamond-mines of South Africa were worked as open quarries; but, serious difficulty having arisen from falls of the surrounding rock, known locally as 'reef,' systematic underground mining has been introduced. Outside the pipe a shaft is sunk, and galleries are thence driven into the diamond ground. The blue earth, when first hauled up, is extremely hard, but by exposure to air and water it is readily disintegrated, and the diamonds are then separated by washing. (For account of the South African diamond-mines, *v. G. F. Williams*, *The Diamond Mines of South Africa*, 1902, new ed. 1906; P. A. Wagner, *Die Diamantführenden Gesteine Südafrikas*, 1909.)

More recently, diamonds have been found in other parts of South Africa, namely, in Southern Rhodesia and in German South-West Africa. In the latter region, large numbers of small diamonds were discovered in 1908 in the sand-dunes of Lüderitz Bay.

Borneo has yielded diamonds from remote antiquity. They occur in alluvial clays, river sands, and drift gravels; occasionally, too, they have been found in an Eocene conglomerate, but this is a derived rock, and the original matrix is unknown (*v. Posewitz's Borneo*, Berlin, 1889).

In Australia, diamonds are known to occur at numerous localities, especially in New South Wales, but the stones are invariably small. They have been worked commercially in drift gravels on the Cudgegong river, near Mudgee, and at Bingera and Inverell in New South Wales (*v. Liversidge*, *Min. of New South Wales*, 1888, 116). Diamonds have also been found, though but rarely, near Echunga in South Australia, and at Beechworth and elsewhere in Victoria.

Numerous localities for diamonds are known in the United States. They occur in association with gold in North Carolina, in Georgia, and in Butte Co., California; while they are found with platinum in Oregon. A crystal weighing 23¾ carats was found in 1855 at Manchester in Virginia, and after cutting became known as the On-i-nur, or 'Sun of light.' (On diamonds in United States, *v. G. F. Kunz*, in successive volumes of *Mineral Resources*, by United States Geol. Survey.)

Other localities for diamonds are in British Guiana, where stones were first met with in 1890 in the upper courses of the Mazaruni river. The only European localities are in the Ural Mountains, where a few isolated crystals have been found in the gold washings at different times since 1829, and in Lapland.

It has lately been shown that the diamond is to be included in the list of extra-telluric minerals. Microscopic crystals of carbonado have been detected in the meteoric stones which fell at Novo-Urei in Russia on September 22, 1886, and also in the meteoric irons of Cañon Diablo in Arizona.

Carbonado is the name given to a black or dark-grey form of diamond, which was discovered in 1842 in the state of Bahia in Brazil, and is at present known to occur only in Brazil

and Borneo. It is generally found in irregular or rounded masses, occasionally with indistinct crystalline form, and presenting on fracture a compact granular or cellular structure. Its sp.gr. is less than that of true diamond, being in some cases as low as 3.01; nor is it so pure as crystallised diamond, some specimens yielding on combustion as much as 2 p.c. of ash. Notwithstanding its impurity, it exceeds in toughness any other form of diamond; and this has led to its extensive use in the arts. In the diamond-mounted rock-drills of Leschot and Beaumont, pieces of carbonado are firmly embedded in the inner and outer edges of the steel tube which forms the head of the drill; and so valuable is the carbonado that a single crown, with its setting, may be worth 2000*l.* The carbonado is also used in tools for dressing mill-stones and emery wheels.

Another variety of diamond used in the arts is known as *bort* or *boart*. Mineralogists recognise under this name an impure translucent and imperfectly crystallised variety, generally occurring in small concretionary masses of dark-grey or black colour, with a rugose exterior. It is slightly less dense than crystallised diamond, its sp.gr. not exceeding 3.505; but it is extremely hard. True *bort* occurs in most diamond-bearing districts, but much of the *bort* of commerce is merely coarse diamond, too much flawed or splintered to be used by the jeweller. The *bort* is crushed in a steel mortar, and the powder is extensively employed by lapidaries and others as a powerful abrading agent.

The art of cutting and polishing the diamond is generally attributed to Ludwig van Berquen, of Bruges, who is said to have first practised it about 1476. The forms into which diamonds are cut at the present day are known as the *brilliant* and the *rose* or *rosette*. The former may be roughly described as consisting of two truncated and faceted pyramids, applied base to base: the upper part, or *crown*, is more truncated than the lower part; the edge of union between the two parts is termed the *girdle*, while the broad flat upper face is the *table*, and the small lower plane the *cullet*. The rose has a flat base, from which rises a hemispherical dome covered with triangular facets (*v.* figs.).

In cutting a diamond, the first step is usually to reduce it by cleavage to a convenient shape. To cleave the crystal, the operator embeds it in a cement of resin and brickdust, carried at the end of a small wooden bâton. The cement having been warmed, the diamond is fixed in such a position that only the part to be split is exposed. Along the direction of cleavage a furrow is cut by means of another diamond; into this groove a thin steel blade is inserted, and by a sharp blow, skillfully delivered on the blade, the cleavage is effected.

After cleavage, the stone is cut, or rather rubbed, into the required shape. Two diamonds, each embedded in cement, with only a small surface exposed, are patiently rubbed together until, by mutual attrition, two approximately plane surfaces are formed. The operator wears stout gloves to protect the fingers, and takes care that every particle of dust resulting from the friction is carefully preserved. When the faces have been roughly formed by this rubbing, or 'bruting,' they require to be polished

on the mill. The diamond is embedded in a ball of fusible metal, carried in a hemispherical cup at the end of an arm, which being loaded with movable weights enables the manipulator to adjust the pressure on the wheel. The wheel is a circular iron disc, about 10 inches in diameter, rotating in a horizontal plane at the rate of about 2000 or 3000 revolutions per minute. The rotating discs are fed with diamond-dust and olive oil.

Brilliant-cut.

Rose-cut.

The diamond-cutting industry has for centuries been centred in Amsterdam, where it is mainly in the hands of Jews; but mills have also been established at Antwerp, and, of late years, at Hanau, near Frankfort; in Switzerland, London, and New York. The trade has received a great impetus in recent years by the enormous output of the South African mines, which now practically supply the world.

DIASTASE or *Amylase* is the name given to the enzyme or mixture of enzymes which converts starch and glycogen into maltose. In France, the word 'diastase' is used as a general term for all enzymes, a custom which causes

considerable confusion, and which it is to be hoped will lapse.

Diastase is very widely distributed in plants and in animals. It is found in blood serum, in muscle, liver and pancreas, and particularly in the saliva, this latter enzyme being long known under the name *ptyalin*.

The power of germinated barley to hydrolyse starch was discovered by Kirchoff in 1814, and the enzyme preparation was first made by Payen and Persoz in 1833. Diastase is found very generally in the leaves and twigs, in the germinating seeds, in the bark, in the pollen grains, and in the latex of plants. It occurs in yeast and in most of the mould fungi, the enzyme of *Aspergillus oryzae*, the so-called *Taka diastase* being well known on account of its industrial use in the manufacture of the Japanese beverage, *koji*.

Diastase, like all other enzymes, has not been prepared in anything approaching a pure state. Considerable uncertainty exists also as to whether it is a single enzyme or a mixture of enzymes acting in turn to convert starch into dextrin and dextrin into maltose. Modern evidence favours the view that it consists of a starch-liquefying enzyme or *amylopectase*, and a saccharifying enzyme able to hydrolyse soluble starch, but without much action on raw starch until this has been rendered soluble by the amylopectase. The two enzymes are found together, but in unequal proportions. Wheat flour, for example, frequently has a deficiency of liquefying enzyme.

There are well-marked differences between the enzymes present in resting barley and in malt (*cf.* Lintner and Eckhardt, *Zeitsch. Ges. Brauw.* 1899, 389; J. L. Baker, *Chem. Soc. Trans.* 1902, 81, 1177), one of the chief of these being that the diastase of raw grain possesses little if any starch-liquefying power. Baker has shown that the products of hydrolysis of starch by alcohol-precipitated enzymes from the two sources, are not the same. Brown and Morris have termed the enzyme of resting barley 'translocation diastase,' that of malt 'secretion diastase' (*Chem. Soc. Trans.* 1890, 58, 458; 1893, 63, 604). They regarded these as not only different in their actions, but as formed from different materials. This latter assumption has been disputed (*cf.* Ling, *J. Inst. Brewing*, 1908, 14, 494; Ford and Guthrie, *l.c.*, 1908, 14, 61).

Some authors consider the saccharifying enzyme to be a mixture, attributing a different enzyme to each stage in the simplification of the starch molecule. It is impossible at present to make any definite statement on this point. In support of it, it appears that exposure to a temperature of 68° acts more injuriously on the conversion of dextrin to maltose than on that of starch into dextrin. Heating diastase does not affect the liquefying power, though the saccharifying action largely disappears.

The quantity of diastase contained in the barley grain increases gradually in the course of germination: it is said to reach a maximum in about 8 or 9 days, when the plumules are twice as long as the grains.

Preparation.—A great variety of methods have been proposed for the preparation of diastase, the majority of these starting from malt. According to O'Sullivan (*Chem. Soc.*

Trans. 1884, 45, 2), finely ground pale barley malt is saturated with water, adding enough to slightly cover it and after 3–4 hours as much of the solution as possible is expressed by means of a filter press. After filtering, alcohol (sp.gr. 0.83) is added, as long as a flocculent precipitate forms, the addition being discontinued as soon as the liquid becomes opalescent or milky. The precipitate is collected, washed with alcohol of increasing strength until dehydrated, pressed between cloth and dried *in vacuo* over sulphuric acid.

Lintner (*J. pr. Chem.* 34, 378) treats 1 part of green barley malt or flour of air-dried malt with 2 to 4 parts of 20 p.c. alcohol for 24 hours, and precipitates the extract with 2½ volumes of absolute alcohol. The precipitate is washed with alcohol and ether to dehydrate it, and dried *in vacuo*.

Loew extracts germinated barley with 4 p.c. alcohol, and precipitates the extract with basic lead acetate. The precipitate is suspended in water, lead removed with hydrogen sulphide, and the enzyme precipitated with a mixture of alcohol and ether.

Wroblewsky extracts finely powdered malt, first with 70 p.c. and then twice with 45 p.c. alcohol. Alcohol is added to the two last extracts until 70 p.c. is present, the precipitate formed is collected, washed with alcohol and ether, and dried.

For further purification, both Wroblewsky and Osborne and Campbell dissolve the enzyme in water, and precipitate it with ammonium sulphate, which is added, drop by drop, until the liquid contains 50 p.c. On standing, a very active yellowish flaky precipitate is obtained.

Green barley malt may also be extracted with glycerol, and the diastase precipitated by alcohol. Effront extracts with water and induces alcoholic fermentation in the extract so as to remove carbohydrate and protein matter. It is then filtered and the diastase precipitated by alcohol.

Animal diastase is best obtained from saliva. Cohnheim uses freshly prepared calcium phosphate as precipitant, extracts this precipitate with water, and adds alcohol to obtain the enzyme. Alcohol is also used for direct precipitation, likewise ammonium sulphate. Von Wittich extracts pancreas diastase with glycerol.

For the preparation of an active diastatic extract for laboratory use, ground malt should be extracted with twenty times its weight of distilled water at 21° for 3 hours and filtered bright.

Preparations of diastase obtained as described above are colourless, amorphous, and friable, readily dissolving in water; but if allowed to dry without being dehydrated, they are horny and not easily penetrated by water. They invariably contain ash, which consists of potassium, calcium, and magnesium phosphates, with a trace of sulphate. They give a deep blue colour with a 1 p.c. alcoholic solution of gum guaiacum and hydrogen peroxide.

Lintner's diastase gave the reactions of the proteins, and was found to contain C, 46.66 p.c.; H, 7.35 p.c.; N, 10.42 p.c.; S, 1.12 p.c., calculated on the ash-free product. Osborne (*Ber.* 1898, 31, 254) found for his most active preparation, which had a diastatic power of 600 and

contained 0.66 p.c. of ash, C=52.5 p.c., H=6.72 p.c., N=16.1 p.c., S=1.9 p.c.; and Wroblewsky gives N=16.5 p.c. for his purest diastase. Both authors regarded diastase as a protein combined, according to Osborne, with a proteose.

The most recent work of Frankel and Hamburg (Beitr. Chem. Physiol. n. Path, 1906, 8, 389) leads to the conclusion that diastase contains neither protein groups nor reducing carbohydrates in its molecule. Impurities were removed from the enzyme solution with lead acetate, the solution sterilised by filtration, and further purified by fermentation with a yeast which had been rendered nitrogen-hungry. This preparation could be divided by dialysis into two distinct enzymes, one of which—the saccharifying—passed through the paper, while the other—the liquefying—was left behind. It showed absence of typical protein reactions, but contained a pentose in small amount.

The activity of diastase is very greatly influenced by the nature of the substrate on which it acts, more particularly as to whether this is alkaline or acid. Certain substances, such as the amphoteric amino-acids and asparagine, also ammonium and calcium phosphate, increase the activity, asparagine being especially effective in some instances. Vegetable diastase exhibits the maximum activity in presence of traces of weak organic acids. The very smallest quantities of alkali stop action, though this begins again as soon as the alkali is neutralised. In reality, the above accelerating substances are all of acid nature, and the apparently favourable effect of acid is due not to the acid *per se*, but to its neutralising alkaline impurities present. Maximum activity is attained in neutral (in the sense that water is neutral) solution. Minute traces of metallic impurities have an adverse influence. The temperature of maximum activity of diastase is about 55°; heated above this, it begins to show decomposition.

Estimation of diastatic power.—Since it has not been obtained in a pure state, the absolute estimation of diastase is an impossibility; moreover, the very great influence of external conditions on diastatic activity, to which allusion has been already made, makes it difficult to do more than compare the relative activities of a number of materials under precisely similar conditions. As this is an important operation in brewery control, the methods of analysis have been accurately laid down. The diastatic power is often termed the Lintner value, and expressed in degrees Lintner. The standard is 100° when 0.1 c.c. of a 5 p.c. solution of malt, acting on a 2 p.c. solution of soluble starch for 1 hour at 70°F., produces reducing sugar equivalent to 5 c.c. of Fehling's solution.

To obtain accurate results, great stress must be laid on the purity of the distilled water and soluble starch used: commercial starches are frequently alkaline. All work must be carried out in hard-glass apparatus (*cf.* Ford, J. Soc. Chem. Ind. 1904, 23, 8).

The method adopted by the Malt Analysis Committee of the Institute of Brewing (J. Inst. Brewing, 1906) for malt, is as follows: 25 grams ground malt are extracted with 500 c.c. of distilled water for 30 hours at 70°F. and filtered bright. 3 c.c. is allowed to

act on 100 c.c. of 2 p.c. soluble starch at 70°F. for 1 hour. Diastatic action is then stopped by the addition of 10 c.c. *N*/10-sodium hydroxide, and the liquid made up to 200 c.c. Sugar is then determined either volumetrically or gravimetrically. The results are calculated by the formula

$$\text{Diastatic power} = 1000/xy$$

where x = the number of c.c. of malt extract contained in 100 c.c. of the fully diluted starch-conversion liquid, and y = the number of c.c. of the same liquid required to reduce 5 c.c. of Fehling's solution. When the diastatic capacity exceeds 50°, 2 c.c. or less of malt extract are taken, particularly for the malts over 80° used by distillers and vinegar makers. The diastatic power of English brewing malt ranges between 35° and 40°, that of green malt from 110°-125°, showing that a large proportion of the enzyme is destroyed during the kilning.

Lintner tests solid preparations of the purified enzyme by dissolving 0.2 to 0.5 gram in 50 c.c. water and adding to a series of test-tubes, each containing 10 c.c. of 2 p.c. soluble starch solution, 0.1, 0.2, &c., up to 1 c.c. of the enzyme solution. After an hour, each tube is boiled in the water-bath with 5 c.c. of Fehling's solution, and that determined in which the copper solution is just completely reduced. A second series enables this point to be ascertained with greater accuracy.

Similar methods have been based on the colourations with iodine, shown by starch and dextrin solutions. Wohlgemuth sets increasing quantities of enzyme in a series of tubes with 5 c.c. of a 1 p.c. starch solution under precisely similar conditions. After 30 to 60 minutes at 40°, the tubes are cooled in ice and a drop of *N*/10 iodine solution added. Colours varying from dark-blue, blue-violet, reddish-yellow, and yellow are obtained. Wohlgemuth selects the tube in which the violet shows as indicating complete conversion to dextrin.

Uses.—Diastase plays a most important part in the brewing, distilling, and baking industries. Malt extracts, concentrated *in vacuo* at a low temperature to viscid syrups, are largely used by bread bakers and in some food preparations. Considerable quantities of such active preparations, made from malts of high diastatic power, also find employment in laundries for the purpose of removing starch from stiff collars, shirts, &c. (*See also* articles STARCH; FERMENTATION; HYDROLYSIS.) E. F. A.

DIATOMACEOUS EARTHS, DIATOMITE *v.* KIESELGUHR.

DIAZINE BLACK, -BLUE, -GREEN *v.* AZO-COLOURING MATTERS.

DIAZO-COMPOUNDS. These organic substances, like the azo-compounds, contain the characteristic group $-N_2-$, but whereas, in the latter series, this bivalent radicle is invariably attached to two carbon atoms, $C \cdot N_2 \cdot C$, in the former it is generally, although not invariably, combined with only one carbon atom, the other valency being satisfied by (1) an electro-negative ion Ac in the *diazonium salts* $C \cdot N_2 \cdot \text{Ac}$; (2) an oxygen atom in the *diazohydroxides* ('*diazohydrates*') $C \cdot N_2 \cdot \text{OH}$ and *diazo-oxides* ('*diazo-*

lates') $C \cdot N_2 \cdot OR$; (3) a nitrogen atom in diazoamines (diazoamino-compounds)

and diazoimines (azimino-compounds)

(4) a sulphur atom in diazosulphonates

and diazosulphides $C \cdot N_2 \cdot S \cdot C$.

The diazocyanides $C \cdot N_2 \cdot CN$ contain the azo-group attached to two carbon atoms, one of which belongs to a cyanogen group, and these compounds which, in general, are distinctly coloured, form an intermediate group between the foregoing diazo-derivatives and the azo-compounds.

Certain aliphatic diazo-compounds (*v. infra*) contain the group $-N_2-$ attached by both its active valencies to the same carbon atom.

I. DIAZONIUM SALTS.

These diazo-derivatives are generally, but not exclusively, prepared from aromatic amines, and the process, which is termed *diazotisation*, is carried out with the undissociated salt of the amine, and not with the free base. In a hydrolysing solvent like water, it is therefore customary to diazotise aniline and its derivatives with sodium nitrite (1 molecule) and excess ($2\frac{1}{2}$ to 3 equivalents) of mineral acid.

AROMATIC DIAZONIUM SALTS.

The diazotisation of the benzenoid and naphthalenoid amines is frequently carried out on a manufacturing scale owing to the employment of aromatic diazonium salts in the production of azo-colouring matters. More than 1000 tons of para-nitraniline are diazotised annually in the production of 'para-nitraniline red.'

The aromatic base is dissolved in dilute hydrochloric or sulphuric acid (3 equivalents in 10-20 p.c. aqueous solution) and the solution treated with an equivalent quantity (1 molecule) of sodium nitrite in 10-20 p.c. solution. The diazotisation is completed when the liquid contains a slight excess of nitrous acid as indicated by starch and iodide paper.

With aniline and its homologues, the temperature of the diazo-solution is generally maintained at 0° - 5° to prevent, so far as possible, the decomposition of the unstable diazonium salt, but in other cases, *e.g.* the nitranilines, naphthylamines, benzidine, and other diphenyl bases, the diazotisation is carried out most readily at 10° .

In the manufacture of soluble azo-dyes, the diazonium salts are generally employed in aqueous solution, but solid diazo-compounds, in dry or paste form, have been introduced to enable dyers to prepare 'ingrain' azo-colours which are developed on the textile fibres (*v. Eng. Pat. 18429, 21227, 1894; 8989, 11757, 1895; 1645, 1896; 15353, 1897; D. R. PP. 55387, 88949, 91280, 1894; 89437, 1896*).

In alcoholic or acetic acid solution, diazotisation can be effected on the salt of the amine without using an excess of acid, and ethyl or amyl nitrite may, with advantage, be substituted for sodium nitrite.

Benzenediazonium chloride $C_6H_5 \cdot N_2Cl$, the simplest example of an aromatic diazonium salt, is prepared by adding the calculated quantity

of amyl nitrite to aniline hydrochloride suspended in glacial acetic acid at 10° ; it is precipitated from the clear solution thus obtained by the addition of ether.

Benzenediazonium sulphate $C_6H_5 \cdot N_2 \cdot HSO_4$ is prepared in a similar manner from aniline sulphate suspended in glacial acetic acid, the precipitation being effected with alcohol and ether.

Benzenediazonium nitrate $C_6H_5 \cdot N_2 \cdot NO_3$, which was first precipitated from aqueous solution by ether and alcohol (Griess, *Annalen*, 1866, 137, 39), can also be produced in alcoholic or glacial acetic acid solution (Knoevenagel, *Ber.* 1890, 23, 2995; Bamberger, *ibid.* 1896, 29, 446; Hirsch, *ibid.* 1897, 30, 92; Hantzsch and Jochem, *ibid.* 1901, 34, 3337).

Diazonium salts have been obtained with a large variety of anions: *platinichlorides, aurichlorides, stannichlorides, ferricyanides, nitroprussiates* (*Ber.* 1879, 12, 2119; 1885, 18, 965), *chromates* (*Jahresberichte*, 1867, 915; *Chem. Soc. Trans.* 1905, 87, 1), *carbonates* and *nitrites* (*ibid.* 1905, 87, 921), *fluorides* (*Ber.* 1903, 36, 2059), *perchlorates* (*ibid.* 1906, 39, 2713, 3146), *picrates* (*Chem. Soc. Trans.* 1907, 91, 1316), *azides* (*ibid.* 1910, 97, 1697; *Ber.* 1903, 36, 2056).

All diazonium salts are liable to explode in the dry state, for they are endothermic compounds (Berthelot and Vielle, *Compt. rend.* 1881, 92, 1076; Sventoslavsky, *Ber.* 1910, 43, 1479) and in some cases the explosion point has been determined (*Ber.* 1899, 32, 1691; 1900, 33, 527). The diazonium chromates and perchlorates decompose with considerable violence, so that the former have been suggested as explosives (*Bull. Soc. chim.* 1867, [2] 7, 270; *Fr. Pat.* 73286).

Bisdiazonium salts (*Tetrazo-salts*). These compounds are produced from aromatic diamines which do not contain their amino-groups in *ortho-* or *peri-* positions (*v. Cyclic diazo-compounds*, p. 230).

When the two amino-groups are in the same aromatic nucleus, complete diazotisation is effected only with some difficulty. *Meta-phenylenediamine hydrochloride* and sodium nitrite furnish the azo-colouring matters included under the term 'Bismarck brown' (*Ber.* 1897, 30, 2111, 2899; 1900, 33, 2116), but when a solution of the base in excess of hydrochloric acid is added quickly to a large excess of well-cooled aqueous nitrous acid, complete diazotisation takes place and *benzene-m-bisdiazonium chloride* $C_6H_4[N_2Cl]_2$ is produced. *Para-phenylenediamine hydrochloride*, when diazotised in the usual way, gives a mixture of diazonium and bisdiazonium chlorides, but when the hydrochloride is added to excess of nitrous acid, *benzene-p-bisdiazonium chloride* is obtained.

In the naphthalene series, 1:4-naphthylenediamine is diazotised with difficulty, owing to its oxidisability, but in producing its azo-derivatives, this difficulty is surmounted by working with its monoacyl-derivatives and diazotising in two stages with an intervening hydrolysis (*Eng. Pat.* 18783, 1891). The heteronuclear naphthylenediamines, excepting the 1:8-compound, can be completely diazotised, yielding *naphthalenebisdiazonium salts* (*Ewer and Pick. D. R. PP. 45549, 45788; Badische Anilin und Soda Fabrik. D. R. P. 130475; Morgan and*

Micklethwait, Chem. Soc. Trans. 1910, 97, 255 8) Benzidine, tolidine, dianisidine, and other similar heteronuclear diamines of the diphenyl and ditolyl series are readily diazotised, furnishing bisdiazonium salts (e.g. *diphenylbisdiazonium chloride* $\text{Cl}\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\cdot\text{C}_6\text{H}_4\cdot\text{N}_2\cdot\text{Cl}$), which are employed in the manufacture of substantive azo-dyes (v. *Congo red* and *Benzopurpurin*; art. AZO-COLOURING MATTERS). There are certain substituted para-diamines in both benzene and naphthalene series which have hitherto resisted all attempts at complete diazotisation (Ber. 1884, 17, 603; 1896, 29, 2285; Eng. Pat. 2946 of 1896).

VELOCITY OF DIAZOTISATION.

Under the usual experimental conditions, diazotisation proceeds with great rapidity, but in N/1000 solutions, the velocity of this reaction has been determined by a colorimetric method for estimating the free nitrous acid. The reaction is of the second order, and the values of the constant $C = \frac{x}{t(a-x)}$ are 0.036 for aniline, 0.038 for *p*-toluidine, and 0.041 for *m*-xylylidine, with one molecular proportion of free acid at 0°. At higher temperatures, the rate is increased (Hantzsch and Schumann, Ber. 1899, 32, 1691; 1900, 33, 527). Both colorimetric and electrolytic determinations of the velocity of diazotisation show that, in the absence of disturbing influences, all the aromatic amines are diazotised at the same rate.

ALTERNATIVE METHODS OF PRODUCING AROMATIC DIAZONIUM SALTS.

Nitrosyl chloride or *bromide* has been suggested as a diazotising agent (Tilden and Millar, Chem. Soc. Proc. 1894, 59; Kastle and Keiser, Amer. Chem. J. 1895, 17, 91). *Nitrosyl sulphate* has been used with advantage (Pabst and Girard, D. R. P. 6034; Ber. 1879, 12, 365; Morgan and Micklethwait, Chem. Soc. Trans. 1910, 97, 2558). *Barium nitrite*, when employed in conjunction with sulphuric acid, furnishes diazo-solutions free from inorganic salts (Witt, Ber. 1903, 36, 4388). The last-named investigator has brought forward an interesting process which consists in dissolving the base in cold concentrated *nitric acid* and adding the calculated amount of *potassium metabisulphite* required to produce sufficient nitrous acid for the diazotisation (Ber. 1909, 42, 2953).

Diazonium bromides are formed by the interaction of *hydrazines* and *diazonium perbromides*

(Chattaway, Chem. Soc. Trans. 1908, 93, 958). An *electrolytic* process for the production of diazonium salts has been patented (Boehringer & Sons, D. R. P. 152926, and Eng. Pat. 2608 of 1904).

Diazonium salts can also be prepared from compounds not containing amino-groups; mercury diphenyl and nitrous fumes give benzenediazonium nitrate (Ber. 1897, 30, 509), and the same salt is produced from nitroso-benzene and nitric oxide in chloroform solution (*ibid.* 1898, 31, 1528). Fuming nitric acid reverses the coupling process and regenerates the diazonium salt from its azo-derivatives (Meldola, Chem. Soc. Trans. 1889, 55, 608; 1894, 65, 841; and O. Schmidt, Ber. 1905, 38, 3201).

Vor. II.—T.

Certain complex or highly substituted amines resist diazotisation unless treated under pressure (D. R. P. 143450) or with excess of nitrons and mineral acids (Annalen, 1873, 165, 187; 1891, 260, 224; Ber. 1900, 33, 520).

(For indirect methods of forming diazonium salts, v. Annalen, 1879, 199, 320; 1888, 243, 282; 1892, 270, 116; Ber. 1893, 26, 2190; 1899, 32, 1809; 1900, 33, 1718; J. pr. Chem. 1896, [ii.] 54, 496; Gazz. chim. ital. 1900, 30, 1526; Bull. Soc. Chim. 1891, [iii.] 6, 94.)

REACTIONS OF AROMATIC DIAZONIUM SALTS.

In addition to their power of coupling with phenols, aromatic amines, and their sulphonic acids to form the technically important azo-colouring matters, the diazonium salts are synthetical agents of the greatest value, and the following is a synopsis of the principal reactions in which they take part:—

1. Decomposition of Diazonium Salts by Water.

(Cf. Ber. 1874, 7, 1061; 1894, 17, 2704; 1899, 32, 1773; 1890, 23, 3635; 1902, 35, 89; J. pr. Chem. 1881, [ii.] 24, 476; Chem. Soc. Trans. 1902, 81, 77; 1903, 83, 688; 1905, 87, 5; 1906, 89, 19.)

The decomposition of soluble diazonium salts by water is a unimolecular reaction, and is represented by the well-known equation:

$$C = \frac{1}{t} \log \frac{A}{A-x}$$

The relative stability of the diazonium salts is ascertained by comparing the values of the constant C for a given temperature. The most successful method of making this determination consists in heating solutions of the diazo-compounds at a fixed temperature, and measuring the rate at which nitrogen is evolved. A convenient apparatus, which can be used in this determination and also for studying the decomposition of diazo-compounds in general, is indicated in the following figure.

These quantitative decompositions show that the diazonium salts from aniline and ortho- and meta-toluidine are among the least stable of the series, whereas considerably greater stability is exhibited by the diazotised nitranilines and the diazonium sulphonates derived from the benzenoid and naphthalenoid amino-sulphonic acids.

The rate of decomposition of diazo-compounds increases with the temperature, and in

accordance with Arrhenius's formula for the temperature coefficient

$$t_1 = t_0 e^{\frac{\epsilon A(T_1 - T_0)}{T_1 T_0}}$$

The rate of decomposition is independent of the quantity of mineral acid present, and equivalent solutions of benzenediazonium chloride, bromide, sulphate, nitrate, and oxalate decompose with the same velocity; this change is, however, accelerated by colloidal platinum or silver, owing to catalytic action (Hantzsch, Ber. 1900, 33, 2517; Hauser and Muller, Bull. Soc. chim. 1892, [iii.] 7, 721; 1893, 9, 353; Compt. rend. 1892, 114, 549, 669, 760, 1438; Schwalbe, Zeitsch. Farb. Ind. 1905, 4, 433; Ber. 1905, 38, 2196, 3071; Cain, Chem. Soc. Trans. 1902, 81, 1412; 1903, 83, 206, 470; 1905, 38, 2511; Euler, Annalen, 1902, 325, 292).

In general, the decomposition of a diazonium salt by water leads to the formation of a phenol

The sulphate is the best salt to employ in this reaction, because the chloride and nitrate are apt to lead respectively to alternative or secondary changes. Benzenediazonium sulphate and its homologues furnish phenol and the cresols and xylenols; diphenyl-4:4'-bis-diazonium sulphate gives rise to 4:4'-dihydroxy-diphenyl. Aurin is similarly obtained from diazotised rosaniline (Annalen, 1878, 194, 306).

In certain cases, more especially in the naphthalene series, the product is contaminated by azo-compounds, resulting from the coupling of the hydroxy-derivative with a portion of the still undecomposed diazonium salt (Chem. Soc. Trans. 1903, 83, 221). To obviate this difficulty, so far as possible, excess of acid is used in the decomposition. The manufacture of the α -naphtholsulphonic acids (e.g. OH:SO₃H=1:4 and 1:8) from the corresponding α -naphthyl-aminesulphonic acids and the production of 1:8-dihydroxynaphthalene-3:6-disulphonic acid (chromotrope acid), are typical examples of the technical application of the process.

Secondary reactions occur even in the simplest cases (Ber. 1890, 23, 3705), and in many instances, where the boiling is protracted owing to the great stability of the diazo-compound, not a trace of the hydroxy-derivative can be isolated (Amer. Chem. J. 1889, 11, 319; Cain, Chem. Soc. Trans. 1903, 83, 688). When the phenolic product is volatile in steam, the normal change is facilitated by operating with solutions boiling above 100°. A good yield of guaiacol is obtained by adding the diazo-salt of ortho-anisidine to a mixture of sodium sulphate and dilute sulphuric acid boiling at 135°-145°, the volatile product being removed at the moment of formation (Kalle & Co., Eng. Pat. 7233 of 1897; cf. Annalen, 1889, 253, 281; Ber. 1874, 7, 1008; D. R. P. 167211; Chem. Soc. Trans. 1906, 87, 19).

(For other exceptional decompositions of diazo-compounds, *v.* Ber. 1874, 7, 1061; 1884, 17, 2704; 1899, 32, 1773; 1902, 35, 89; Chem. Soc. Trans. 1896, 69, 1327; 1902, 81, 77, 1905; 87, 5; 1906, 89, 19.)

The diazo-compounds are very sensitive to light, which induces the phenolic decomposition even in certain cases where the action of hot water or acids is very slight (Chem. Soc. Trans.

1907, 91, 35; cf. Compt. rend. 1881, 92, 1074; Ber. 1890, 23, 3131; 1901, 34, 1668; D. R. PP. 53455, 56606; J. Soc. Chem. Ind. 1890, 9, 1001).

2. Decomposition of Diazonium Salts by Alcohols.

The reaction between diazonium salts and alcohols may proceed in two different ways:

1. $R \cdot N_2 \cdot X + C_2H_5 \cdot OH = R \cdot H + C_2H_5O + N_2 + HX.$
2. $R \cdot N_2 \cdot X + C_2H_5OH = R \cdot O \cdot C_2H_5 + N_2 + HX.$

The former of these changes was originally regarded as the general reaction, but more recent researches have shown that the second is the normal change. The factors determining the course of the reaction are, however, numerous and complicated, involving (1) the nature of the alcohol; (2) the influence of substituents in the diazonium salt; (3) the pressure and temperature at which the decomposition is effected.

The tendency to replace the diazo-group by hydrogen increases with the molecular weight of the alcohol employed. Benzenediazonium chloride or sulphate and methyl alcohol give anisole exclusively. With ethyl alcohol, these salts yield chiefly phenetole, but benzene is also produced. The diazonium sulphates from *p*-chloro- and *p*-bromo-aniline furnish only *p*-chloro- and *p*-bromo-benzene with ethyl alcohol, but with methyl alcohol they give rise mainly to the methyl ethers of *p*-chloro- and *p*-bromo-phenol (Amer. Chem. J. 1898, 20, 229; cf. Annalen, 1871, 159, 191; Ber. 1901, 34, 3337; 1903, 36, 2061; Amer. Chem. J. 1893, 15, 518; 1897, 19, 531, 547, 561).

The diazo-salts of the simpler amines (aniline and its homologues) react chiefly in the direction indicated by the second of the foregoing equations, and yield mixed ethers, but the presence of acid substituents

favours the predominance of the first change. The nitranilines (ortho-, meta-, and para-) give respectively 87, 51, and 40 p.c. of nitrobenzene the 1:2-, 2:1-, and 1:4-nitronaphthylamines furnish the corresponding nitronaphthalenes, whereas α - and β -naphthylamines yield α - and β -ethoxynaphthalenes (Remsen and others, Ber. 1885, 18, 65; Amer. Chem. J. 1886, 8, 243; 1887, 9, 587; 1891, 13, 153; 1892, 14, 15).

The yield of alkyl ether increases with rise of pressure, but the addition of zinc-dust or an alkali (sodium hydroxide or ethoxide, potassium carbonate) inhibits almost entirely the formation of mixed ether and leads to the substitution of the diazo-group by hydrogen (Amer. Chem. J. 1893, 15, 105, 301, 320, 379; 1894, 16, 235; 1895, 17, 454; 1897, 19, 163, 531; 1898, 20, 298; 1904, 31, 119).

3. Replacement of the Diazo-Group by Hydrogen.

In addition to the action of alcohol, the diazo-group can be eliminated by the use of a variety of reducing agents:—

(i.) The diazonium salt is reduced to the corresponding *hydrazine* and the *hydrazino-group* $NH \cdot NH_2$ removed by boiling with *copper sulphate* (Baeyer and Pfitzinger, Ber. 1885, 18, 90, 786).

(ii.) Reduction of the diazo-compound with *alkaline sodium stannite* (Friedländer, Ber. 1889, 22, 587).

(iii.) By various other reducing agents, *stannous formate* (Ber. 1885, 18, 357; J. pr.

Chem. 1889, [ii.] 40, 97), *hypophosphorous acid* (Ber. 1902, 35, 162), *sodium hyposulphite* (*ibid.* 1907, 40, 858), *formic acid* and *copper powder* (*ibid.* 1890, 23, 1632).

4. Replacement of the Diazo- Group by Halogen, Cyanide, Cyanate, and Thiocyanate Radicles.

Fluorine may be introduced into the aromatic nucleus in place of the diazo-group by treating the diazonium salt with hydrofluoric acid. Diazoamino-compounds (*v. infra*) are also employed in bringing about this replacement, and when treated with concentrated hydrofluoric acid they yield the corresponding fluoro-derivative; fluorobenzene is thus produced from diazoaminobenzene or diazobenzene-piperidide (J. pr. Chem. 1870, [ii.] 1, 395; Ber. 1875, 8, 893; 1879, 12, 581; 1889, 22, 1846).

The first really successful process for replacing the diazo-group by *chlorine* (or *bromine*) was discovered by Sandmeyer; it consists in adding the diazotised solution to cuprous chloride (or bromide) dissolved in warm hydrochloric (or hydrobromic) acid, when nitrogen is evolved and the corresponding chloro- or bromo-derivative is produced (Ber. 1884, 17, 1633, 2650; 1885, 18, 1492, 1496; 1886, 19, 810; 1890, 23, 1628, 1880; Annalen, 1893, 273, 141).

The first stage in the *Sandmeyer reaction* is considered to be the formation of an additive compound of diazonium salt and cuprous chloride; the decomposition of this intermediate product proceeds readily only above a certain temperature, which is different for each diazonium salt (Erdmann, Annalen, 1893, 272, 141; *cf.* Votoček, Chem. Zeit. Rep. 1896, 20, 70; Hantzsch and Blagden, Ber. 1900, 33, 2544). The substitution of bromine for diazo-nitrogen follows a similar course (Phil. Trans. 1864, 154, 673; Annalen, 1866, 137, 49; Amer. Chem. J. 1891, 13, 486; Gazz. chim. ital. 1890, 20, 631).

The foregoing substitutions are also effected by the addition to solutions of diazonium chlorides or bromides of finely divided copper or the copper bronze of commerce (Gattermann, Ber. 1890, 23, 1218; 1892, 25, 1074; Ullmann, *ibid.* 1896, 29, 1878; *cf.* Angeli, *ibid.* 1891, 24, 952).

Iodine is readily substituted for the diazo-complex by treating the acid diazo-solutions with potassium iodide even in the absence of copper or cuprous salts.

The Sandmeyer reaction includes the important synthetical operation of replacing the diazo-group by a *cyanide* radicle, the diazonium salt being added to a warm solution of potassium cuprocyanide. The Gattermann process is also applicable to this synthesis, the addition of copper powder to a mixture of diazonium salt and potassium cyanide inducing a similar replacement (Ber. 1890, 23, 1218). The *cyanate* radicle is introduced in the place of the diazo-group by adding successively to a solution of diazonium salt, potassium cyanate, and copper powder (Ber. 1890, 23, 1220; 1892, 25, 1086). The *thiocyanate* group is introduced by adding potassium thiocyanate and cuprous thiocyanate to a solution of diazonium sulphate (*ibid.* 1890, 23, 738, 770).

5. Replacement of the Diazo- Group by Sulphur and Sulphur-containing Radicles.

These reactions are of importance as furnishing methods for the synthetical production of sulphonic acids.

Thiophenols or *disulphides* are obtained by treating diazonium salts with potassium xanthate and then hydrolysing the resulting aromatic xanthate (Leuckart, J. pr. Chem. 1890, [ii.] 41, 179; *cf.* Ber. 1887, 20, 349; Chem. Soc. Proc. 1895, 11, 141). Phenyl sulphide is produced by treating benzenediazonium salts with hydrogen sulphide or ammonium sulphide (Ber. 1882, 15, 1683). Benzenoid diazonium salts yield sulphides on treatment with sodium cuprous thio-sulphate, but diazotised α -naphthylamine only gives α -azonaphthalene (Ber. 1901, 34, 3968).

The replacement of a diazonium by a *sulphonic* group is effected by saturating with sulphur dioxide an acid solution of diazonium sulphate and adding copper powder; nitrogen is evolved and the resulting sulphonic acid extracted with ether (Gattermann, Ber. 1899, 32, 1136).

The foregoing thiophenols, disulphides and sulphonic acids yield the corresponding *sulphonic acids* on oxidation (D. R. P. 70286; Eng. Pat. 11865 of 1892).

6. Replacement of the Diazo- Group by Nitro-, Nitroso-, and Amino-Radicles.

The introduction of a *nitro*-group is brought about either by heating the diazonium salt with nitrous acid and cuprous oxide or by mixing the diazonium sulphate with cupro-cupric sulphite and adding excess of alkali nitrite. By the latter process, 2:4:6-tribromobenzenediazonium sulphate gives 65 p.c. of 1-nitro-2:4:6-tribromobenzene and diazotised β -naphthylamine gives 25 p.c. of β -nitronaphthalene, a substance prepared with considerable difficulty by other processes (Ber. 1887, 20, 1497; 1900, 33, 2544). The introduction of a *nitroso*-group is effected by treating a diazonium chloride with alkaline potassium ferrocyanide (Ber. 1893, 26, 471). The addition of hydroxylamine to a solution of diazonium salt results in the regeneration of the original amine (Ber. 1892, 25, 372; 1902, 35, 2593, 3920).

7. Formation of Azoimides.

The introduction of the azimino-group N_3 into the aromatic nucleus is effected by the following reactions: (1) action of hydroxylamine on diazonium sulphates (Ber. 1892, 25, 372; 1893, 26, 1271; Forster and Fierz, Chem. Soc. Trans. 1907, 91, 855, 1350); (2) interaction of ammonia and diazonium perbromides; (3) direct action of sodium azide on diazonium salts in excess of sulphuric acid (Nöling and Michael, Ber. 1893, 26, 86; Forster and Fierz, Chem. Soc. Trans. 1907, 91, 1942). The last of these processes is carried out so readily that the production of an azimino-compound may be used to estimate the number of diazo-groups in a diazonium salt (Meldola and Hawkins, Chem. Soc. Proc. 1892, 8, 133; Morgan and Micklethwait, Chem. Soc. Trans. 1910, 97, 2560).

Miscellaneous substitutions, *v.* Chem. Soc. Trans. 1888, 53, 460; Amer. Chem. J. 1888, 10, 368; Ber. 1902, 35, 1964.

CONDENSATIONS EFFECTED BY MEANS OF AROMATIC DIAZONIUM SALTS.

Azo-compounds are formed, to a slight extent, during the Sandmeyer reaction, and this

condensation takes place to a greater extent when the usual order of mixing is reversed and the cuprous chloride added to the cold solution of diazonium salt. Aniline, *o*-chloraniline, and *o*- and *p*-toluidine give considerable quantities of azo-derivatives, but the nitranilines and their homologues furnish diphenyl compounds (Niementowski, Ber. 1901, 34, 3325; Ullmann and Forgan, *ibid.* 3802; D. R. P. 126961). Cuprous oxide dissolved in ammonia or hydroxylamine also promotes the diphenyl condensation (Annalen, 1902, 320, 122), diphenyl itself being readily prepared by adding copper, zinc, or iron powder to benzenediazonium sulphate in dilute alcohol (Ber. 1890, 23, 1226): $\beta\beta$ -dinaphthyl is similarly produced from β -diazonaphthalene sulphate (Chem. Soc. Trans. 1895, 67, 653).

INTERCHANGE OF GROUPS IN DIAZONIUM SALTS.

The diazonium salts of the more highly substituted amines frequently undergo remarkable transformations, some of which have been suggested for use in the technical production of azo-compounds.

The dinitroanisidines, containing nitro-groups either in ortho- or para-positions with regard to the amino-group, exchange these radicles for hydroxyl during the process of diazotisation. In certain instances, the methoxyl group present in these compounds undergoes demethylation, &c., with the production of internal diazo-oxides (quinonediazides). The nitro-group is set free in the form of nitrous acid, which continues the diazotisation process on further quantities of the base (Meldola and others, Chem. Soc. Trans. 1900, 77, 1172; 1901, 79, 1076; 1902, 81, 988; 1905, 87, 1205). A sulphonic group is replaced by hydroxyl in the diazotisation of *m*-phenylenediaminedisulphonic acid (Eng. Pat. 18283 of 1903), and certain of the dinitronaphthylamines, when diazotised, yield internal diazo-oxides, owing to the initial replacement of a nitro-group by hydroxyl (Ber. 1894, 27, 2211; 1895, 28, 1951; *cf.* Chem. Soc. Trans. 1895, 67, 908).

The replacement of an acidic (electro-negative) substituent by hydroxyl frequently occurs on treating the diazonium salt with alkalis.

A sulphonic acid group may be similarly eliminated as in β -naphthylamine-1:5:7-trisulphonic acid which, when diazotised and treated with weak alkali, yields naphthylene-2-diazo-1-oxide-5:7-disulphonic acid (D. R. P. 141750; Eng. Pat. 16811, 20551, of 1901; 1561, 6615, 23993, of 1902; 16995, 27372, of 1903; 4997, of 1904).

These replacements sometimes take place even when the diazo-solutions are diluted with water, or spontaneously when the diazonium base is present as the salt of a weak acid (acetate, oxalate, carbonate, &c.) (*c.* Orton, Proc. Roy. Soc. 1902, 71, 153; Chem. Soc. Trans. 1903, 83, 796; 1907, 91, 1554; Nölting and Battagay, Ber. 1906, 39, 79).

undergoes a remarkable molecular transformation when dissolved in alcohol containing a trace of hydrochloric acid. The thiocyanate and chlorine radicles change places, and on adding ether to the solution, *p*-thiocyanobenzene diazonium chloride is precipitated (Hantzsch, Ber. 1896, 29, 947). Similarly, 2:4:6-tribromobenzenediazonium sulphate in presence of excess of potassium thiocyanate is converted into 2:4:6-trithiocyanobenzenediazonium thiocyanate and many brominated diazonium chlorides pass into chlorinated diazonium bromides (Ber. 1897, 30, 2334; 1898, 31, 1253; 1900, 33, 505; *cf.* Chem. Soc. Trans. 1902, 81, 1376). The last of these transformations has been studied quantitatively, and the following generalisations have been established:—

(i.) Bromine atoms are replaced by chlorine only when present in the ortho- or para- position with respect to the diazonium group, those in ortho- positions being most readily removed. A bromine atom in the meta- position is not affected.

(ii.) The ease of transformation increases with the number of bromine atoms present.

(iii.) The transformation constant, calculated from the equation for a unimolecular reaction $K = 1/t(\log A/A-x)$, increases with the temperature and is also influenced by the solvent, having its minimum value in water, and becoming greater as the series of alcohols is ascended.

(iv.) Diazonium salts containing two bromine atoms are stable when dry, but are rapidly transformed in ethyl alcohol; 2:4:6-tribromobenzenediazonium chloride becomes transformed in the dry state.

These changes do not occur either with iodated diazonium chlorides or with brominated diazonium fluorides (Hantzsch, Ber. 1903, 36, 2069).

CONSTITUTION OF AROMATIC DIAZONIUM SALTS.

Aromatic diazonium salts are generally soluble in water to a neutral solution, thus showing, by an absence of hydrolytic dissociation, that the diazonium base is a stronger base than the aromatic amine from which it was derived. The strength of the diazonium base has been confirmed by physico-chemical measurements.

Determinations of the electrical conductivity of solutions of benzenediazonium chloride and nitrate show that the benzenediazonium radicle is strictly comparable with other quaternary ammonium ions. The rate of migration of the benzenediazonium ion at 25° is 45.7, the corresponding constants for the methylpyridinium and tetramethylammonium ions being 44.3 and 43.6 respectively. The molecular electrical conductivity of solutions of diazonium salts increases with dilution, just as in the case of the corresponding potassium and ammonium compounds.

The affinity constant of benzenediazonium hydroxide at 0° is 70 times greater than that of ammonium hydroxides, and somewhat exceeds that of piperidine. The affinity constants of *p*-methoxybenzenediazonium and ψ -cumidine-diazonium hydroxides are even greater, and approximate closely to those of the alkali hydroxides. A comparison of the electrical

conductivity experiments, with the results obtained in the hydrolysis of ethyl acetate by benzenediazonium hydroxide, shows that in *N*/128 solutions at 0°, approximately 33 p.c. of the base exists in the ionised condition (Ber. 1890, 23, 3220; 1895, 28, 1737; 1898, 31, 1612).

Benzenediazonium (*Diazobenzene*) behaves like an alkali or a complex ammonium cation.

Benzenediazonium hydroxide (*Diazobenzene hydrate* or *hydroxide*) is only known in solution, and is produced by treating aqueous benzenediazonium chloride with the calculated amount of silver oxide, or by adding barium hydroxide to a solution of benzenediazonium sulphate (Hantzsch, Ber. 1898, 31, 340). The solution is strongly alkaline, and gives at once an azo-compound with β -naphthol; the dissolved base decomposes, however, fairly rapidly even at 0°.

The striking similarity in the physical and chemical properties of the diazonium and quaternary ammonium salts suggests the existence of quinquevalent nitrogen in the former compounds, and on these grounds the following formula, formerly proposed by Blomstrand (1869), Strecker (1871), and Erlenmeyer (1874), has now been generally adopted for benzenediazonium chloride and its homologues:

although, for many years, the alternative configuration, $\text{C}_6\text{H}_5 \cdot \text{N}=\overset{\text{N}}{\text{N}}-\text{Cl}$, suggested by Kekulé, was usually employed.

The close analogy existing between the diazonium and alkali salts is shown further by the facility with which the former yield double salts with cobaltic nitrite and with the chlorides of platinum, gold, and mercury. Diazonium perchlorides are also known, corresponding with the perchlorides of potassium, rubidium, caesium, and quaternary ammonium bases (Ber. 1895, 28, 1736, 2754).

The benzenoid diazonium salts with colourless anions (nitrates, sulphates, chlorides) are generally colourless, but the corresponding bromides, iodides, and thiocyanates are coloured, and the deeper the colour the more explosive the salt. When cooled in liquid air, these coloured salts become less coloured; moreover, their aqueous solutions are colourless.

The development of colour and increase in explosibility are considered by Hantzsch to indicate a change in constitution, the coloured substance being regarded as an equilibrium mixture of diazonium salt and *syn*-diazocompound (*v. infra*). This equilibrium is disturbed in the sense of forming more colourless diazonium salt by lowering the temperature or by dissolving the substance in water (Hantzsch, Ber. 1897, 33, 2179; 1900, 33, 2179; Euler, Ber. 1895, 31, 4168). But although in the benzene series the diazonium chlorides, nitrates, and sulphates are colourless, yet in the diphenyl and naphthalene series, many diazonium salts with these anions are coloured and comparatively stable. Moreover, this colour (yellow or orange) is retained either in aqueous solution or at the temperature of liquid air. Apart from their colour, these salts have all the properties of the simpler diazonium salts (neutral solutions, coupling with phenols, &c.). These facts indicate that increase in the complexity of the

organic portion of the diazonium cation leads to the development of colour in normal diazonium salts.

(*Coloured diazonium salts, v. Hantzsch, Ber. 1900, 33, 3183; 1901, 34, 4168; Annalen, 1900, 312, 126; Cain, Chem. Soc. Trans. 1905, 87, 5; Morgan and others, ibid. 1907, 91, 1311, 1505; 1908, 93, 614; 1909, 95, 1319.*)

The idea embodied in Blomstrand's diazonium formula (*v. supra*) fails to express one important point, namely, the dependence of the stability of the diazo-complex on the presence of an unsaturated group. Yet this is a matter of fundamental importance, for hitherto no amine in which the basic nitrogen is attached to a fully saturated ring or complex has yielded a diazonium salt.

Cain has suggested an alternative formula, (2), giving expression to this circumstance (Chem. Soc. Trans. 1907, 91, 1051), in which the diazonium salt is represented as having a parahemiquinonoid constitution; and this conception has been extended by Morgan (*ibid.* 1908, 93, 617; 1910, 97, 2563) so as to include the equally admissible ortho-hemiquinonoid configurations (1) and (3):

Euler has also advocated a para-hemiquinonoid structure for diazonium salts (Ber. 1908, 41, 3979).

NON-AROMATIC DIAZONIUM SALTS.

The foregoing hypotheses of the constitution of aromatic diazonium salts, which bases their existence on the unsaturated nature of the aromatic complex, accord with the fact that certain non-aromatic primary amines containing unsaturated organic groups manifest, in some degree, the property of diazotisability. Among these bases are aminotriazole (I.) and its derivatives, and aminoantipyrene (II.):

(Thiele and Manchot, *Annalen*, 1898, 303, 33; Knorr and Stolz, *ibid.* 1896, 293, 67; *cf.* Ber. 1900, 33, 1158; 1906, 39, 2925; *Annalen*, 1900, 312, 133). In addition to non-aromatic amines containing an unsaturated cyclic structure, it has also been shown (K. G. Hofmann, Hock and Roth, Ber. 1910, 43, 682, 1087) that amino-guanidine gives rise to diazonium salts, derived, however, not from the salts of aminoguanidine itself, but from a more complex molecule containing two guanidine residues, and having a greater degree of unsaturation. The diazonium nitrate, for example, is represented by the formula:

containing a diazo-complex associated with an open chain having three unsaturated linkings.

III.

IV.

corresponding respectively with the foregoing formulæ (I. and II.) for the internal diazo-oxides. Successive nitration of the phenyl group gradually increases the stability of these *p*-diazoinimes (Chem. Soc. Trans. 1903, 93, 604).

The para-diazoimides are produced from the acyl- and aryl-sulphonyl-derivatives of the para-diamines, and similar products are obtained from the arylsulphonyl-1:8-naphthylenediamines. The production of these diazoimides takes place in two stages, the diazonium salt first produced being decomposed by sodium acetate or mild alkali, yielding the internal condensation product:

V.

VI.

These para-diazoimides (VI.) are yellow sparingly soluble substances readily reconverted by strong acids into the corresponding diazonium salts. They combine additively with phenols, naphthols, naphthylamines, and their sulphonic acids, yielding azo-colouring matters (Morgan and Micklethwait, J. Soc. Dyers and Colourists, 1909, 25, 107; *cf.* Chem. Soc. Trans. 1905, 87, 74, 921, 1302; 1906, 89, 1162; 1907, 91, 1509; 1908, 93, 615; Badische Anilin- und Soda-Fabrik. D. R. P. 205037).

III. DIAZOAMINES.

The diazoamines or diazoamino-compounds have the general formula $\text{XN}_2 \cdot \text{NH}_2$, and may be either aromatic, mixed aromatic-aliphatic, or aliphatic in character, according as to whether X and Y are aromatic or aliphatic hydrocarbon radicles.

1. AROMATIC DIAZOAMINES.

The aromatic diazoamines are produced (1) by the action of nitrous acid (1 molecule) on two molecular proportions of a primary benzenoid amine; (2) by coupling a diazonium salt with a primary or secondary benzenoid amine.

Diazoaminobenzene $\text{C}_6\text{H}_5 \cdot \text{N}_2 \cdot \text{NH} \cdot \text{C}_6\text{H}_5$, yellow crystals, m.p. 98°, is produced in quantitative yield by dissolving 10 parts of aniline in two parts of water containing 12 parts of hydrogen chloride, diazotising with 8 parts of sodium nitrite, and adding the diazo-solution to a solution of 10 parts of aniline in the calculated amount of hydrochloric acid. The diazoamine is precipitated on the addition of sodium acetate.

When warmed with aniline containing aniline hydrochloride, diazoaminobenzene is transformed into *p*-aminoazobenzene (*v.* AZO-COLOURING MATTERS), the velocity of transformation obeying the law of unimolecular reactions.

Diazoamino-*p*-toluene $\text{C}_7\text{H}_7 \cdot \text{N}_2 \cdot \text{NH} \cdot \text{C}_7\text{H}_7$, is prepared in a similar manner, and undergoes transformation into an ortho-azo-compound, but the velocity of this change is only about one-ninth of that of the preceding transformation to para-azo-derivative.

The coupling of diazonium salts with meta-phenylenediamine, diphenylamine, the naphthylamines and their alkyl derivatives, leads directly

to the production of azo-derivatives; in these cases, intermediate diazoamines have not been isolated, except when the reactive ortho- or para-positions are already substituted (Morgan, Chem. Soc. Trans. 1902, 81, 91; 1907, 91, 370).

When an aromatic base, XNH_2 , is coupled with a diazonium salt YN_2Cl , the resulting diazoamine is identical with that produced from XN_2Cl and YNH_2 , and is generally regarded as being an equilibrium mixture of the two isomerides $\text{XNH} \cdot \text{N}_2\text{Y}$ and $\text{XN}_2 \cdot \text{NH}_2$. This explanation assumes the migration of the diazo-group which has been observed to occur in several instances (Ber. 1882, 15, 2190; 1896, 29, 287; 1897, 30, 1412).

(For the constitution of the unsymmetrical aromatic diazoamines, $\text{XNH} \cdot \text{N}_2\text{Y}$, *v.* Meldola and Streatfield, Chem. Soc. Trans. 1886, 49, 624; 1887, 57, 102, 434; 1886, 53, 664; 1889, 55, 412; 1890, 57, 785; *cf.* Forster and Garland, *ibid.* 1909, 95, 2051.)

2. ALIPHATIC-AROMATIC DIAZOAMINES.

The diazoamines containing one aliphatic and one aromatic group can be produced by (1) coupling a diazonium salt with an aliphatic amine (Ber. 1888, 21, 1016, 1112; 1889, 22, 938, 1302); (2) by treating an azide with Grignard reagent:

(Dimroth, Ber. 1903, 36, 909; 1905, 38, 670, 2328; 1907, 40, 2390). Diazoamines present the possibility of stereoisomerism, but their relative stability and the fact that they couple only slowly with β -naphthol, confirm the view that they are generally *anti*-diazo-compounds.

(For stereoisomeric diazoamines, *v.* J. Russ. Phys. Chem. Soc. 1906, 38, 587; Zentsch. angew. Chem. 1900, 13, 762; 1902, 15, 1209.)

Aromatic bisdiazaminobenzene compounds, e.g. $(\text{C}_6\text{H}_5 \cdot \text{N}_2)_2 \cdot \text{N} \cdot \text{C}_6\text{H}_5$, have been obtained by the action of 2 molecular proportions of a diazonium salt on one of an aromatic amine (Ber. 1894, 27, 1863, 2597; 1895, 28, 170).

Mixed aliphatic-aromatic bisdiazaminobenzene derivatives (v. Ber. 1888, 21, 1016; 1889, 22, 933; 1907, 40, 2390).

Diazo- ψ -semicarbazines (v. Forster, Chem. Soc. Trans. 1906, 89, 223).

3. ALIPHATIC DIAZOAMINES.

Dimroth's general method may be applied to the production of purely aliphatic diazoamino-compounds. In this way, the simplest member of the series, **diazoaminomethane (dimethyltriazene)** $\text{CH}_3\text{N} : \text{N} \cdot \text{NH} \cdot \text{CH}_3$, has been prepared from methyl azide and magnesium methyl iodide. This substance, which is isolated by distilling its copper derivative with diazoaminobenzene under reduced pressure, is a colourless liquid, solidifying at -12° and boiling at 92° (Dimroth, Ber. 1905, 38, 1575; 1906, 39, 3905).

IV. DIAZO-OXIDES.

When a diazonium salt couples with a phenol the product is generally an ortho- or a para-hydroxyazo-compound (the C-azo-derivative),

but in all probability, the O-azo- derivative is first produced, for in a few instances, when the velocity of transformation has been lessened by substitution, the intermediate O-azo- compound or diazo-oxide has been isolated. *p*-Bromobenzenediazonium chloride and *p*-nitrophenol give *p*-bromobenzenediazo-4-oxynitrobenzene

which, at 80°, becomes transformed into its isomeride, *p*-bromobenzene-2-azo-4-nitrophenol

(Ber. 1908, 41, 4027, 4304).

Occasionally traces of these intermediate diazoamines and diazo-oxides can be detected in the commercial azo- colouring matters (Vaubel, Zeitsch. Farben. Textil. Ind. 1902, 1, 3).

V. METALLIC DERIVATIVES OF DIAZO-COMPOUNDS.

In 1894 Schraube and Schmidt (Ber. 27, 514) found that on adding a 10 p.c. solution of *p*-nitrobenzenediazonium chloride to 18 p.c. aqueous sodium hydroxide at 50°-60°, a sodium diazo- derivative separated in golden-yellow leaflets, to which they gave the formula

regarding the compound as the sodium derivative of *p*-nitrophenylnitrosamine. This view of the constitution of the product was confirmed by the action on the compound of methyl iodide when *p*-nitrophenylmethylnitrosamine

was obtained.

This sodium salt, which was regarded by Hantzsch as having the constitution of an anti-diazo- compound, sodium *p*-nitrobenzenediazo-oxide (*v. infra*), has been manufactured for use in the production of 'nitrosamine red' (Badische Anilin- und Soda-Fabrik D. R. PP. 78874, 80263, 81134, 81202). The addition of excess of mineral acid to this metallic diazo- derivative, determines the regeneration of the original diazonium salt, but treatment with dilute acetic acid leads to the formation of a yellow product, *p*-nitrophenylnitrosamine $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{NH}\cdot\text{NO}$, a substance showing little tendency to couple with β -naphthol.

The silver derivative obtained from the foregoing sodium salt yields on methylation an oxygen ether $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{N}:\text{N}\cdot\text{O}\cdot\text{CH}_3$, a reaction suggesting the possibility of tautomeric change. In many instances, two isomeric modifications of these metallic diazo- derivatives have been isolated.

Benzenediazonium chloride and cold concentrated potassium hydroxide yield the normal labile form of potassium benzenediazo-oxide (I.), which readily couples with β -naphthol. The stable modification of potassium benzenediazo-oxide (II.) is produced by heating the strongly alkaline solution of the normal or labile salt at 130°-140°; this isomeride couples only very slowly with β -naphthol.

According to Hantzsch, these isomerides have respectively the following formulæ:—

I. *Syn*- (labile form).

II. *Anti*- (stable form)

Dobbie and Tinkler (Chem. Soc. Trans. 1905, 87, 273) have found, however, that these isomeric potassium salts have totally different ultra-violet absorption spectra. But as stereoisomerides, like the benzaldoximes, have identical absorption spectra, it seems probable that the above isomeric salts are structurally dissimilar. Confirmation of the stereochemical theory would be obtained by isolating the *anti*-diazo-hydroxide from the stable (*anti*-) potassium salt, but on treating this with an acid, the nitrosamine separates. Moreover, the product supposed by Hantzsch and Pohl to be an *anti*-diazo-hydroxide (Ber. 1902, 35, 2964) was shown by Orton to be a mixture of quinonediazide and a hydroxyazo- compound (Proc. Roy. Soc. 1903, 71, 153; Chem. Soc. Trans. 1903, 83, 796).

The existence of the *syn*- diazo-hydroxides is doubtful, and diazonium hydroxides (*v. supra*) are only known in solution.

Diazo- anhydrides $\text{R}\cdot\text{N}:\text{N}\cdot\text{O}\cdot\text{N}:\text{NR}$ or $\text{R}\cdot\text{N}\cdot\text{O}\cdot\text{N}:\text{NR}$ are very unstable explosive com-

pounds produced by the action of acetic acid on the metallic *syn*- diazo-oxides. The *anti*-diazo-oxides, when thus treated, give nitrosamines.

VI. DIAZO-CYANIDES.

The addition of the calculated amount of potassium cyanide to a cold acid solution of a diazonium salt determines the formation of a sparingly soluble diazo- cyanide. In many instances, two modifications of the diazo- cyanides can be distinguished, and these varieties are regarded by Hantzsch as being stereoisomeric forms. *p*-Chlorobenzenediazonium chloride, from *p*-chloraniline, yields first the yellow labile *syn*-*p*-chlorobenzenediazo- cyanide (I.), which readily evolves nitrogen, yields

I. *Syn*-diazocyanide.

II. *Anti*-diazocyanide.

p-chlorobenzonitrile on treatment with copper powder, and passes into the stable *anti*-*p*-chlorobenzenediazo- cyanide (II.). The latter substance, which is not affected by copper powder, may be distilled in steam without decomposition.

Confirmation of this stereochemical theory of the constitution of the diazo- cyanides has been obtained by a study of the cyanides derived from *p*-methoxybenzenediazonium chloride. This salt with potassium cyanide in alcoholic solution yields the *syn*-diazocyanide (III.), an orange-red insoluble substance (m.p. 51°), which couples with β -naphthol and slowly changes into the non-coupling *anti*- diazo- cyanide (IV.), a brownish-red compound, melting at 121°.

The existence of a third isomeric cyanide is indicated by evaporating at the ordinary temperature in the presence of excess of hydrocyanic acid, an aqueous solution of *p*-methoxybenzenediazonium hydroxide. The colourless crystalline product has the composition:

IV.

and possesses all the properties of a true metallic salt; it is very soluble, and its solution is an electrolyte. Moreover, this double salt couples with β -naphthol, and is converted by alkalis into the yellow *syn*-diazocyanide. These properties correspond with those of the normal diazonium salts, and the foregoing soluble cyanide is regarded as having the following constitution:

(Hantzsch, Ber. 1900, 33, 2161; 1904, 34, 4166).

The two pairs of diazo-cyanides from *p*-chloraniline and *p*-anisidine were examined spectroscopically by Dobbie and Tinkler, who found that each pair gave almost identical ultra-violet absorption spectra, whereas the above soluble diazonium cyanide gave an entirely different spectrum. These results are in accordance with Hantzsch's view of the configuration of the diazo- and diazonium cyanides (Chem. Soc. Trans. 1905, 87, 273).

It has, however, been suggested by several workers in this field that the isomerism of the diazo-cyanides is structural, the *syn*-compounds being *iso*-cyanides R·N:N·NC and their *anti*-isomerides, cyanides R·N:N·CN (Ber. 1895, 28, 861; Chem. Soc. Trans. 1903, 83, 805).

VII. DIAZO-SULPHONATES.

Although the stereochemical theory of the constitution of diazo-cyanides is supported by physical as well as chemical evidence, yet it is significant that the only other series of salts in which this isomerism has been detected is one derived from sulphurous acid, a substance resembling hydrocyanic acid in giving rise to organic isomeric derivatives which are structurally dissimilar.

The diazo-sulphonates, prepared by adding potassium sulphite to aqueous solutions of benzenoid diazonium chlorides, frequently exist in two differently coloured modifications, but in most cases the *syn*-isomeride is too unstable to be isolated in a pure state.

Potassium *syn*-2:4-diiodobenzenediazosulphonate (I.) is an orange substance, whilst the *anti*-salt (II.) is yellow:

The diazotised naphthylamines behave exceptionally, yielding only *syn*-diazosulphonates, which, on warming pass, not into their *anti*-isomerides, but into the corresponding azo-naphthalenes (Ber. 1897, 30, 71).

The *syn*- and *anti*-modifications of **potassium benzenediazosulphonate** $\text{C}_6\text{H}_5\cdot\overset{\cdot\cdot}{\text{N}}\cdot\text{N}\cdot\text{SO}_3\text{K}$, were found by Dobbie and Tinkler (*l.c.*) to have identical ultra-violet absorption spectra. This fact supports the stereochemical theory of their structures (*cf.* Ber. 1894, 27, 1726, 2099, 2586, 2930, 3527; 1895, 28, 242, 447, 834, 861; J. pr. Chem. 1894, [ii.] 50, 239; Meyer and Jacobson, Lehrbuch der Org. Chem. ii. 303).

VIII. ALIPHATIC DIAZO-COMPOUNDS.

The amines of the aliphatic series, when treated with nitrous acid, generally lose their basic nitrogen, the amino-group becoming re-

placed by hydroxyl. In some cases, however, the nitrogen is retained and an aliphatic diazo-compound is produced, having the general

entirely to the same carbon atom.

Although glycine is converted by nitrous acid or alkyl nitrites into glycollic acid, yet its ethyl ester gives rise to **ethyl diazoacetate**

24° and boiling at 143°-144°/72 mm. (Curtius, Ber. 1883, 16, 2230).

One kilogram of ethyl aminoacetate hydrochloride and 750 grams of sodium nitrite are added successively to 2 litres of water containing 5 grams of sodium acetate. The mixture is shaken until the temperature falls to 0°; 5 c.c. of 10 p.c. sulphuric acid and 500 c.c. of ether are added and the liquids thoroughly agitated. The ethereal layer separated and the treatment with dilute acid and ether repeated until red fumes are evolved. The ethereal extracts are washed with dilute aqueous sodium carbonate till alkaline, dried with calcium chloride, and the solvent removed on the water-bath. The yield of ethyl diazoacetate is 94.7 p.c. of the calculated quantity (Silberrad, Chem. Soc. Trans. 1902, 81, 600).

With iodine, ethyl diazoacetate yields diiodoacetic acid, and with aldehydes it condenses to form ketonic esters:

One of the most remarkable reactions of this diazo-ester is its condensation with benzene and its homologues, giving rise to a series of esters containing seven-membered hydrocarbon rings (Bucherer, Ber. 1896-1903, 29, 106; 30, 632, 1949; 31, 399, 402, 2004, 2241, 2247; 32, 705; 33, 184; 36, 3509; Annalen, 1908, 358, 1).

Ethyl diazoacetate, when heated with alkalis undergoes a series of complex polymeric changes (Curtius, Ber. 1885, 18, 1283; 1906, 39, 1383, 3398, 4140; 1907, 40, 84, 815, 1176, 1194, 1470; 1908, 41, 3116, 3140, 3161; J. pr. Chem. 1888, [2] 38, 408; Hantzsch, Ber. 1900, 33, 58; *cf.* Chem. Soc. Trans. 1902, 81, 598).

Diazo-derivatives are not obtained from free α -amino-carboxylic acids, and only from those amino-esters of aliphatic acids containing the amino-group in the α -position with respect to alkylated carboxyl group. The esters of those polypeptides which contain the amino-group in the α -position to a carboxyl-group can also be transformed into diazo-derivatives.

The α -aminoketones (*e.g.* α -aminoacetophenone $\text{C}_6\text{H}_5\cdot\text{CO}\cdot\text{CH}_2\cdot\text{NH}_2$) give diazo-compounds (Ber. 1904, 37, 2080), and so also do certain uric acid compounds, *e.g.* aminomethyluracil.

Diazomethane $\text{CH}_2\cdot\overset{\text{N}}{\underset{\parallel}{\text{C}}}$, the simplest ali-

phatic diazo-compound, is prepared by adding methyl-alcoholic potassium hydroxide to an ethereal solution of nitrosomethylurethane

and distilling the mixture on the water-bath, when the distillate consists of an ethereal solution of the diazo-compound, the yield being 50 p.c. of the calculated quantity. This substance is also produced by the action of hydroxylamine on dichloromethylamine

Diazomethane is a poisonous yellow gas condensing in snow and calcium chloride to a yellow liquid boiling below 0° . It is a powerful methylating agent, converting hydroxyl groups into methoxyl, and alkylating primary and secondary bases. With iodine, diazomethane gives nitrogen and methylene iodide, and aldehydes are converted into methyl ketones (cf. Monatsh. 1905, 26, 1295, 1311; Ber. 1907, 40, 479; 1908, 41, 3199; 1909, 42, 2559; Chem. Soc. Trans. 1908, 93, 242).

Diazomethane combines additively with unsaturated compounds; with acetylene it gives pyrazole (Ber. 1898, 31, 2910), and with ethyl fumarate it furnishes ethyl pyrazolincarboxylate.

Diazoethane $\text{CH}_3\text{CH:N}_2$ and **phenyldiazomethane** $\text{C}_6\text{H}_5\text{CH:N}_2$ have both been prepared (Ber. 1902, 35, 897). The former closely resembles diazomethane, the latter is a dark-red oil.

Diazomethane should not be confused with **azomethane** $\text{CH}_3\text{N:NCH}_3$, the simplest azo-compound which is produced by oxidising symmetrical dimethylhydrazine (hydrazomethane) with chromic acid (Thiele, Ber. 1909, 42, 2575). Azomethane is a colourless gas condensing to a pale-yellow liquid (b.p. 1.5°).

Diazomethanedisulphonic acid, a noteworthy example of an aliphatic diazo-compound, results from the interaction of potassium cyanide and potassium bisulphite in presence of caustic potash. The solution, acidified and treated with nitrous acid, yields successively aminomethanedisulphonic acid and the diazo-compound. Sulphurous acid and diazomethanedisulphonic acid yield an additive compound which, on boiling, furnishes hydrazine (v. Pechmann, Ber. 1895, 28, 2374; 1896, 29, 2161).

Metallic diazo-derivatives of the aliphatic series are produced by treating nitrosoalkyl urethanes with concentrated caustic potash solution or ethereal potassium ethoxide. **Potassium methyl diazo-oxide** $\text{CH}_3\text{N:NOK, H}_2\text{O}$ separates in white crystals, when nitrosomethylurethane is added to concentrated aqueous caustic potash at 0° . **Potassium benzyl diazo-oxide**

is similarly prepared from nitrosobenzylurethane. These metallic derivatives are very unstable; they are decomposed by water with explosive violence, yielding respectively diazomethane and phenyldiazomethane (Hantzsch and Lehmann, Ber. 1902, 35, 897).

DIBASIC ACIDS. *Oxalic acid series.* A

numerous and important group of acids, having the general formula $\text{C}_n\text{H}_{2n-2}\text{O}_4$. The lowest member of the series is *oxalic acid* $\text{C}_2\text{H}_2\text{O}_4$, and the highest member at present known, *dicytyladipic acid* $\text{C}_{35}\text{H}_{74}\text{O}_4$. As the radicle C_nH_{2n} is capable of existing in a variety of ways, it follows that these acids may exist in many isomeric forms. Unlike the fatty acids, the lowest members of the oxalic acid series are solids.

The naturally occurring acids exist partly free and partly as salts or esters. Thus oxalic acid occurs chiefly as the potassium salt in different varieties of *Oxalis* and *Rumex*; malonic acid as the calcium salt is found in the sugar beet; succinic acid in amber, certain varieties of lignite, resins, turpentine oils, and animal fluids; rocellic acid in *Rocella tinctoria* (D. C.). Other members of this series are obtained by the oxidation of naturally occurring substances. Thus suberic acid is obtained by boiling cork with nitric acid; azelaic acid by the oxidation of castor oil; adipic acid by the oxidation of suet or tallow. The higher members of the series are prepared by the oxidation of members of the fatty acid series.

General methods of preparation.

(1) By the oxidation of the diprimary glycols, primary hydroxyaldehydes, dialdehydes, primary hydroxy-acids, or aldehyde-acids; e.g. glycol, glycollic acid, glyoxal, or glyoxylic acid \rightarrow oxalic acid.

(2) By the oxidation of the fatty acids or of acids of the oleic acid series; e.g. erucic acid \rightarrow brassylic acid.

(3) By the reduction of unsaturated dicarboxylic acids; e.g. fumaric acid \rightarrow succinic acid.

(4) By the action of silver (powder) on mono-iodo- (or bromo-) fatty acids; e.g. β -iodopropionic acid \rightarrow adipic acid.

Exception.—The reaction is abnormal when *a*-bromisobutyric acid is used, di- and tri-alkylglutaric acids being produced.

(5) By the conversion of monohalogen substituted fatty acids or of the halogen addition products of the alkenes C_nH_{2n} into cyan-derivatives and saponification of the latter; e.g. cyanacetic acid \rightarrow malonic acid; ethylene dicyanide \rightarrow adipic acid.

(6) By the replacement of the hydrogen atoms of the CH_2 group in the malonic esters by various alkyl-groups; e.g. sodium malonic ester and methyl iodide \rightarrow *iso*-succinic ester.

(7) By the electrolysis of concentrated solutions of potassium alkyl salts of the dicarboxylic acids; e.g. potassium ethyl malonate \rightarrow diethyl succinate.

(8) By the introduction of acid residues into the acetoacetic esters, and decomposition of the product with alkali; *e.g.* acetosuccinic ester \rightarrow succinic acid.

(9) By the decomposition of tricarboxylic acids containing two carboxyl-groups attached to the same carbon atom; *e.g.* ethanetri-carboxylic acid \rightarrow succinic acid.

The acids of this series behave differently on the application of heat, depending upon the position of the carboxylic groups. Oxalic acid, the first member of the series, breaks down on heating mostly into carbon dioxide, carbon monoxide, and water, and partly into carbon dioxide and formic acid. This latter decomposition is typical of those homologues of oxalic acid in which the two carboxyl-groups are attached to the same carbon atom; they are the β -dicarboxylic acids, and of these malonic acid is the type. On application of heat, malonic acid splits into acetic acid and carbon dioxide. The next class, the γ -dicarboxylic acids, in which the two carboxyl-groups are attached to adjacent carbon atoms, when heated, lose a molecule of water and pass into anhydrides. Succinic acid is the type of these acids. Acids, such as glutaric acid, in which the carboxyl-groups are attached to two carbon atoms separated by a third, behave similarly to the γ -dicarboxylic acids, but form anhydrides less readily. When the carbon atoms to which the carboxyl-groups are attached are separated by two carbon atoms, *e.g.* adipic acid, they do not influence one another on the application of heat. For these reasons, the paraffin dicarboxylic acids are arranged in different groups, the general properties of which will be discussed under MALONIC ACID, SUCINIC ACID, and GLUTARIC ACID, which are types of the several groups mentioned above.

(For melting-points of the dibasic acids, *v.* Massol, Bull. Soc. chim. [3] 21, 578; melting-points of their esters, *v.* Schneider, Zeitsch. physikal. Chem. 22, 228; electrical conductivity of the acids, *v.* Walden, *ibid.* 8, 448; volatility in steam, *v.* Auwers, Annalen, 292, 159.)

DI-*iso*-BUTYLACETIC ACID *v.* DECATOIC ACIDS.

2·6-DI-*iso*-BUTYLPIMELIC ACID

Prepared by heating 1.5 di-*iso*-butylpentane-tetracarboxylic acid at 200°–220° (Perkin and Prentice, Chem. Soc. Trans. 1891, 842); m.p. 82°–84°.

DICENTRINE *v.* VEGETO-ALKALOIDS.

DICETYLMALONIC ACID $\text{C}_{16}\text{H}_{32}\text{O}_4$. Prepared by heating dicetylbutanetetra-carboxylic acid to 205° (Lean, Chem. Soc. Trans. 1894, 1016). Two isomers are thus produced, which may be separated by crystallisation from alcohol, α -acid, m.p. 42°–43°; β -acid, m.p. 32°–34°.

DICETYLIC ACID $\text{CH}(\text{C}_{16}\text{H}_{32})_2\text{COOH}$ is obtained by heating dicetylmalonic acid; m.p. 69°–70° (Guthzeit, Annalen, 206, 365).

DICETYLMALONIC ACID

The ethyl ester is formed by treating diethylmalonic ester with sodium methoxide and cetyl iodide: the ester is decomposed with a concen-

trated solution of caustic potash; m.p. 86°–87° (Guthzeit, Annalen, 206, 362).

DICHLOROCARBAMIDE *v.* HYDRAZINES.

DICYANDIAMIDE, *Cyanoquanidine*

Obtained by the polymerisation of cyanamide in aqueous solution on long standing or on warming, especially after addition of a drop of ammonia (Beilstein and Geuther, Annalen, 108, 99; 123, 241; Haag, *ibid.* 122, 22); by treating thiourea with mercuric aniline (Montecchi, Gazz. chim. ital. 28, ii. 434). Prepared by heating ammonium sulphate and sodium cyanamide on the water-bath; cyanamide separates as a yellow oil, which, after some hours, with frequent shaking, changes into dicyandiamide (Hermann, Monatsch. 1905, 1025). Soll and Stutzer (Ber. 1908, 4534) make crude calcium nitride into a paste with water and heat to boiling. The hot liquid is filtered by suction, and dicyandiamide separates out from the filtrate. Crystallises in needles; m.p. 205° (Pohl, J. pr. Chem. 77, [2] 533). By warming with dilute acids, it is transformed into *dicyandiamidine* (*guanyl urea*) $\text{NH}_2(\text{NH}:\text{C}:\text{NH}:\text{CO}:\text{NH}_2$. It is used in quantitative analysis to separate nickel from cobalt. The solution containing nickel and cobalt is made alkaline, and to it is added a small quantity of sugar solution. To this is added dicyandiamidine sulphate (prepared by dissolving dicyandiamide in dilute sulphuric acid), whereby the nickel salt of dicyandiamidine is precipitated, the cobalt remaining in solution. The precipitate is filtered through a Gooch crucible, dried at 115°–160°, and weighed as anhydrous nickel dicyandiamidine $\text{Ni}(\text{C}_2\text{H}_5\text{N}_4\text{O})_2$ (Grossmann and Schüek, Analyst, 1910, 247; 1909, 455; 1907, 273, 394). Dicyandiamide is reduced by zinc and dilute hydrochloric acid at the ordinary temperatures to methylamine and guanidine, the methylamine being formed by the reduction of the prussic acid first produced (Bamberger and Seeberger, Ber. 1893, 1583); a mixture of nitric and sulphuric acids converts it into nitrodicyandiamidine (Thiele and Uhlfelder, Annalen, 303, 107); it condenses with dialkylcyanacetic or malonic esters yielding pyrimidine derivatives; thus with diethylcyanacetic ester a condensation product is obtained which yields diethylbarbituric acid on treatment with sulphuric acid (Bayer & Co., D. R. P. 165223; Chem. Zentr. 1906, i, 514). All manures containing calcium cyanamide contain also dicyandiamide, formed by the spontaneous polymerisation of the calcium cyanamide; it is not poisonous to plants if not used in too large quantities (Perotti, Atti. R. Accad. Lincei, 15, i. 48; Chem. Zentr. 1909, i. 1497; Inouye, J. Soc. Chem. Ind. 1909, 1054; Aso, *ibid.*). The Cyanide-Gesellschaft (Chem. Zentr. 1904, ii. 1079; D. R. P. 154505) treat calcium carbide or a carbide-forming mixture with nitrogen, lixiviate the mass with water, and use the product, which contains calcium cyanamide, dicyandiamide, &c., as a manure (*v. also* Frank, Zeitsch. angew. Chem. 19, 835). The constitution of dicyandiamide is regarded as $\text{NH}_2(\text{NH}:\text{C}:\text{NH}:\text{C}:\text{N}$ or the tautomeride $(\text{NH}_2)_2\text{C}:\text{N}:\text{C}:\text{N}$ (Bamberger, Ber. 1883, 1459; 1891, 899; Biltz, J. pr. Chem. 77, [ii.] 533; Prianichnikov, J. Soc. Chem. Ind. 1909, 724).

DIDYMIN *v.* SYNTHETIC DRUGS.

DIDYMIUM *v.* PRASEODYMIUM and NEO-DYMIUM.

DIETHYLACETIC ACID. *Pseudo-caproic acid* (*v.* CAPROIC ACID).

DIETHYLALLOXAN *v.* ALLOXAN.

DIETHYLSAFRANIN *v.* AZINES.

DIFFUSION. In any gaseous mixture or liquid solution, even when protected from mechanical disturbances and kept at a uniform temperature throughout, the composition ultimately becomes the same at all points, whatever the original distribution of the gaseous or dissolved substances may have been. The process by which this condition is reached is termed 'diffusion,' and it depends, not on the circulation of the unequally distributed substances as a whole, but on molecular movement. According to the kinetic theory, a mass of gas which, as a whole, is at rest, is yet the scene of great activity on the part of the constituent molecules. These are endowed with a high velocity, and alter the direction of their motion only when they collide with one another or with the walls of the containing vessel. If this point of view is adopted, then the occurrence of diffusion in a mixture of irregularly distributed gases becomes intelligible. There are, moreover, many experimental grounds for extending the kinetic theory to the liquid state, and for the view that the molecules of a liquid also are in a state of constant motion. With this conception the phenomenon of diffusion of a dissolved substance is obviously in harmony.

Diffusion of Gases.

When two vessels containing different gases at the same temperature and pressure are put into free communication, each gas penetrates the other until its partial pressure is uniform in both vessels. The experimental investigation of this phenomenon on quantitative lines is not easy, but it appears to be well established that the diffusion coefficient of each gas varies from point to point of the diffusion system (*see* Lœschmidt, Sitzungsber. Akad. Wiss. Wien, 1870, 61, 367; 1870, 62, 468; von Obermayer, *ibid.* 1880, 81, 1102; 1882, 83, 147, 748; 1883, 87, 188; 1887, 96, 546; Waitz, Ann. Physik, 1882, 17, 201, 351; Lonius, *ibid.* 1909, 29, 664).

When the concentration of a gas is maintained constant at one point of a system and zero at another point, a static condition of affairs is established analogous to what is observed when one end of a metal bar is kept at a high temperature and the other end at a low temperature. If, for instance, a tall cylinder, communicating freely with the atmosphere, contains at the bottom a layer of caustic alkali, there is a regular concentration gradient from the top downwards, the carbon dioxide being completely absorbed at the surface of the alkali. Provided the concentration difference between the top and bottom of the cylinder is maintained constant, a steady condition of diffusion is attained, and the rate of flow of the carbon dioxide, as deduced from the amount absorbed by the alkali, is inversely proportional to the length of the diffusion column (*see* Brown and Escombe, Phil. Trans. B, 1900, 193, 223; also Winkelmann, Ann. Physik, 1884, 22, 1, 152).

Much attention has been devoted to the

phenomenon of diffusion across porous diaphragms, through capillary tubes, and from narrow apertures. Graham showed (*see* Chemical and Physical Researches, p. 44) that the exchange of two gases across a porous diaphragm, the pressure on the two sides remaining the same, takes place in such a way that the volumes of the gases diffused in a given time are inversely proportional to the square roots of their densities. This observation is of very great interest in connection with the kinetic theory, from the assumptions of which it follows that the mean velocity of the molecules of a gas is inversely proportional to the square root of its density. Graham's law is not accurate except when the diaphragm is extremely thin, but it is nevertheless the basis of a method for separating two gases of different densities. Thus, for instance, when a mixture of hydrogen and oxygen in the proportion of 2:1 by volume is passed at a suitable rate through a train of clay-pipe stems, the gas collected at the further end will ignite a glowing splint. By experiments of this kind it was shown that atmospheric nitrogen is a mixture of at least two gases of different density (*see* Rayleigh and Ramsay, Phil. Trans. 1895, 186, 206). The operation of separating gases by this method is termed 'atmolysis.'

In the passage of a gas through a capillary tube—'transpiration,' as it is sometimes called—friction generally plays a considerable part, but it has been found that if the diameter of the tube is small in comparison with its length and with the mean free path of the gas molecules, then the quantity of gas passing through a given tube in unit time is inversely proportional to the square root of the density (Knudsen, Ann. Physik, 1909, 28, 75).

The time required for the escape or 'effusion' of a given volume of gas through a fine aperture in a thin plate into a vacuum is approximately proportional to the square root of the density of the gas. The thinner the plate and the smaller the aperture, the more nearly is this relationship fulfilled (*see* Graham, Chemical and Physical Researches, p. 88; Bunsen, Gasometry, p. 121; Timoféeff, Zeitsch. physikal. Chem. 1890, 6, 586; Donnan, Phil. Mag. 1900, 49, 423; Emich, Monatsh. 1903, 24, 747; Knudsen, Ann. Physik, 1909, 28, 999). An apparatus for determining the relative density of two gases, based on this principle, has been described by Bunsen (*l.c.*) (*v.* SPECIFIC GRAVITY).

The passage of a gas across a diaphragm takes place, not only when the diaphragm is porous in the ordinary sense, but also when it has the power of dissolving or absorbing the gas. Thus, at high temperatures, platinum and palladium absorb considerable quantities of hydrogen, and this gas readily diffuses through the walls of a vessel made of either metal. Winkelmann (Ann. Physik, 1901, 6, 104; 1902, 8, 388) has shown that the rate of diffusion of hydrogen through glowing platinum or palladium is not, as might be expected, proportional to the pressure of the hydrogen; at lower pressures the gas diffuses relatively more rapidly. The experimental data seem to indicate that it is the atoms, not the molecules, of hydrogen which can pass through the metal. On the ability of hydrogen and the inability of other gases to diffuse through heated palladium,

there is based the osmotic cell described by Ramsay (Phil. Mag. 1894, 38, 206).

The rate of diffusion of gases across a layer of water or aqueous solution depends mainly on the solubility and the density of the gas. According to Exner, who made experiments on the diffusion of gases across a film of soap solution, the velocity is, *ceteris paribus*, directly proportional to the absorption coefficient of the gas, and inversely proportional to the square root of its density (Exner, Sitzungsber. Akad. Wiss. Wien, 1874, 70, ii. 465; cf. Müller, Ann. Physik, 1891, 43, 554). Other workers, who have studied the diffusion of gases through a jelly, through a layer of water supported by a plate of hydrophane, or through a rubber membrane, find that Exner's law is only an approximate statement of the facts (see Wroblewski, Pogg. Ann. 1876, 158, 545; Ann. Physik, 1879, 8, 29; Hüfner, Zeitsch. physikal. Chem. 1898, 27, 227; Hagenbach, Ann. Physik, 1898, 65, 673). Except for oxygen, the diffusion coefficients of gases are smaller in gelatine solution than in pure water.

Diffusion of Dissolved Substances.

The foundation of our knowledge of this subject was laid by the classical experiments of Thomas Graham (see Chemical and Physical Researches, pp. 444-600). In his experiments, 700 cub. cm. of water were placed in a cylindrical jar, and then 100 cub. cm. of the solution to be diffused were carefully conveyed to the bottom of the jar by a pipette. After a suitable time, portions of 50 cub. cm. were successively drawn off; these portions were evaporated, and the amount of substance that had diffused into each layer was thus ascertained. Graham's comparative experiments on the diffusive power of different substances in aqueous solution led him to draw a distinction, which has become of the highest importance, between the behaviour of easily crystallisable substances, and that of substances which are marked by the absence of the power to crystallise. So far as diffusibility is concerned, the distinction in question is based on the following figures, representing approximate times of equal diffusion: hydrochloric acid, 1; sodium chloride, 2.3; sucrose, 7; magnesium sulphate, 7; albumin, 4.9; caramel, 98. The difference in diffusive power of crystalloids and colloids is very evident from these figures.

The significance of the quantitative results obtained by Graham was emphasised by Stefan (Sitzungsber. Akad. Wiss. Wien, 1878, 78, ii. 957; 1879, 79, ii. 161), who showed that they were in harmony with Fick's diffusion law; that is, the diffusion of substances in aqueous solution is comparable with the distribution of heat in conductors. Fick's law is expressed algebraically by the formula $dS = -kq \frac{dc}{dx} dt$, where dS is the amount of substance crossing a section of the diffusion column in time dt , the sectional area of this column being q sq. cm., and dc/dx being the concentration gradient; k is known as the 'diffusion coefficient.'

The diffusion of dissolved substances, notably electrolytes, has been the subject of repeated investigation, but the method employed has not differed materially from that of Graham,

described above (see Scheffer, Zeitsch. physikal. Chem. 1888, 2, 390; Arrhenius, *ibid.* 1892, 10, 51; Abegg, *ibid.* 1893, 11, 248; Euler, Ann. Physik, 1897, 63, 273; Abegg and Bose, Zeitsch. physikal. Chem. 1899, 1, 17; Thøvert, Compt. rend. 1902, 134, 826; Graham, Proc. Roy. Soc. 1903, 72, 212; Öholm, Zeitsch. physikal. Chem. 1904, 50, 309). The general result of these investigations has been to substantiate the validity of Fick's law, although the opposite opinion also has been expressed (see Wiedeberg, Zeitsch. physikal. Chem. 1892, 10, 509).

Special interest has attached to the diffusion of electrolytes since the enunciation of Arrhenius's dissociation theory, according to which the ions of an electrolyte in aqueous solution are to be regarded in many respects as separate units. The researches of Kohlrausch have proved that the contribution which the one ion of an electrolyte makes to the equivalent conductivity is independent of the other ion associated with it, and Nernst has shown that the mobility which is thus characteristic of each ion must be a determining factor in the diffusive power of any electrolyte of which the ion forms a part (Zeitsch. physikal. Chem. 1888, 2, 613). He has further deduced a theoretical relationship between the diffusion coefficient of a binary electrolyte and the conductivities of the two ions, and the values of the diffusion coefficient calculated on this basis are in good agreement with the results of experimental work.

By allowing substances to diffuse into a jelly the effects of convection currents and mechanical disturbances are eliminated and the difficulties attending the experimental study of liquid diffusion are diminished. The rate of diffusion is, at most, very slightly lower in a jelly than in water at the same temperature. Experiments, in which the ends of cylinders of agar-agar jelly were immersed in aqueous solutions of various substances, have shown that the total amount of substance diffusing into the jelly is proportional to the square root of the time during which diffusion has taken place. This is a result in harmony with Fick's law (see Voigtländer, Zeitsch. physikal. Chem. 1889, 3, 316; cf. Chabry, Journ. de Physique, 1888, 7, 115; Morse and Pierce, Zeitsch. physikal. Chem. 1903, 45, 589; Hausmann, Zeitsch. anorg. Chem. 1904, 40, 110).

Experiments have been made also on the diffusion of various electrolytes and non-electrolytes in alcohol (Kawalki, Ann. Physik, 1894, 52, 166, 300; 1896, 59, 637), of various metals in mercury, fused lead, &c. (Meyer, *ibid.* 1897, 61, 225; 1898, 64, 752; Humphreys, Chem. Soc. Trans. 1896, 69, 243, 1679; Roberts-Austen, Phil. Trans. 1896, 187, 383; von Wogau, Ann. Physik, 1907, 23, 345), and of chlorine, bromine, and iodine in some organic solvents (Euler, Ann. Physik, 1897, 63, 273; Walden, Zeitsch. Elektrochem. 1906, 12, 77). In the last-mentioned connection, Walden has shown that, when a given halogen is considered, the product 'diffusion coefficient \times viscosity of solvent' is a constant, independent of the nature of the solvent. The value of the product for the different halogens is inversely proportional to the square root of the molecular weight (cf. Pissarjewsky and Karp, Zeitsch. physikal. Chem. 1908, 63, 257).

The different rates of diffusion found by Graham for different substances suggested to him that the process of diffusion might be useful in separating the constituents of an aqueous solution. In this connection, he found that the difference in diffusive power between crystalloids and colloids, referred to above, was greatly accentuated by the interposition of a colloid membrane between solution and solvent, and the method of separation by diffusion through a septum of gelatinous matter he termed 'dialysis.' A sheet of parchment paper, for instance, is tied tightly over the end of a cylindrical or bell-shaped glass vessel, provided with a flange, and into the receptacle so formed, a 'dialyser,' as it is called, the mixed solution of crystalloids and colloids is poured. The outside of the parchment membrane is bathed with water, which is frequently renewed, and the result is that the contents of the dialyser, after a few days, are found to be practically free from crystalloids. Instead of the apparatus just described, a sausage-skin dialyser may be employed: the parchment tube is charged with the solution of crystalloid and colloid, and is hung up by its ends in a vessel of water.

Collodion may be used as a membrane instead of parchment, and it is obtainable in any desired form by the evaporation of the ordinary collodion solution (see Lillie, Amer. J. Physiol. 1907, 20, 127; Schryver, Proc. Physiol. Soc. 1908, 23).

Dialysis plays a considerable part in the technical production of beet sugar. In the diffusion process for the extraction of the sugar, beet cuttings are treated with hot water. Such treatment kills the protoplasm, and the cell membrane, which in the living state is impermeable to sugar, now allows this substance to pass out into the water. The high temperature also favours rapid diffusion. The albuminous substances in the beet juice, however, cannot readily penetrate even the dead protoplasm, which acts as a differential membrane, and thus leads to a dialytic separation of the sugar from some of the non-sugar constituents of the cell sap. In the treatment also of beet sugar molasses dialysis with parchment membranes is employed. The result of this procedure is to reduce the salt content of the molasses, and so make possible the crystallisation of a further portion of the sugar (v. SUGAR).

Diffusion of Solids.

The efficiency of certain cementation processes indicates that one solid can slowly penetrate another. The occurrence of diffusion in solids has been proved and investigated by Roberts-Austen (Phil. Trans. 1896, 187, 383), who finds that at temperatures between 100° and 200° there is an appreciable diffusion of gold into solid lead in 30 or 40 days, although the penetration is much slower than into the fluid metal. Experiments lasting over four years have shown that gold diffuses into solid lead, even at the ordinary temperature (Roberts-Austen, Proc. Roy. Soc. 1900, 67, 101).

DIGITALINUM VERUM v. SYNTHETIC DRUGS.

DIGITALIS. *Foxglove. (Digitalis, Fr.; Fingerhut, Ger.)* The foxglove, or *Digitalis purpurea* (Linn.), is well known throughout the British Islands and most parts of Europe for its elegant appearance and beautiful purple-crimson flowers (cf. Woodville, Med. Bot. 24; Benth. a. Trim. 195). Foxglove is a powerful arterial sedative, reducing the force and frequency of the heart's action, and has been in use in medicine since the sixteenth century. The leaves are generally employed, but the seed possesses a like activity. (For time of gathering, see Brit. Pharm. 1885; Schneider, Bull. Pharm. 1870, 164; Nativelle, J. Pharm. Chim. [4] 20, 81.)

Numerous attempts have been made to isolate the constituent or constituents upon which the physiological action of digitalis depends, and more or less definite substances have been from time to time announced, the relation of which to one another is at the present day a matter of uncertainty. A *résumé* of the early work is given by Pereira (Mat. Med. 1850, 2, 1386). Active extractives were obtained, and variously named *digitaline*, *picrin*, or *sceptin*, in addition to other constituents common to plants.

Homolle was, however, the first investigator to prepare a fairly definite physiologically active substance from foxglove leaves. To obtain the *digitaline of Homolle*, a dried alcoholic extract of the leaves is exhausted with acetic acid and water, the solution purified by treatment with animal charcoal, and the soluble acetate converted into insoluble tannate, from which the digitaline is set free by the action of oxide of lead. The crude product is freed from inactive constituents by washing with ether. The digitaline thus obtained is exceedingly bitter, and irritating to the nasal membranes. It is white, inodorous, and imperfectly crystalline. It is insoluble in water and ether, but dissolves in alcohol. In sulphuric acid it dissolves brown to crimson after standing a few days, and in hydrochloric acid yellow to green. This is the digitalin which has from time to time found a place in the pharmacopœias (Homolle, J. Pharm. Chim. [3] 7, 57; Henry, *ibid.* [3] 7, 460; Homolle and Quevenne, Mémoires sur le Digitaline, Paris, 1851). It possesses the physiological activity of digitalis (Homolle; Bouchardat and Sandras, Ann. Thérap. 1845, 60).

Nativelle, in a series of communications (J. Pharm. Chim. [4] 15, 192; 9, 255; 16, 430; 20, 81), describes a *crystallised digitalin*. One method of obtaining this is to exhaust the dried leaves with alcohol, concentrate the solution, and mix with three times its bulk of water, when a precipitate comes down. The precipitate contains the digitalin, together with another compound, *digitin*, the former soluble and the latter insoluble in chloroform, and an important amorphous compound, *digitaleïn*, remains in the solution (v. Palm, Zeitsch. anal. Chem. 23, 22). Nativelle's digitalin consists of rosettes of slender needles, which, treated with hydrochloric acid, dissolve with an emerald-green colour. Flücker (Neuer. Jahr. Pharm. 29, 129) employs, in the place of hydrochloric acid, warm phosphoric acid, on a watch-glass, to which a few

crystals of digitalin are added. The acid becomes yellow and the digitalin of a beautiful green colour (cf. Brunner, Ber. 6, 86; Zeitsch. anal. Chem. 13, 72; Lafon, Compt. rend. 100, 1463; Hock, J. 1881, 977; and Almqvist, Arch. Pharm. [3] 5, 515). Digitalin is almost insoluble in water and ether, but dissolves in absolute, or, better, in 90 p.c. alcohol, and in chloroform. Digitin $C_4H_9O_2$ consists of stellate groups of needles. It is insoluble in water, very slightly soluble in ether, chloroform, and benzene, but soluble in alkalis and hot alcohol. Sulphuric acid dissolves it forming a brown to purple solution, but it gives no green colour reaction with hydrochloric acid (cf. Goerz, Pharm. Zeit. 1873, 385 and 417). Of the three constituents discovered by Nativelle, digitalein is the only one, according to Goerz, possessing marked physiological activity. It is a bitter, light-yellow powder. When inhaled through the nose, it causes violent sneezing. It is soluble in water and alcohol, and nearly insoluble in ether, chloroform, and benzene. It gives the green colour reaction with hydrochloric acid, and, treated with sulphuric acid and bromine, changes to red and purple. It contains no nitrogen, and very closely resembles the digitalin of Walz, which was probably the only important active constituent in the original preparation of Homolle. Like the digitalin of Walz, digitalein yields, when treated with dilute acids, glucose and a compound called digitali-retin.

Schmiedeberg (Arch. exp. Path. u. Pharm. 1874, 3, 16) found that commercial digitalin contains a new constituent, digitoxin, and in addition three glucosides—digitonin, digitalin, and digitalein. These constituents have been investigated at great length by Kiliani (Ber. 23, 1555; 24, 239, 3951; 25, 2116; 31, 2454; Arch. Pharm. 230, 250, 261; 233, 299, 311; 234, 273, 481; 235, 425; 243, 5); Kiliani and Windaus (Arch. Pharm. 237, 466); Kiliani and Merk (Ber. 34, 3562); Kiliani and Schweissinger (*ibid.* 37, 1215). The following is a brief summary of some of the more important facts brought to light. The seeds of *Digitalis purpurea* contain (1) *digitonin*, a crystalline inactive glucoside, which forms about 50 p.c. of the glucosides present, and is useless as a therapeutic agent. On hydrolysis, it yields digitogenin, galactose, and lactose; (2) *digitoxin*, which consists of minute white crystals, insoluble in water and very active physiologically,—when hydrolysed with alcoholic hydrochloric acid, digitoxigenin and digitoxose are obtained; (3) *digitalin*, having the same physiological action as digitalis. The following are given as tests for digitalis: (a) a few particles treated with 2 c.c. of 10 p.c. aqueous potash should remain colourless for at least one minute, the presence of other glucosides causes immediate colouration; (b) the sample is stirred with water to a thin paste, 22 parts of amyl alcohol added, with shaking, for every 100 c.c. water used. If digitonin is present, this will separate out within 24 hours in small crystalline agglomerates. When digitalin is heated with strong hydrochloric acid, it yields digitaligenin $C_{16}H_{22}O_2$, dextrose and digitalose $C_7H_{14}O_6$. The existence of a definite digitalein is very doubtful.

Digitalis leaves contain neither digitonin nor digitalin (see, however, Keller, Chem. Zentr.

1897, i. 1211; Cloetta, *ibid.* 1901, i. 1102); but digitoxin is present and also a glucoside digitophyllin $C_{32}H_{52}O_{10}$, probably identical with the French 'digitaline cristallisée.' This is more insoluble than digitoxin, and not so easily attacked by reagents. Other compounds obtained from foxglove leaves are *digitalic* and *antirrhinic acids*, isolated by Morin (J. Pharm. Chim. [3] 7, 294); while Walz, by distilling with water, obtained *digitalosmin*, a sort of camphor, and valerianic acid (v. also GLUCOSIDES).

The leaves of *Digitalis purpurea* contain a yellow colouring matter, *digitoflavone* $C_{15}H_{10}O_6$ (Fleischer, Ber. 32, 1184); but this, according to Kiliani and Meyer (*ibid.* 1901, 34, 3577), is in reality *luteolin*. A. S.

DIGITALON v. SYNTHETIC DRUGS.

DIGITOXIN v. SYNTHETIC DRUGS.

DIHEPTYLACETIC ACID (C_7H_{15}), CH_2COOH is obtained by treating diheptylacetacetic ester with potassium hydroxide (Jourdan, Annalen, 200, 116); m.p. $26^\circ-27^\circ$.

DIHYDRAZINES v. HYDRAZINES.

DIHYDROXY-ACIDS v. HYDROXY-ACIDS.

DIHYDROXYBENZOIC ACIDS v. PROTO-CATECHUIC ACID.

DIHYDROXYTARTARIC ACID v. KETONES.

DI-iodoform v. SYNTHETIC DRUGS.

DIKA-BREAD. An edible cake made by the natives of Sierra Leone and the Gaboon from the fruit of the mango tree, indigenous to most tropical climates. The fruit resembles chocolate in appearance, and contains a large quantity of fatty matter. It has occasionally ripened under hot-house cultivation in this country.

DIKA FAT GROUP. Under this name may be comprised several fats which are characterised by high saponification values, like the fats of the Cocoa Nut Oil group, but which differ from them by the absence of volatile fatty acids. The high saponification value indicates a preponderant proportion of lauric acid. These fats are further characterised by low iodine values. The most prominent of this group are: (1) *Dika fat*, obtained from the seed-kernels of various kinds of *Iringia*: *I. gabonensis* (Baill.), *I. Barteri* (Hook, fil.), (?) *Tangkallak fat*, obtained from the fruits of *Lepidadenia Wightiana* (Nees; Bl.), *Cylicodaphne sebifera* (Bl.), *Tetranthera calophylla* (Miquel), *Tetranthera laurifolia* (Jacq.), *Litsea Sebifera* (Pers.), *Sebifera glutinosa* (Lour.). (3) *Iringia butter*, *Cochin-China wax*, or *Cáy-cáy fat*, the fat obtained from *Iringia Oliveri* (Pierre), *Iringia malayana* (Oliv.), *Iringia Harmandiana* (Pierre), *Buchanania fastigiata* (H. Baillon). The Cáy-cáy tree—'candle tree'—is a tropical tree indigenous to Cochin China and Cambodia. Large quantities of the fat are used by the natives as candles. The freshly prepared fat is employed for edible purposes. (4) *Kusu oil*, contained in the fruit of the camphor-yielding tree, *Cinnamomum camphora* (Nees), *Lauraceae*. From its chemical characteristics, the conclusion may be drawn that it consists of pure laurin with a few per cent. only of olein. J. I.

DIKETONES v. KETONES.

DIKETOSUCCINIC ACID v. KETONES.

DILATOMETER. A term originally used to denote an apparatus for measuring the

thermal expansion of liquids. Subsequently given by Silbermann to an instrument for determining the strength of aqueous alcohol.

DILITURIC ACID, *nitrobarbituric acid*, *nitromalonylurea*, $\text{CO} \begin{array}{c} \text{NH} \cdot \text{CO} \\ \text{NH} \cdot \text{CO} \end{array} \text{CH} \cdot \text{NO}_2 \cdot 3\text{H}_2\text{O}$, obtained by treating alloxantin first with hydrochloric acid and subsequently with nitric acid (Schlieper, *Annalen*, 56, 24); by warming hydruilic acid with nitric acid (Baeyer, *ibid.* 127, 211); by nitrating barbituric acid with fuming nitric acid (Baeyer, *ibid.* 130, 140); by oxidising violuric acid (nitrosobarbituric acid) (Ceresole, *Ber.* 16, 1134); or by oxidising with nitric acid the compound $\text{C}_{16}\text{H}_{22}\text{O}_{11}\text{N}_{12}\text{S}_2$ obtained by condensing isodialuric acid with thiocarbamide (v. Vogel, *Annalen*, 315, 259; Bartling, *ibid.* 339, 37).

Dilituric acid crystallises in colourless quadratic prisms or plates, is sparingly soluble in cold, more readily so in hot water, is sparingly soluble in alcohol and insoluble in ether. It forms chloropierin when warmed with bleaching powder, is reduced by hydriodic acid to *uramil* (*aminobarbituric acid*), and suffers partial reduction when heated with glycerol, yielding *violuric acid*. Dilituric acid is tribasic, but most of the salts are acidic, and contain only one equivalent of the metal; they are sparingly soluble in water, and are not generally decomposed by mineral acids. The *ammonium salt*

the *sodium salt* $\text{C}_4\text{H}_2\text{NaO}_5\text{N}_3 \cdot 4\text{H}_2\text{O}$, *potassium salt* $\text{C}_4\text{H}_2\text{KO}_5\text{N}_3$, *calcium salt*

the *barium compound* $\text{BaCl}(\text{C}_4\text{H}_2\text{O}_5\text{N}_3) \cdot \text{H}_2\text{O}$, *ferrous salt* $\text{Fe}(\text{C}_4\text{H}_2\text{O}_5\text{N}_3)_2 \cdot 8\text{H}_2\text{O}$, and the *silver salt* $\text{C}_4\text{H}_2\text{AgO}_5\text{N}_3 \cdot 2\text{H}_2\text{O}$, are colourless; the *ferric salt* $\text{Fe}(\text{C}_4\text{H}_2\text{O}_5\text{N}_3)_3 \cdot 6\text{H}_2\text{O}$ is bright yellow, the *copper salt* $\text{Cu}(\text{C}_4\text{H}_2\text{O}_5\text{N}_3)_2 \cdot \text{H}_2\text{O}$ is greenish, the *dipotassium salt* $\text{C}_4\text{HK}_2\text{O}_5\text{N}_3$ is bright-yellow (Schlieper, *l.c.*), and the *triargentic salt* $\text{C}_4\text{Ag}_3\text{O}_5\text{N}_3$ is lemon-yellow (Baeyer, *Annalen*, 130, 140).

According to Holleman (*Rec. trav. chim.* 1897, 16, 162), dilituric acid and its homologues are aliphatic nitro-compounds in which the *iso*-form (*cf.* Hantzsch and Schultze, *Ber.* 1896, 29, 699, 2251; Hantzsch and Veit, *ibid.* 1899, 32, 607) is the stable modification. The aqueous solution of dilituric acid is faintly yellow and decomposes carbonates; the molecular conductivity for 1 gram-molecule dissolved in *v* litres of water is 323.4 (*v*=32), 341.4 (*v*=512), (μ_x should be 356); the acid is therefore almost completely dissociated in aqueous solution; the addition of one equivalent of a base does not appreciably change the colour of the solution, but on adding a second equivalent, the solution assumes the deep-yellow colour characteristic of the aqueous solutions of the salts of this acid. Assuming

that the formula $\text{CO} \begin{array}{c} \text{N} = \text{C}(\text{OH}) \\ \text{NH} \cdot \text{CO} \end{array} \text{C} \cdot \text{N} \cdot \text{OH}$ re-

presents the constitution of the acid, Holleman states that the anion

is colourless and slowly hydrolyses into the yellow anion $\text{CO} \begin{array}{c} \text{N} = \text{C}(\text{O}) \\ \text{NH} \cdot \text{CO} \end{array} \text{C} \cdot \text{N} \cdot \text{O}^-$.

Methyl dilituric acid, *1-methyl-5-nitrobarbituric acid* $\text{CO} \begin{array}{c} \text{NMe} \cdot \text{CO} \\ \text{NH} \cdot \text{CO} \end{array} \text{CH} \cdot \text{NO}_2 \cdot 1.5\text{H}_2\text{O}$,

prepared by oxidising methylvioluric acid with concentrated nitric acid (Andreash, *Monatsh.* 1900, 21, 281), crystallises from aqueous solution, and the anhydrous acid is colourless; it melts and decomposes at 143°, is readily soluble in hot water, less so in cold water, alcohol, or acetone, and sparingly soluble in ether. The aqueous solution of the acid is intensely yellow, and decomposes carbonates; the aqueous solutions of the salts are also yellow, but the solid salts are colourless or pale-yellow and sparingly soluble; the *potassium salt* $\text{C}_5\text{H}_4\text{KO}_5\text{N}_3$, the *sodium salt* $\text{C}_5\text{H}_4\text{NaO}_5\text{N}_3 \cdot \text{H}_2\text{O}$, the *ammonium salt* $\text{C}_5\text{H}_4(\text{NH}_4)_3\text{O}_5\text{N}_3$, are colourless; the *barium salt* $(\text{C}_5\text{H}_4\text{O}_5\text{N}_3)_2\text{Ba} \cdot \text{H}_2\text{O}$, the *cadmium salt* $(\text{C}_5\text{H}_4\text{N}_3\text{O}_5)_2\text{Cd} \cdot 2\text{H}_2\text{O}$, are pale-yellow; the *strontium salt* $(\text{C}_5\text{H}_4\text{O}_5\text{N}_3)_2\text{Sr} \cdot 3\text{H}_2\text{O}$ is colourless, but becomes yellow on losing its water of crystallisation. Methyl dilituric acid is stable with bases; it reacts readily with chlorine to form *methylchlorid dilituric acid*

m.p. 121°; the corresponding bromo-compound melts and decomposes at 138°-139°.

Dimethyl dilituric acid, *1:3-dimethyl-5-nitro-barbituric acid* $\text{CO} \begin{array}{c} \text{NMe} \cdot \text{CO} \\ \text{NMe} \cdot \text{CO} \end{array} \text{CH} \cdot \text{NO}_2$

obtained by oxidising dimethylvioluric acid with concentrated nitric acid (Teehow, *Ber.* 27, 3085; Andreash, *Monatsh.* 16, 26); forms colourless microscopic crystals from acetone; dissolves in 5.98 parts of water at 14°, is sparingly soluble in alcohol, melts at 152° and changes into dimethylalloxan (Holleman, *Rec. trav. chim.* 16, 162), and is reduced by hydriodic acid to dimethyluramil.

Dimethyl dilituric acid is intensely yellow in aqueous solution, and this is due to the presence of the coloured anion of the *isonitro*-form

$\text{CO} \begin{array}{c} \text{NMe} \cdot \text{CO} \\ \text{NMe} \cdot \text{CO} \end{array} \text{C} \cdot \text{NO} \cdot \text{OH}$, for on adding concentrated nitric acid, the colour almost entirely disappears; further, the molecular conductivity of the acid for 1 gram-molecule dissolved in *v* litres of water is 313.3 (*v*=32), and 337.6 (*v*=1024), (μ_x should be 352), so that in each solution the acid is almost completely ionised (Holleman, *Rec. trav. chim.* 16, 162). The salts of dimethyl dilituric acid are coloured, the *sodium salt* $\text{C}_6\text{H}_6\text{NaO}_5\text{N}_3 \cdot \text{H}_2\text{O}$ is yellow, the *potassium salt* $\text{C}_6\text{H}_6\text{KO}_5\text{N}_3$ is greenish-yellow, the *magnesium salt* $(\text{C}_6\text{H}_6\text{O}_5\text{N}_3)_2\text{Mg} \cdot 4\text{H}_2\text{O}$ is yellowish-green, the *calcium salt* $(\text{C}_6\text{H}_6\text{O}_5\text{N}_3)_2\text{Ca}$ is bluish-green, the *strontium salt* $(\text{C}_6\text{H}_6\text{O}_5\text{N}_3)_2\text{Sr}$ is pale-green, the *barium salt*

is rose-red, and the *silver salt* $\text{C}_6\text{H}_6\text{AgO}_5\text{N}_3$ is greyish-violet (Andreash, *l.c.*, and Montash, 21, 295).

Dimethylchloridilituric acid

prepared by passing chlorine into an aqueous solution of dimethylchloridilituric acid; melts and decomposes at 150°; the corresponding *bromo-derivative* melts partially at 152° (Andreassch, l.c.). Dimethylchloridilituric acid is readily decomposed by the action of bases forming water, carbon dioxide, and dimethylnitromalonamide.

DIMETHYLETHYL ACETIC ACID *v.* CA-
PROIC ACID.**DIMETHYLGLYOXIME** (*βγ*-*dioximinobutane*)CH₃:C:N:OH

, was originally obtained by Schramm, in 1883, by acting upon methyl-oximino-ethyl ketone with aqueous hydroxylamine hydrochloride (Ber. 16, 180). It is readily prepared in quantity by the following method (Gandarin, J. pr. Chem. 1908, 77, [ii.] 414):—

850 grams of commercial methyl ethyl ketone are mixed with 30 c.c. of hydrochloric acid of sp.gr. 1.19, and 1 litre of amyl nitrite is allowed to run in slowly with vigorous stirring. This takes 1½ hours, and the temperature should be maintained below 40°–50°. When the reaction is over, 800 grams of ice are added, followed by 875 grams of sodium hydroxide in 800 c.c. of water, and the mixture is shaken for half an hour. After standing, the layer of amyl alcohol is removed, and the aqueous liquid twice extracted with ether. 100 c.c. of the alkaline liquid are treated with the calculated amount of hydroxylamine hydrochloride, and the dimethylglyoxime produced is collected and weighed. If the original volume of the alkaline liquid is *v* c.c., *a* grams the weight of dimethylglyoxime obtained from the 100 c.c. of liquid, then the amount of hydroxylamine hydrochloride in grams required for the remaining liquid is equal to $656(v-100)a/109500$. This weight of hydroxylamine hydrochloride is dissolved in a little water, added to the alkaline liquid, and the whole warmed on the water-bath for an hour. The liquid is acidified with acetic acid, and the dimethylglyoxime, which separates, is filtered, washed, and dried. This product is sufficiently pure, but it may, if desired, be recrystallised from alcohol. Yield, 650–700 grams.

(For other methods of preparation, *v.* Biltz, Zeitsch. anal. Chem. 1909, 48, 164; Tschugaeff, Ber. 1905, 38, 2520.)

Properties.—Dimethylglyoxime forms colourless, glistening needles, and is insoluble in water, but soluble in alcohol. It melts at 234°, and begins to sublime at 215°. Its dibenzoyl derivative forms rhombic plates, melting at 223° (Diels and Stern, Ber. 1907, 40, 1629).

When boiled with soda, or heated with water

at 160°, dimethylglyoxime is converted into its anhydride, *dimethylfurazan*, a colourless liquid boiling at 156° (Wolff, Ber. 1895, 28, 69). It yields a peroxide, boiling at 222°–223° (726 mm.), on oxidation with nitrogen peroxide in ethereal solution (Scholl, Ber. 1890, 23, 3490); this is reduced to the dioxide again when treated with zinc and acetic acid (Rimini, Gazz. chim. ital. 1895, 25, [ii.] 266).

Application in analysis.—Dimethylglyoxime is now an important analytical reagent, owing to its property of forming a bright scarlet insoluble nickel derivative. It thus becomes possible to estimate nickel simply and accurately, in the presence of iron, aluminium, chromium, cobalt, zinc, or manganese, all of which form soluble derivatives. In addition, an excellent qualitative test for nickel in the presence of cobalt is supplied. For the latter purpose, a pinch of the oxime is added to the solution containing excess of ammonia or sodium acetate, and the liquid boiled. A scarlet precipitate is obtained even when there is present only one part of nickel in two million parts of solution (Tschugaeff, Ber. 1905, 38, 2520; Compt. rend. 1907, 145, 679; Kraut, Zeitsch. angew. Chem. 1906, 19, 1793). 0.1 milligram of nickel can be detected in the presence of 5000 times as much cobalt.

For the quantitative estimation of nickel, the acid solution is heated nearly to boiling; a slight excess of 1 p.c. alcoholic dimethylglyoxime is added, and then a small excess of either ammonia or sodium acetate. The precipitate is filtered while hot on to a Gooch crucible, washed with hot water, and dried at 110°–120°. Its formula is (CH₃:C:NO)₂Ni+(CH₃:C:NOH)₂, and it contains 20.31 p.c. of nickel; it has no definite melting-point, but sublimes at 250°. Ammonium salts do not interfere; if the acetate method is employed, the original solution should be nearly neutralised with ammonia before adding the oxime and acetate (Brunck, Zeitsch. angew. Chem. 1907, 20, 834).

By either of the above methods, cobalt and zinc may be separated from nickel; but about twice the theoretical amount of reagent is necessary. Manganese, of course, can only be separated by the acetate method. Iron, aluminium, and chromium may be separated by the ammonia method, if tartaric acid be previously added (and, in addition, ammonium chloride in the case of chromium). Iron may also be separated in acetic acid solution, provided it is in the ferrous state (Brunck, Zeitsch. angew. Chem. 1907, 20, 1845; Pretner, Chem. Zeit. 1909, 33, 396, 411; Ivanicki, Chem. Zeit. Rep. 1908, 32, 644; Rhead, Analyst, 1910, 35, 97; *v. also ANALYSIS*).

The oxime is sufficiently expensive to make its recovery desirable. This may be effected by dissolving the nickel derivative in aqueous potassium cyanide and acidifying with acetic acid. The precipitated dimethylglyoxime is purified by recrystallisation from hot alcohol, after decolourisation with charcoal (*v.* KETONES).

DIPHENAZINE *v.* AZINES.

o-DIPHENETIDINE *v.* DIPHENYL.

DIPHENYL. This hydrocarbon, which has the molecular formula, $C_{12}H_{10}$, is structurally composed of two benzene nuclei joined together by a bond linking two carbon atoms, one in each ring. The carbon atoms are numbered for the purposes of nomenclature in the following way:—

Although of minor importance, diphenyl is nevertheless the parent substance of a large number of important bases which have found application in the preparation of the so-called substantive cotton dyes, that is to say, of colouring matters which will affix themselves to the vegetable fibres without the aid of a mordant. These bases are, however, not derived directly from the hydrocarbon, but are prepared by an indirect method which will be described later.

Diphenyl was originally obtained by Fittig (*Annalen*, 121, 363) from an ethereal solution of bromobenzene by the action of metallic sodium $C_6H_5Br + BrC_6H_5 + 2Na \rightarrow C_6H_5-C_6H_5 + 2NaBr$ but it is more conveniently prepared by the method discovered by Berthelot (*Ann. Chim. Phys.* [4] 9, 453; [4] 12, 185), who obtained it by passing the vapour of benzene through a red-hot tube

The following procedure is recommended (Schultz, *Ber.* 9, 547; Hubner, *Annalen*, 209, 339); Apparatus, La Coste and Sorger (*ibid.* 230, 5). The vapour from a quantity of benzene (free from thiophene), contained in a large flask heated on the water-bath, is allowed to pass

through an iron tube, filled with pumice, which is heated to a red heat in a combustion furnace; the lower end of the iron tube is attached to a condenser and receiver, in which the products are collected. When all the benzene has distilled over, the distillate is again placed in the flask, and the vapour passed anew through the red-hot tube. The ultimate product is then fractionally distilled, and the portion boiling between 250°-260°, which solidifies on cooling, is purified by recrystallisation from alcohol. Diphenyl separates from alcohol as large, lustrous laminae which melt at 70.5°. It boils at 254° (*corr.*), and is insoluble in water. The hydrocarbon, when oxidised by chromic acid, passes into benzoic acid.

Derivatives of diphenyl and their orientation.

—The more important derivatives of diphenyl are not prepared directly from the hydrocarbon, but from certain nitro-derivatives of benzene in a manner to be described later. The hydrocarbon yields, however, halogen, nitro- and sulphonic acid derivatives analogous to those prepared from benzene, substitution taking place in either one or both rings according to the conditions of the experiment. The method of orientation adopted for these compounds may be briefly described as follows (Schultz, *Annalen*, 174, 201; Schmidt and Schultz, *ibid.* 207, 320). When diphenyl is treated with bromine, it yields a monobromodiphenyl, a substance which, on oxidation, is converted into *p*-bromobenzoic acid, thus:

It follows, therefore, that in bromodiphenyl the bromine atom must have entered in the *para*-position with respect to the linking carbon atom. When bromodiphenyl is treated with nitric acid, it is converted into a monobromonitrodiphenyl, a substance which, on oxidation, yields a mixture of *p*-bromobenzoic acid and *p*-nitrobenzoic acid. It is therefore apparent that the formula of this bromonitro-derivative must be:

Now, one of the most important derivatives of diphenyl is benzidine, a diamino-derivative of diphenyl, the preparation of which is described later. Since benzidine can be readily converted through its tetrazonium salt into the above bromonitrodiphenyl, it follows that benzidine must be 4-4'-diaminodiphenyl of the formula

The transformation of the simplest aromatic hydrocarbon benzene into diphenyl by the action of heat has already been mentioned. This transformation can, however, be effected much more readily by the oxidation of certain derivatives of benzene, and especially those which, like the phenols, have a reactive hydrogen in the *para*-position with respect to the substituting group. Thus phenol itself and also resorcin readily pass into derivatives of diphenyl when fused with potash (Barth, *Annalen*, 156, 95). With hydroquinone, the transformation is still more readily effected and the action of the

acyl derivatives lose water and form acridine derivatives. Formyldiphenylamine gives acridine

The acetyl compound yields methylacridine (Bernthsen and Bender, Ber. 1883, 16, 767). Diphenylamine also gives acridine by heating with chloroform and zinc chloride or aluminium chloride

(O. Fischer and Körner, Ber. 1886, 17, 101). With excess of oxalic acid, diphenylamine is converted into diphenylamine blue

Carbon tetrachloride reacts like oxalic acid, and gives the same blue colour. With sulphur, thiodiphenylamine, the parent substance of methylene blue, is produced:

(Bernthsen, Ber. 1883, 16, 2897). When the vapour of diphenylamine is passed through a red-hot tube, carbazole is formed:

(Graebe, Annalen, 167, 127); and the latter is also obtained from thiodiphenylamine and copper powder (Goske, Ber. 1887, 20, 233).

Tests.—A solution of diphenylamine in conc. sulphuric acid gives a deep indigo-blue colour with nitric, nitrous or chloric acid. The commercial product is a pale-yellow solid, melting not much below 54°; it should contain no oil, possess no unpleasant odour, nor turn brown on exposure to air.

Derivatives.—By passing chlorine into a solution of diphenylamine in acetic acid, a tetrachlorodiphenylamine is formed. Bromine in alcoholic solution produces a tetrabromodiphenylamine; in acetic acid, a hexabromoderivative; and at a high temperature in presence of iodine, an octo- and deca-bromo-compound. Diiododiphenylamine is formed by the action of iodine in alcoholic solution in presence of mercuric oxide. By nitration in acetic acid solution, a tetranitro-derivative is formed, whilst direct nitration yields a hexanitro-compound, crystallising in yellow prisms, and melting at 238°. The latter has strongly acid characters, and gives an ammonium salt which is used as a yellow dye known as *aurantia* (*q.v.*). Nitrosodiphenylamine is obtained by acting upon the base with amyl nitrite.

Alkyl derivatives.—Methyldiphenylamine is obtained by heating together diphenylamine (100 parts) conc. hydrochloric acid (68 parts), and methyl-alcohol (24 parts) for 10 hours to 250° in an autoclave (Girard, Bull. Soc. chim. [i.] 23, 2). It is a liquid; b.p. 282°. The ethyl derivative is obtained in a similar way; b.p. 293°. The amyl derivative boils at 330°–340°. Benzyl chloride produces a benzyl derivative which is

used in the preparation of viridine and alkali green.

Amino-derivatives.—2-Chloro-5-nitrobenzenesulphonic acid combines with *p*-phenylenediamine to form 4-nitro-4-aminodiphenylamine sulphonic acid

which, on reduction, gives *p*-diaminodiphenylamine sulphonic acid (Baeyer & Co. D. R. P. 86250, 1894). Similar derivatives are obtained by the action of *p*-aminophenol, aminophenol-sulphonic acid, and *p*-aminosalicylic acid. The sulphonic acid group may be removed by heating with dilute acids under pressure (Meister, Lucius, and Brüning, D. R. P. 112180, 1899). Paraphenylenediamine and phenol in presence of copper salts and a solution of hypochlorite are oxidised to *p*-amino-*p*-hydroxydiphenylamine (Aktien Gesell. D. R. P. 204596, 1907). Diphenylamine derivatives prepared by the action of primary aromatic bases such as *p*-phenylenediamine, *p*-aminophenol, and aminosalicylic acid on (1.3.4)-dinitrochlorobenzene, (1.3.4.6)-dinitrodichlorobenzene, and (1.4.3)-nitrochlorobenzene sulphonic acid, are used in the preparation of sulphide colours, of which the most important is dinitroxydiphenylamine

obtained from *p*-aminophenol and dinitrochlorobenzene.

Diphenylaminedicarboxylic acid is obtained by the action of anthranilic acid on *o*-chlorobenzoic acid in presence of finely divided copper. Other amino-acids behave similarly (Meister, Lucius, and Brüning, D. R. P. 148179, 1902).

Diphenylamine combines with formaldehyde, and the product forms an additive compound with sodium bisulphite

DIPHENYLENEMETHANE *v.* **FLUORENE.**

DIPHENYLHYDRAZINE *v.* **HYDRAZINES.**

DIPHENYLHYDRAZONES *v.* **HYDRAZONES.**

DIPHENYLMETHANE was first obtained by Jena, in 1870 (Annalen, 155, 86), by the dry distillation of barium diphenylacetate

According to Zincke (Annalen, 159, 374), it is produced by the action of finely divided copper, iron, or zinc or their chlorides, on a mixture of benzyl chloride and benzene or by heating benzoylbenzoic acid with soda-lime. Friedel and Crafts (Bull. Soc. chim. [ii.] 41, 324) and Schwartz (Ber. 1881, 14, 1526) obtained it by the action of benzene on methylene chloride in presence of aluminium chloride; E. & O. Fischer

(Annalen, 194, 253), as a by-product in the formation of triphenylmethane from chloroform and benzene in presence of aluminium chloride; and Hirst and Cohen (Chem. Soc. Trans. 1895, 67, 826), by the action of the aluminium-mercury couple on a mixture of benzyl chloride and benzene. It is also formed by the reduction of benzophenone (Zincke, Thörner, Ber. 1877, 10, 1473; Staedel, Annalen, 194, 307; Graebe, Ber. 1874, 7, 1624). But the methods which have found a technical application in the production of diphenylmethane derivatives, as well as of the parent hydrocarbon, are those of (1) Meyer and Würster, which consists in heating a mixture of benzyl alcohol, benzene and conc. sulphuric acid (Ber. 1873, 6, 963), and of (2) Baeyer, in which benzene, formaldehyde, or methylal are shaken together in presence of conc. sulphuric acid (Ber. 1873, 6, 221).

Properties.—Diphenylmethane crystallises in long, colourless, prismatic needles, possesses a fragrant smell, melts at 26°–27°, and distils without decomposition at 261°–262°. It dissolves easily in alcohol, ether, and chloroform.

Reactions.—On oxidation with chromic acid, it yields benzophenone. On passing the vapour through a red-hot tube, it is converted into *o*-diphenylenemethane. On heating it with sulphur to 250°, it gives tetraphenylethylene, and on prolonged chlorination with iodine chloride at 350° it breaks up into hexachlorobenzene and carbon tetrachloride (Ruoff, Ber. 1876, 9, 1485).

Nitro-derivatives.—On nitration, diphenylmethane yields two dinitro-derivatives, one of which melts at 183°, and the second, which is the chief product, at 118°. Other dinitro-derivatives are obtained from nitrobenzyl chloride, benzene and aluminium chloride, nitrobenzyl alcohol, benzene and sulphuric acid or nitrobenzene, formaldehyde and sulphuric acid, in a similar manner to the parent hydrocarbon. Also nitrohydroxy-derivatives can be prepared by condensing nitrophenols and their ethers with formaldehyde and conc. sulphuric acid (D. R. P. 72490). The prolonged action of nitric and sulphuric acids gives rise to a tetra-nitro-derivative.

Amino-derivatives.—The only substances possessing at the present time an industrial value are the amino-derivatives of diphenylmethane. They may be obtained by the reduction of the nitro-derivatives by tin and hydrochloric acid; but the more common method is to effect condensation between the aromatic base and formaldehyde, a general process for which a number of patents have been granted in recent years. Thus, by heating aniline, aniline hydrochloride and formaldehyde, 40 p.c., to 100°, 4,4'-diaminodiphenylmethane is produced (D. R. PP. 53937 and 55565). The reaction appears to occur in two stages, for on heating aniline, formaldehyde, and a strong alcoholic solution of potassium hydroxide, the following change takes place:—

and the latter when heated with aniline and its hydrochloride passes into the diphenylmethane

derivative. A tetramethyldiamino-compound is obtained in a similar manner from dimethyl-aniline and formaldehyde in acid solution. Similarly, a diphenyldiamino-derivative

has been prepared from diphenylamine and formaldehyde (D. R. P. 58072), a tetramethyldiaminodihydroxy-derivative

from dimethyl-*m*-amino phenol (D. R. P. 63081 and 67001) and a diethoxydiaminodiphenylmethane $\text{NH}_2(\text{C}_2\text{H}_5\text{O})\text{C}_6\text{H}_3\cdot\text{CH}_2\cdot\text{C}_6\text{H}_3(\text{OC}_2\text{H}_5)_2\text{NH}_2$ from *o*-phenetidine and formaldehyde in presence of hydrochloric acid (D. R. PP. 70402, 72490, 73951, 73946).

Other methods for obtaining 4,4'-diaminodiphenylmethane are (1) the action of *p*-aminobenzyl alcohol on aniline hydrochloride in aqueous solution (D. R. P. 96762), and (2) heating *p*-aminobenzylaniline with hydrochloric acid (D. R. P. 107718)

DIRECT BLUE, -BROWN, -GREY, -INDONE BLUE, -ORANGE, -ROSE, -YELLOW *v.* AZO-COLOURING MATTERS.

DISAZO- and TETRAZO- COLOURING MATTERS. The terms 'disazo' and 'tetrazo' are both used to indicate the presence of two azo-groups (:N:N:) in the molecule of a colouring matter, but at the same time they indicate the mode of preparation of such dye-stuffs rather than, strictly speaking, their constitution. Tetrazo-colouring matters may be regarded as a special division of the disazo-colouring matters, as will be seen from the following classification.

Primary disazo-colouring matters are obtained by the action of two molecules of a diazo-compound (derived either from two molecules of an amine or from two different amines) on one molecule of an amine (*e.g.* *m*-phenylenediamine, *m*-tolylene-diamine), a phenol (*e.g.* phenol, resorcinol, a dihydroxynaphthalene) or an aminophenol (*e.g.* aminonaphtholsulphonic acids). The position taken up by the diazo-groups may be illustrated by the commonest cases (*see also* AZO-COLOURING MATTERS). *m*-Phenylenediamine: The azo-groups occupy the two positions para- with respect to the two amino-groups. When one of these para-positions is occupied, as in *m*-tolylene-diamine, the second azo-group enters the ortho-position with respect to the second amino-group; thus:

Phenol, α -naphthol. The para- and ortho-positions with respect to the hydroxy- group are occupied.

Resorcinol. Two isomeric disazo- dyestuffs may be formed. When the combination is effected in alkali hydroxide solution, the symmetrical compound (I.) is obtained, but when

the reaction takes place in the presence of sodium acetate or sodium carbonate, the unsymmetrical compound (II.) is produced.

Dihydroxynaphthalene. Here the azo-groups enter the usual position with respect to the hydroxy- groups, as would be expected if these groups represented two independent naphthols (cf. AZO-COLOURING MATTERS).

Aminonaphtholsulphonic acids. In this case also, the compound may be regarded both as an independent naphthylamine and as a naphthol; one molecule of the diazo- compound is combined in acid solution, when the position taken up by the azo- group is the same as if the substance were a naphthylamine, and the second molecule is combined in alkaline solution as if the substance were a naphthol.

Secondary disazo- colouring matters are obtained by the action of a diazoazo- compound on an amine or phenol; their general formula is $X \cdot N_2 \cdot Y \cdot N_2 \cdot Z$, the essential difference from the primary class being that Y does not contain auxochrome groups (NH_2 or OH).

Tetrazo- colouring matters are produced from diamines, both amino- groups of which are diazotised (i.e. the diamine is tetrazotised) and combined with two molecules of the same or different components (amines or phenols). These are mostly derived from benzidine, tolidine, dianisidine, &c.; some, however, are prepared from *p*-phenylenediamine, and in this case direct tetrazotisation cannot conveniently be effected, but the monoacetyl compound is first diazotised and combined, the acetyl- group being then eliminated and the free amino- group is diazotised and combined with the second molecule of a component.¹ When the first combination has been effected with an amine (in practice nearly always a naphthalene derivative), and in consequence a diamino- compound is produced on saponification, treatment with one molecule of nitrous acid leads to the diazotisation of the benzenoid amino- group, that attached to the naphthalene ring not being attacked.

For the sake of completeness, it is necessary here to describe these dyestuffs which contain three or more azo- groups.

Trisazo- colouring matters are obtained in the following ways. (1) Combination of three mole-

cules of a diazo- compound with a phenol. This method is of only theoretical importance, and has hitherto been applied only to the cases of phenol (Wallach and Fischer, Ber. 1882, 15, 2814; Grandmougin and Freimann, *ibid.* 1907, 40, 2662; J. pr. Chem. 1908, [ii.] 78, 384; Heller and Nützel, *ibid.* 1907, [ii.] 76, 58; Heller, *ibid.* 77, 189), phloroglucinol (A. G. Perkin, Chem. Soc. Trans. 1897, 71, 1154), and resorcinol (Orndorff and Ray, Ber. 1907, 40, 3212; Amer. Chem. J. 1910, 44, 1). (2) Combination of one molecule of a diazoazo- and a diazo- compound with a phenol, amine, or aminophenol. The diazoazo- compound may be produced, for example, by diazotising an aminoazo- compound such as *p*-sulphobenzeneazo- α -naphthylamine, or the intermediate product, obtained by combining a tetrazotised diamine (benzidine, &c.) with one molecule only of a component (such as salicylic acid, &c.), may be used. (3) Combination of a diazotised tetrazo- colouring matter (which must, of course, contain a diazotisable amino- group) with a phenol or amine, either in substance or on the fibre. (4) Combination of a triamine (e.g. magenta), having each amino- group diazotised, with three molecules of a component.

Tetrakisazo- colouring matters, containing four azo- groups, are obtained (1) by the combination of two molecules of a diazoazo- compound with a phenol or amine (e.g. Mekong yellow, *v.* AZO-COLOURING MATTERS); (2) by combining two molecules of a diazo- compound with one of a tetrazo- colouring matter (e.g. Benzo brown G); (3) by combining a tetrazo- compound with two molecules of a monoazo- colouring matter (e.g. Hessian brown BB); (4) by tetrazotising a tetrazo- colouring matter (containing two diazotisable amino- groups) and combining with two molecules of a component (e.g. Cuba black); (5) by diazotising a trisazo- colouring matter (containing one diazotisable amino- group) and combining with a phenol or amine either in substance or on the fibre.

Colouring matters, containing more than four azo- groups, can be prepared, but, generally speaking, their tinctorial power is little or no greater than those described above. J. C. C.

DISINFECTANTS. A disinfectant is an agent that will kill lower organisms which act injuriously on the higher forms of life. Although most disinfectants are also antiseptics and deodorants, a clear difference between the three classes lies primarily in their uses and objects. Disinfectants are germicides; antiseptics may only retard or inhibit the growths. It is not essential for a disinfectant to effect absolute sterility; in practical disinfection, there is nearly always a residue of highly resistant and non-pathogenic organisms. To destroy these involves great additional time and cost, and may even be disadvantageous when they act as natural scavengers in removing objectionable organic matter and antagonising dangerous forms. The choice of an agent will obviously depend on considerations of safety, convenience, and economy in use.

Ordinary oxygen acts slowly by the aid of aerobic organisms. Its activity is slightly increased by compression; it becomes exceedingly energetic when converted into its allotropic form of Ozone as obtained by passing an

¹ An alternative method is first to combine diazotised *p*-nitroaniline with the component, then to reduce the nitro- group with sodium sulphide, and diazotise the amino- group thus formed.

electric discharge through ordinary air. Since ozone is decomposed by heat and absorbed by most metals and by otherwise inert organic matter, the chief conditions for success and economy in working are (1) avoidance of sparking; (2) keeping the gas and the apparatus cool; (3) straining the air, and also partially drying when it is desired to prevent the formation of oxides of nitrogen; (4) parts in contact with ozone must be made of, or lined with, unoxidisable materials; (5) the grosser organic impurities, as well as sulphuretted hydrogen and ferrous iron, should be removed before disinfection. The use of ozone on the large scale for purifying water and sewage is now well known, and the principal types of apparatus for the purpose have been described by Don (Inst. Mechan. Engineers, Jan. and Feb. 1909), and by the writer (J. R. San. Inst. 30, 1, 1909), while a good account of European and American plants is also given in the Engineering News, New York, April 28, 1910. Rideal found at St. Maur Waterworks, Paris, that with the sand-filtered (Marne) river water, containing a fluctuating number of bacteria, 28 to 320 per c.c., with a mean frequency of *coli* organisms of 1 per 100 c.c. (in more than one-third of the tests it was 1 in 40 c.c.), ozone in the proportion of about 0.6 gram per cubic metre of water (6 lbs. per million gallons) destroyed all bacteria except an average of 1 per c.c. of innocuous spore-bearing organisms of the *subtilis* type. The ozonised air was applied in a De Frise tower at the rate of about 40 p.c. of the volume of water treated, and contained 1.4-1.8 grams of ozone per cubic metre (determined at frequent intervals by neutral potassium iodide). It is a great advantage of ozone that in disinfecting the water it produces no alteration beyond a great physical and chemical improvement, and it has been fully proved that where water is not too contaminated with organic matter, sulphuretted hydrogen, or ferrous iron, ozone will destroy all pathogenic organisms at a reasonable cost. In the dry state, like chlorine, it has very little action on micro-organisms, and therefore does not act powerfully on bacilli in air. Some American experiments, however, seem to show that 8 grams per cubic metre of air in a room ordinarily closed accomplish disinfection in 3 hours. Its use as an adjunct to ventilation has often been proposed, but its irritant action on the lungs is a difficulty. All observers have found that when moist it is a very powerful germicide. Ozonised air, under pressure, has been used successfully for destroying moulds and bacteria in brewers' foul casks, and has been introduced into wort in the latter part of the fermentation 'to destroy noxious germs' (Eng. Pat. 22355, 1898). On account of its rapid consumption by oxidisable substances, it can only be effective in disinfecting the surfaces of organic solids. At the Pittsburg Homeopathic Hospital, ozone, besides purifying the water supply, is used for sterilising instruments, bandages, &c., and for dressing wounds and ulcers. In cold storage it would probably be useful for destroying injurious organisms and odours, thereby possibly lessening the amount of refrigeration required. Many attempts have been made to utilise it for disinfecting, combined with bleaching, textiles, feathers, and

other surface-contaminated articles, and have been only limited by questions of expense.

Patent 4153 of 1902, for 'fixing ozone in liquids,' states that pure acetaldehyde dissolves 2823 times its volume of ozone; that 10 p.c. solutions of acetaldehyde in water dissolve 536, in alcohol 748, in ether 859 volumes of ozone; that these solutions are very stable, and have been successfully used in surgery.

Hydrogen peroxide. The first experiments (Ber. 15, 1585) showed that this was a bactericide which, in the dilute state, appeared inert to enzymes such as diastase,¹ ptyalin, pepsin, and pancreatin; did not injure foods; and is also innocuous and non-corrosive. These properties suggested its use for killing pathogenic organisms, and those that cause change in articles of diet, especially milk (Renard), and also as an internal disinfectant. Althoefer (Centr. Bakt. 1890, viii, 129) and most later observers give 1 per 100 of H₂O₂ as required to destroy pathogenic organisms in 24 hours. In 1903 the writer found that in milk raised to 50°, then treated with 0.6 gram of H₂O₂ per litre, and the heat maintained at 52°-55° for 8 hours, pathogenic organisms and even the spores of *B. anthracis* and *subtilis* were killed, the milk was not physically altered, and kept for over a month unchanged in the closed receptacles (Budde's patent 10903, 1903). Similar results have been obtained by Lewin and others, and by Hewlett (Lancet, Jan. 27, 1906). So that hydrogen peroxide aids pasteurisation, and enables it to be efficient at a lower temperature. The solution is frequently used as a spray, gargle, or dressing. Peroxide of hydrogen is present in 'Sanitas' (*q.v.*), 'Perhydrol' is a 30 p.c. or 100 volume solution of H₂O₂. The use of peroxide of hydrogen in medicine depends partly on its bactericidal action. Registered names of solutions are 'Dioxogen' (3 p.c.), 'Hydrozone,' 'Glycozone' and 'Pyrozone' (dental practice); and 'Peroxols' are mixtures of H₂O₂ with various disinfectants. Peroxides of sodium, magnesium ('Hopogan'), zinc ('Ektogan' or 'Dermogen') and mercury, generate oxygen or H₂O₂, and have analogous use. Hydrogen peroxide is more stable in ether than in water; 'ozonic ether' is an ethereal solution containing about 1.2 p.c. of H₂O₂, which has been used in whooping-cough and scarlet fever.

Foregger and Philipp (J. Soc. Chem. Ind. 1906, 298) treat at length on the applications of peroxides, and suggest calcium peroxide instead of H₂O₂ for sterilising milk, as more lasting in effect. For water sterilising, tablets of magnesium peroxide and citric acid are made; Park found that 0.1 gram of this peroxide killed upwards of 2 million typhoid organisms in 150 c.c. of water in 30 minutes, and 0.2 gram gave the same result in 1 minute. Patents for similar uses of H₂O₂ and other peroxides are very numerous.

Nitric acid and oxides of nitrogen. The corrosive action of nitric acid limits its value as an active disinfectant. J. C. Smith used it with success in 1780 for fumigation in a violent

¹ The enzyme *catalase* (present in malt, yeast, milk, and many organic liquids) and hydrogen peroxide mutually decompose one another (Van Laer, J. Soc. Chem. Ind. 1906, 489; 1909, 950); but the above statement remains practically true. (See also *ibid.* 1909, 1267.)

outbreak of *typhus* fever in the British fleet (Vallin, *Disinfectants*, 1882, 265). Disinfection of rooms by nitrogen peroxide was carried out during the siege of Paris; 48 hours were occupied, and the cost was very high. Severe bronchitis and several deaths from poisoning have resulted from breathing this gas, and nitric disinfection has been replaced by safer methods, except in the local destruction of bacteria as in laboratories.

Sulphur. Dusting with sulphur is used for killing insects and fungi on plants, as sulphurous acid is gradually formed. The use of sulphur internally is due to its forming sulphuretted hydrogen in the system, and thereby destroying or enfeebling micro-organisms and higher parasites. A solution containing calcium polysulphides, made by boiling milk of lime with sulphur, has been extensively used as an insecticide (*see* Agric. Bull. 319 and 320, New York, 1909).

Sulphur dioxide disinfection is still a subject of controversy, but certain of the unfavourable results adduced have been due to faulty application. Spores are not generally killed by it, and the dry gas has very little effect on micro-organisms, but it destroys all vermin, and therefore is of special value in combating insect-borne diseases. As to its effect on the lungs, about 5 p.c. in the air has produced fatal results, but $\frac{1}{2}$ p.c. can be tolerated for some time, and a larger amount with the protection of a wet towel alkalisied with washing soda. 1 lb. of sulphur burnt in a room of 1000 cubic feet produces theoretically an air-content of 1.15 p.c. SO_2 , and requires 0.56 lb. of water to turn it into sulphurous acid. Such an amount of moistening is, however, not necessary, on account of the natural moisture of the air. Prescriptions as to the proper quantity of SO_2 have varied greatly, partly because in some cases it has been considered sufficient to destroy only a special organism. Klein, Houston, and Gordon (Report, Med. Off. L.C.C. 1902) found that with $3\frac{1}{4}$ lbs. S per 1000 cubic feet in 24 hours, *B. typhosus*, *diphtheriæ*, *pyocyanæus*, and *Staph. p. aureus* were killed, but not anthrax spores nor *B. tuberculosis* in dried sputum. In America, 5 lbs. per 1000 cub. feet have been found sufficient to kill all spore-bearing organisms after 16 hours' exposure (Rosenau). Rideal's results with the liquefied gas were as follows. Silk threads and paper slips infected with *B. coli* and *Staph. p. aureus* were sterilised after 24 hours' exposure in a sealed room of 1500 cub. feet, into which 20 ozs. of SO_2 were passed. *Subtilis* spores were not killed. With 10 ozs., the threads were again sterilised, but the paper slips were not. When shallow pans of water were exposed in the room to supply moisture, the SO_2 content of the air was actually *lowered* after the 24 hours (through absorption by the water), from 0.5 p.c. present in the previous experiment to 0.2 p.c., and the organisms were still living. Therefore moisture should only be supplied by washing or lightly spraying the surfaces. In chemical disinfection, it is generally recommended that walls should be previously stripped and fabrics spread out in lines; but spreading the infection must be carefully avoided. The room must be sealed by obvious means, and, observing this condition, heating is advantageous. Liquid SO_2 in

canisters is more convenient than burning sulphur, and avoids risk of fire: one pound of the liquid = $5\frac{1}{2}$ cub. feet of the gas. SO_2 has the disadvantage that it attacks metals and organic substances from the production of sulphuric acid; a good deal is also absorbed by plaster. It has little penetrating power, and therefore bedding and thick articles must be removed and sterilised by heat. The 'Clayton method' of disinfection is much used for the holds of ships, and has been favourably reported on by Wade and Eyre for the Local Government Board (Rep. 232, 1906; and Med. Off. Rep. 1903-4, 330). Sulphur is burnt in a special apparatus, and the gases, consisting of air, SO_2 , and a visible cloud of sulphuric acid, are forced in till the SO_2 reaches about 10 p.c. of the air in the infected space. (For experience of its use, *see* Rev. d'Hyg. Oct. 1902; N.S.W. Agric. Gaz, 1900 and 1901.)

Sulphurous acid is used beneficially as a germicidal spray or wash in various parasitic affections (*e.g.* diphtheria), also internally in cholera and gastric fermentation, for rectal injections, and other allied objects. 'Thioeamf' is a liquid obtained by the action of the gas on camphor. It can be preserved without pressure in well-closed vessels, and on exposure to air a 6-oz. bottle should evolve about 20 litres of SO_2 .

Sulphurous acid and bisulphites are widely used for checking fermentations and preserving food. Lehmann states that an amount equivalent to 0.004 p.c. of SO_2 may be allowed without injury to health. The Report of the British Departmental Committee on Preservatives, 1901, 26, leaves the matter open. Some commercial preparations are 'Meat preserve crystals,' 'Freeze-cm,' and 'Hawke's anti-ferment.' For objections to the use of sulphites in food, *see* Thresh and Porter, *Preservatives*, 1906, 70-77; also an article by Durham in the *J. of Hygiene*, April, 1909. The latter recommends the fixing of a maximum legal limit, not exceeding 0.01 p.c. of 'total sulphur dioxide,' with a declaration of the amount, but less than 0.001 or 0.002 p.c. might be simply declared as a 'trace.'

Sulphuric acid, like acids generally, is anti-septic, and in some cases disinfectant. 0.05 p.c. (which is a palatable strength) is fatal to *Sp. cholerae* in 15 minutes. Stutzer found that this strength disinfected iron pipes, cleaning out rust and sediment without sensibly attacking the metal. With 0.04 p.c. Ivanhoff destroyed cholera organisms in Berlin sewage, and with 0.08 p.c. in that from Potsdam. The writer finds that 0.035 p.c. kills *B. typhosus* in 30 minutes, and 0.07 p.c. in 15 minutes, in impure water infected ordinarily with typhoid, but with very heavy infections the latter strength requires 45 minutes. He recommended 0.09 p.c. as having advantages over heat sterilisation for dealing with the drainage from hospitals and other infected areas: the acidity would speedily be neutralised on mixing with the bulk of the sewage (*Brit. Assoc.* 1901).

Sodium bisulphate has been introduced by the writer and Dr. Parkes, as a means of sterilising drinking water for armies in the field and travellers. 15 grains of NaHSO_4 to a pint of water in 15 minutes destroys *B. typhosus* and *enteritidis*, *Spirillum cholerae*, and internal

parasitic worms. In effervescent tablets, yielding a slightly acid solution, it was used with success in the South African and Russo-Japanese wars.

Persulphates give off oxygen when moist, and are useful as hand disinfectants (Lancet, 1905, ii. 1106).

Carbon disulphide, if it were not for its other properties, would be a valuable disinfectant and preservative. As well as its alkaline compounds, the xanthates, it has been found useful against fungi, and insect parasites such as the vine phylloxera. Ckeandi Bey's lamp burns it safely for generating SO_2 .

Boric acid is not a disinfectant, but has a power of restraining bacteria which act injuriously in foods. Rideal and Foulerton found that 1 in 2000 of a boric mixture, containing 3 parts of H_3BO_3 and 1 part of crystallised borax, keeps milk sweet for 24 hours without appreciable effect on digestion. The British Departmental Committee already referred to, recommend that the only preservatives allowed to be used in cream, butter, and margarine be boric acid, or mixtures of boric acid and borax, not exceeding 0.25 p.c. of H_3BO_3 for cream, and 0.5 p.c. for butter and margarine. Later, as this quantity appeared insufficient in the cream trade, an official report by Hamill advised that 0.4 p.c. H_3BO_3 should be allowed in cream from May to October inclusive (Food Report 10, L.G.B. 1909).

The Halogens, chlorine, bromine, and iodine, act as disinfectants in several ways: (1) they can combine with H and liberate O in water; (2) they can combine directly with organic matters, or replace the hydrogen in them, precipitating albuminous substances and rendering them imputrescible, killing organisms by combining with and coagulating protoplasm, removing their food or rendering it unsuitable, acting toward them as irritants or direct poisons, also producing substances which have that effect.

Chlorine and the hypochlorites, like other oxidisers, are consumed by otherwise inert organic and inorganic matters present, but in ordinary disinfection leave behind them as substitution compounds which maintain germicidal power—the chloramines, hydrazine, and the chloroproteids (Rideal, J. R. San. Inst. 31, 2, 1910). This paper shows that in dilute solution the Rideal-Walker coefficient of 2.18 for 1 p.c. of available Cl is increased to 6.36 by the addition of an equivalent of ammonia, remains near this level for 24 hours, and even after 72 hours has an enhanced value. Therefore, since the coefficient of chlorine itself averages 220 units, that of ammonia less than 0.7, and ammonium chloride nil, that of the chief product, *chloramine* NH_2Cl , must be over 600 units; hence this substance, but for its instability, would probably be the most valuable of disinfectants. It has a pungent odour, hitherto often mistaken for chlorine or hypochlorous acid, and gives the blue reaction with KI and starch. With excess of ammonia, as in sewages, it gradually disappears, forming a salt of *hydrazine*, which still has a germicidal value (R. W. coefficient of the base at least 24). The action of chlorine on nitrogenous compounds gives compound chloramines, many of which are insoluble: they have a ten-

dency to become fixed on cellulose, and in this way attack the envelopes of organisms.¹

Chlorine in the free state has been generally disused in disinfection on account of difficulties in practice. Hypochlorite preparations must be tested as to the amount of 'available chlorine.'

Chloride of lime, or 'calx chlorinata' (about 33 p.c. available chlorine), has some advantages from being a solid, but is quickly deliquesced and decomposed by air, takes some time to dissolve, and gives a quantity of insoluble waste. Klein found that 1 p.c. of bleaching powder only killed less resistant organisms in 24 hours. There is, in many respects, a preference for the sodium solutions: chlorinated soda or 'Eau de Labarraque' (often called 'Eau de Javel,' which was originally the potash salt), contains about 2.5 p.c. av. Cl; 'Chlorox,' 10 p.c. av. Cl; 'Antiformin' is a solution of caustic soda and hypochlorite used in breweries. Electrolytic preparations are 'Oxychloride,' up to 11.5 p.c. av. Cl, and 'Hermite fluid,' used successfully at Poplar. In the latter solution magnesia is employed as an adjunct in the electrolysis: it contains free hypochlorous acid: av. Cl 4.2 to 4.8 p.c. The electrolytic are somewhat more active than the chemically prepared solutions. The effective strength for local disinfection is 0.35 p.c. av. Cl, which kills non-sporing organisms in 5 to 10 minutes, and anthrax and enteritidis spores in $1\frac{1}{2}$ hours. Chloride of lime has the objection that it leaves the surface for a long time damp from the presence of calcium chloride. The same salt imparts its bitter taste, and increases the hardness, when chloride of lime is applied to the purification of drinking water, while the soda preparations tend to soften the water and are not sensible in the flavour. In trials at Guildford in 1904 (J. R. San. Inst. xxvi. 891) with electrolytic hypochlorite in the proportion of 0.75 to 1.0 part per million of av. Cl, the writer found that water containing an average of 90 organisms per c.c. was practically sterilised, while after standing $1\frac{1}{2}$ hours the odour and taste were normal, and there was no need for further treatment. (Candy's patent, 4212, 1909, removes excess of av. Cl by filtration through coke, and Thresh's, 3023, 1909, by treatment with metallic iron.) After the Maidstone typhoid epidemic, 1897, the infected reservoir, mains, and pipes, were sterilised with 1 p.c. solution of chloride of lime during 48 hours: no corrosion of the iron was observed. During a similar outbreak at Lincoln, in 1905, the water supply was sterilised by sodium hypochlorite (av. Cl, 1 per million) with most satisfactory results. In 1910 Toronto treated its water supply with 0.14 part per million of av. Cl as chloride of lime. Since June, 1909, the writer has been applying 'Chlorox' in the proportion of 1 to 2 parts av. Cl per million to 100,000 gallons daily of the drinking water of a town in the north of England: the liquid is made practically sterile, *coli* is absent from 75 to 85 c.c., and there is no effect on the taste. At Cambridge, in 1910, a portion of the supply (lower chalk) was treated with one in 4 to 8 millions of av. Cl as chloride of lime, and Houston found that this minute quantity destroyed 66 to 98 p.c. of the bacteria, and *coli*, which was always present

¹ Also see Cross Bevan and Bacon, Chem. Soc. Trans. 1910, 244.

before, was afterwards absent in 500 c.c. This water, however, contained hardly any organic matter. In America, treatment of the entire water supply of Jersey City (about 40 million gallons per day, from the Rockaway river) with chloride of lime, has been adopted since the beginning of 1909: the proportion used is now 0.2 part per million of av. Cl, and the daily examination shows that *coli* is absent from 10 c.c. of the treated water.¹

With sewage, of course, a larger dose is required, and the first experiments at Nice, Brest, and Worthing, in 1894, with the Hermite fluid, showed that, as with ozone and other disinfectants, the agent should be applied, not to a raw liquid (except in special cases), but as a 'finisher' to one that was partially purified. In 1898, using an electrolytic brine (Woolf's 'Electrozone') for purifying an effluent at Maidenhead, the writer found that with three parts per million of av. Cl, and a contact of 5 minutes, the bacteria were reduced to 10 per 50 c.c., and that 17 parts per million killed all the organisms in 15 minutes. His long series of trials at Guildford commenced in 1904, using 'Oxychloride,' and proved that with 2.5 parts per million of av. Cl, tertiary effluents could be practically sterilised, but that the raw sewage and septic effluents required 30 to 70 parts; the contact period was 4½ hours (J. R. San. Inst. xxvi. 7, 1905). The oxygen consumed from permanganate in 5 minutes in the cold, as measuring the H₂S and other easily oxidisable substances, was a guide to the amount of the agent used, and in the earlier experiments it was found that when the av. Cl added was 1.7 times this figure, the availability of the chlorine was sufficiently prolonged to ensure the desired sterilising effect, and the subsequent experiments frequently yielded excellent results with an amount equal to this oxygen figure, that is, one to one. (See further, Rideal, Trans. Farad. Soc. iv. 3, 1909.) An important point shown was that the necessary factor of safety could be ascertained by simply testing with KI and starch, and noticing the persistence after 4½ hours of the blue colour, due in this case, as has been mentioned, not to chlorine, but to chloramines. Schumacher used the test similarly in his later extensive experiments on raw sewages (especially those from hospitals) at Hamburg, and states that with them sufficient sterilisation is attained if after 4 or 6 hours the test shows a reaction equal to 19 and 17 parts per million of av. Cl respectively (Ges. Ingenieur, Berlin, 1905). Investigations on the sterilisation of sewage filter effluents with chloride of lime were continued in America by Phelps and Carpenter (U.S. Technological Quarterly, Dec. 1906), who remark that the use of electrolytic chlorine manufactured on the spot would, in the larger works, considerably reduce the cost, and is cheaper than sand filtration, and Kellerman, Pratt, and Kimberley (U.S. Dept. of Agric. Bull. 115, Oct. 1907), who conclude that with a hypochlorite, complete disinfection was effected at a lower cost than with copper sulphate. Later American experiments at several centres

have proved that 2 to 5 parts per million of av. Cl destroy 95 to 98 p.c. of the bacteria in 2 hours, and that 3 parts are sufficient for the trickling filter effluents tried (Mass. Inst. Technol. 5, 1909; 6, 1910).

The Royal Commission on Sewage obtained results at Guildford which were in agreement with those of the writer (Appendix iv. 1910, 87; also *ibid.* 84-171, and Rep. 1908, 195-201).

Sol. hypochlorite solutions are the best means of sterilising swimming baths; they remove from the surfaces growths of algae and fungi which harbour dangerous organisms. (Also see Rideal and Orchard, J. San. Inst. 556, 1906.)

'Ferrochlor' (Duyck) is the name of a treatment with 8 parts per million of ferric chloride and 0.5 part of chloride of lime, which at the same time clarifies water and liberates hypochlorous acid.¹

Chlorine peroxide, obtained from potassium chlorate and sulphuric acid, has been successfully employed in the Howatson-Bergé process at Brussels, Ostend, and Lectoure (South France), for sterilising (previously clarified) polluted waters. The writer found that 20 parts of ClO₂ per million did not kill *B. typhosus* in a vigorous pure culture in 2 hours, but that 50 parts killed it in half an hour. (See also Reychler, Bull. Soc. chim. [3] xxv. 13: Chem. News, 1901, 316.)

On a large scale, chlorine and ozone are both in successful use at present for sterilising water. The latter seems preferable for drinking supplies, the former is suitable for effluents. From questions of efficiency as well as cost, both require that the liquid should be clear or previously clarified, that is, they are *finishers*. In potable waters, on account of the liability to persistence of Cl, several dechlorinating devices have been employed, as mentioned above.

Time, as in all disinfections, is an important factor; in an effort to get the work done quickly, it is sometimes forgotten that a longer time is advantageous, and economises the reagent. For rapid sterilisation of a small quantity, as in the field, a larger proportion of reagent is required, and from questions of portability, bromine and iodine have been used instead of chlorine, but are attended by residual products having a taste and physiological effect. These, in the quantity required for dealing with the moderate pollution ordinarily met with, have been proved to be negligible, although, with heavier contamination, the amount of the halogen consumed by the organic matter before a sterilising excess is present, may become injurious in its products. (Ash, from experiments on anthrax and tubercle, maintained that the quantities of chlorine, bromine, and iodine required for disinfection under the same circumstances were nearly in the ratio of their atomic weights (see R. W. table at end of article). Iodine is, however, a more immediate poison to protoplasm than chlorine.

Bromine is a powerful disinfectant, but its use is obviously limited by its danger. In 1897 Altman patented a solution of Br in KBr for sterilising water, using 40 parts per million of Br with 5 minutes' contact, and removing excess

¹ In England, the 'De-Chlor' system is applied at Reading to the prefiltered river water (Surveyor, Dec. 16th, 1910). At Antwerp 0.2 av. Cl per million is added to the storage reservoirs, with a contact of 12 hours.

¹ For an account of trials at Marseilles of ozone, chlorine, and ultra-violet rays, see Engineering, Jan. 27th and Feb. 3rd, 1911.

by ammonia. The solution is, however, bulky, and the use of a potassium salt has disadvantages. Braithwaite introduced 'Bromidine,' a dry mixture of sodium or potassium bromide and bromate with sodium bisulphate, which with moisture liberates bromine. Schumberg recommended free bromine in thin sealed tubes for the same purpose (Zeitsch. f. Hyg. 1900, 53) in the proportion of 60 parts per million with 5 minutes' contact, removing excess by thio-sulphate (Braithwaite advised 57 parts). Schöder (*ibid.* xxxvii. 306) and others have stated that this treatment is insufficient to sterilise, and the presence of residual bromides is against the process (see also Parkes and Ridal, Trans. Epidem. Soc. xx. 1901; Fraser, Publ. Health, Sept. 1902). It was tried in the Soudan campaign of 1898. The writer found that 20 parts per million of Br sterilised *typhosus* (in water) in less than half an hour. It is more rapidly absorbed by organic matter than iodine.

Iodine owes many of its uses to its germicidal action, as in parasitic diseases. Grossich, in 1908 (Centr. f. Chirurg. No. 4), adopted the tincture as a cutaneous disinfectant before operations, the surface being previously cleansed by a 1 p.c. solution of iodine in benzene (Bogden, *ibid.* Jan. 15, 1910). Instead of the tincture, Chassevant (Lancet, March 26, 1910) suggests the solution in chloroform, as it does not, like the former, cause desquamation; its use is specially advised prior to hypodermic injections (see also Brit. Med. J. Feb. 6, 1909, and Aug. 14, 1910; Lancet, April 16, 1910). During the Sikkim and Tibet expedition, iodine (in some cases as tincture) followed by sodium sulphite, was successfully employed for sterilising drinking water, and Nesfield recommends triple tablets of (A) iodide and iodate, (B) citric or tartaric acid, followed after 2 minutes' contact by (C) sodium sulphite, and states that used in this way 3.8 to 5 parts per million of free iodine sterilises the organisms of typhoid, cholera, and dysentery. The writer, in 1905, confirmed this result as regards distilled water infected with 20,000 p.p.c. of *B. typhosus*, the A and B tablets used gave 4.75 parts of iodine per million.

Iodine trichloride was introduced by Von Langenbach for sterilising the hands and instruments and for other surgical uses. The writer finds that 50 parts per million are required to kill typhoid (in water) in 30 minutes. Iodine cyanide is said, by Kobert, to be universally destructive to lower forms of life, and is suggested for preserving biological specimens.

Organic substitution compounds of chlorine, bromine, and iodine, as a class, inhibit organisms, and may sometimes kill them. The germicidal power of a large number of these has been determined by Bechhold (Zeitsch. Hyg. Infect. 1909, lxiv. 113): he finds that a Br atom gives a greater power than a sulphonic group. *Chloroform* is often used to preserve perishable specimens and infusions. Farrel and Howles (J. Soc. Dyers, 1908, 24, 109) state that CCl_4 kills typhoid, and that pure CHCl_3 does not kill it, whilst 0.62 p.c. aqueous CHCl_3 kills it in less than 30 minutes.

Iodoform was formerly much employed in surgery, and a large number of other iodine compounds have been introduced into medical and surgical practice. Many of them are non-irritant, but their bactericidal power is much

inferior to that of dilute solutions of the element. Fumigation of sick rooms with iodine, sometimes in conjunction with other disinfectants, by burning prepared candles or lamps, has been tried, but apart from the fact that the method is unsatisfactory, no chamber can be disinfected while occupied.

Fluorides, like boric acid, check bacteria, but do not kill them. As food preservatives, they are only moderately efficient, and are not innocent physiologically, as they hinder pancreatic digestion. Sodium silicofluoride ('salufer') and borofluoride ('pyricit') have been tried. Effront introduced the use of hydrofluoric acid and its acid salts for checking injurious fermentations, and J. Brand (Zeitsch. f. Brauw. 1904, xxvii. 115) states that 0.5 to 1 p.c. solution of acid ammonium fluoride is largely used for disinfecting rubber hose in breweries (see also Hehner, Analyst, 1902, 173; Richmond, Dep. Comm. on Preservatives, appendix xxxii.; Thresh and Porter, Preservatives, 1906, 87). Hydrofluosilicic acid is the active constituent of 'Montanin' (obtained from by-products in the pottery industries), and 'Keramyl' (about 25 p.c. H_2SiF_6) (J. Soc. Chem. Ind. 1904, 34; 1909, 904).

Carbonic acid seems to have a certain amount of disinfectant action, since 'aerated' beverages have been shown to be in many cases sterilised, and CO_2 under pressure preserves food (*cf.* J. Soc. Chem. Ind. 1907, 1290).

Cyanogen and hydrocyanic acid are more destructive to insects than to lower organisms. Fumigation of fruit trees with HCN is extensively practised in America, and is considered better than spraying. For greenhouses, zinc capsules containing sodium cyanide are made: they are placed in dilute sulphuric acid, and while the zinc dissolves the operator has time to retire.

Acids. An acid medium is unfavourable to the growth of most bacteria, and acids generally possess considerable disinfectant power. Kitasato found that the growth of *B. typhosus* in nutrient broth or gelatine was entirely prevented by the following percentages of different acids: 0.08 H_2SO_4 ; 0.2 HCl or HNO_3 ; 0.28 SO_2 ; 0.3 to 0.4 phosphoric, acetic, carbolic, formic, oxalic, or lactic; 0.476 tartaric, citric, and malic; 1.66 tannic; and 2.7 boric. The writer has shown that in infected waters, 0.035 p.c. of H_2SO_4 kills typhosus in 30 minutes, that in terms of acidity nitro-hydrochloric was slightly more active, and that with tartaric and citric at least three times the amount of acidity was required (Epidemiological Society, Jan. 1901). But like other disinfectants, the activity of dilute acid solutions is considerably modified by the presence of added matters; for instance, in 1 p.c. peptone broth, *Sp. cholerae* is killed by 0.01 p.c. hydrochloric acid in half an hour, but in 2 p.c. peptone broth, 0.04 p.c. HCl is required.

Paul, Krönig, and Sawey (Pharm. J. 1900) conclude that the germicidal activity of acids generally, depends upon the degree of ionisation in solution, exceptions being HF , HNO_3 and trichloroacetic, which exercise specific toxic influences. In normal solutions, the three latter killed anthrax spores exposed on garnets in 24 hours, while H_2SO_4 , HCl, HBr and HClO_3 were less active. Working with more dilute acid solutions, Winslow

and Lochridge (Mass. Inst. Tech. 1906) have compared the effect on *B. coli* and *typhosus* in tap water and in a 1 p.c. peptone water. With upwards of 10,000 organisms per c.c., sterilisation was obtained by the following percentages of each acid after 40 minutes' contact:—

	<i>B. typhosus</i>		<i>B. coli</i>	
	Tap water	1 p.c. pep- tone water	Tap water	1 p.c. pep- tone water
Hydrochloric acid	0.018	0.174	0.045	0.368
Sulphuric	0.022	0.188	0.081	0.530
Acetic	—	—	0.561	0.836
Benzoic	0.069	0.292	0.242	0.555

In agreement with the results of other workers, larger amounts of each acid are required to disinfect in the presence of peptone; with the organic acids, benzoic and acetic, this diminished activity is not so pronounced. Winslow and Lochridge find that the disinfectant power of the acids is not proportional to their strength in terms of normality, but, in the case of the mineral acids, hydrochloric and sulphuric, to the degree of ionisation of the solution, 99 to 100 p.c. reduction of *B. coli* or *typhosus* being effected with either acid at the same concentration of dissociated hydrogen. The evidence tends to show that the alteration in ionisation in a dilute acid solution brought about by the presence of otherwise inert substances in solution, as, for example, neutral salts of the acid, accounts for the variation in germicidal activity. In practical disinfection, the subject is often rendered still more complex by a further interference—the absorptive effect of solids in suspension. Therefore the acidity, as found by titration, does not give the germicidal value of an acid solution unless these disturbing factors are considered.

Metallic derivatives. Warm alkaline leys are the most ancient of disinfectants: potassium and sodium hydroxides are sterilisers in the proportion of not less than 2 to 5 p.c., their carbonates in 5 to 10 p.c. At 60° a contact of 5 minutes ensures the death of most organisms (Zeitsch. f. Hyg. 1903, 349), hence ordinary soaps have a slight disinfectant value. Strong brine is preservative, but not disinfectant, and the practice, formerly frequent, of washing out milk cans and other utensils with it, is not a safe one. Lode shows (Chem. Zentr. 1902, i. 1122) that 50 p.c. salt solution does not kill the spores of common moulds.

Lime, as quicklime, is fatal to bacteria when it comes in contact with them in an almost dry condition, and has been much used where there is a considerable space and bulk of material to be dealt with. It is not safe, however, to trust entirely to the old method of burying infected bodies in lime, as, on disinterring, the live spores may again be diffused, unless a long period has elapsed. The disinfecting power of milk of lime and whitewash has been much overrated; as to milk of lime, Liborius stated (Zeitsch. f. Hyg. ii. 25) that in the proportion of 74 parts per million of CaO, it destroyed typhoid bacilli, and that 246 parts per million were required for cholera organisms, while 2 p.c. of dry lime was needed for cholera discharges; with in each case 'a few hours' contact. When lime is added to sewage, a great number of bacteria are carried down, but are not killed, and the supernatant liquid is not sterilised. *Zinc chloride*, 'Burnett's fluid,'

formerly in high repute as a disinfectant, is not reliable in its effect, and ranks below copper sulphate and mercuric chloride. The sulphate has still less energy (R. W. coeff. 0.09).

Aluminium chloride, 'chloralum,' was classed by Miquel between zinc chloride and copper sulphate. *Iron salts*, especially ferrous sulphate, were at one time in vogue for sanitation, but are ineffective.

Permanganates and manganates were first introduced as Condy's red and green fluids. Like oxidisers generally, they are largely consumed by otherwise inert matters before attacking organisms, and as complete disinfection cannot be ensured unless an excess of reagent remains, evidenced by a pink colour, which is not always easily visible owing to the brown oxide of manganese produced, their use may be very costly and its execution frequently imperfect. The writer carried out experiments in street-watering of two similar areas of ordinary soiled asphalt roadway: (a) with water alone; (b) with permanganate solution 1 in 5000 (six times the amount then customary), and examined the liquid from the surface. The permanganate was almost immediately decolourised. Sample (b) was nearly inodorous, on keeping became much less foul than (a), and the reduction in the number of organisms was 96 p.c., but the survivors included a large proportion of the dangerous forms (Rideal's Sewage, 1906, 117). For polluted water, Rosenau recommends adding permanganate drop by drop till the pink colour persists for 24 hours. 'Pinking' of wells was many years ago adopted by Hankin in India as a precaution against cholera. Permanganates, used in various ways, are still being patented, chiefly for water purification.

Chromic acid, although a powerful oxidiser and instantly coagulating albumen, is excluded by its cost and poisonous and corrosive nature from the list of useful disinfectants or of preservatives.

Arsenic, like cyanogen, has more effect on higher than on lower forms of life, and is the basis of valuable insecticides, such as the sheep-dip solutions of arsenious oxide or sulphide in soda, frequently associated with tar products and nicotine. See Chemist and Druggist, June 11, 1904; Rep. Dept. Comm. B. of Agric., leading to the Sheep-Dip Act of 1903; and Quibell, J. Soc. Chem. Ind. 1907, 1266. The copper compounds, '*Paris green*' (aceto-arsenite) and others, are used for spraying or dusting trees, combining the actions of arsenic and copper. Several organic arsenic compounds have been introduced as medicinal parasiticides (see Lancet, Brit. Med. J., &c., 1910 and onwards).

Some metals in the free state are antagonistic to germs. Dievert states (Compt. rend. 136, 707) that agitation with granulated zinc kills *B. typhosus* and *coli* in a few hours, and Bayer's method of treating polluted waters with zinc-dust, charcoal, and lime causes, according to Margösches (Leipz. Monats. Textilind. 1901, vi.), practical sterilisation. Rankin (Proc. Roy. Soc. 1910, B, 82, 78) shows that clean strips of Al, Zn, or Cu, in air-free water, do not reduce the number of *coli*, whilst when air is bubbled through there is a great reduction after 1 hour. Except with Cu, peroxide of hydrogen was produced, but the amounts of this and of the metal dissolved

were too small to account for the germicidal effect, which is ascribed to the metal and oxygen together. *Metallic iron* has long been used for purifying water, as in Anderson's process (J. Soc. Arts, Feb. 14, 1896): in this case, galvanic action and the oxides formed come largely into play, but Frankland proved that the metal itself was, to a certain extent, bactericidal. Old Hindoo writings direct water to be kept in vessels of copper: among modern observers, Nageli, Galeotti, and Israel and Klingman hold that there is formed a colloidal solution which renders the water toxic to many algæ and bacteria. In 1904 the U.S. Dept. of Agriculture reported that 1 sq. cm. of bright copper per 100 c.c. of water was sufficient to exterminate *Uroglena* and some forms of *Spirogyra*, and Kraemer showed that the same treatment destroyed colon and typhoid bacilli in 4 hours, whilst colloidal copper was quickly fatal to these organisms. For household purification, he recommended the use of strips of copper, about $3\frac{1}{2}$ sq. inch to each quart (2 sq. cm. to 100 c.c.), immersed in the water for 6 to 8 hours. In a similar way, Rideal and Baines (J. San. Inst. 1904, 594) obtained sterilisation of *typhosus*, *coli*, and *S. py. aureus* in less than 24 hours. Bassett Smith (J. Prev. Med. July, 1904) found that in a bright copper vessel, *B. typhosus* was still living at 12 hours, but was dead at 24, and that of ordinary water organisms, 1020 per c.c. at first, only 8 per c.c. (none of them liquefying) were left after 24 hours. He concluded that clean iron or zinc was nearly equal to copper in first effect, but soon lost the power by oxidation.

Copper salts have a distinctly poisonous action on lower organisms, partly from their coagulating albumen and combining with many of the constituents of the tissues. Kroncke considered *cuprous chloride* to be the most active of the salts: he treated Elbe water, containing 40 to 50 thousand organisms per c.c., with 50 parts per million of Cu_2Cl_2 and 20 parts of ferrous sulphate, allowed 6 hours' contact, then agitated with 10 parts of lime. After settling and filtration through sand, the water was sterilised, clear, and colourless, and free from iron and copper. Schumberg (Chem. Zentr. 1900, ii. 203) corroborated the sterility at the end of 6 hours. The efficiency of soluble cupric salts is generally dependent on their percentage of copper (Green, Zeitsch. f. Hyg. 1893, 495; Rideal and Baines, *l.c.*), but the sulphate is commonly used as most convenient. For disinfecting sewage effluents (and inferentially for reservoirs), American investigations conclude that copper sulphate 'is not so efficient as chlorine compounds, is more seriously affected by carbonates, and is much more expensive' (U.S. Geol. Survey, Water Supply Paper 229, 1909, 32; also see Bull. U.S. Dept. of Agric. No. 100, 1906).

Disinfection of excreta and morbid products, even with considerable quantities of copper salts (*e.g.* 5 to 10 p.c. of the sulphate), is not reliable. For killing agricultural parasites, their use is well known, including that of the sulphate for soaking seeds and against potato blight, also verdigris (acetate), 'Paris green' (arsenite), copper-lime-sugar and copper-soap washes for trees, and 'Bordeaux mixture' (copper sulphate and lime). The last named

was introduced for vines, but has been since extended to other crops. In reference to the general practice of employing the metallic compound in the precipitated or solid form, instead of in solution, the main points stated are (1) that, in the former way, it is not liable to injure the plant or contaminate its tissues; (2) that the copper should remain as an external coating, because the spores germinate on the surface; (3) that uncertainty of composition and inequality of application are overcome by certain precautions and definite prescriptions. See British Board of Agriculture leaflets 23 and 225: the latter (May, 1909) gives a method of preparing and using Bordeaux mixture: 'for a 3 p.c. solution, 3 lb. copper sulphate and 2 lb. freshly burnt quicklime to 10 gallons of water.' See also J. Soc. Chem. Ind. 1896, 332; 1907, 1291; Compt. rend. 1911, 152, 532. Chuard (*ibid.* 1910, 150, 839), estimating that 12,000 tons of copper are thus consumed annually in France, expresses anxiety as to the result of its accumulation in the surface soil, and with a view to reducing the quantity states that a half p.c. aqueous mixture of the oxychloride is as adhesive and effective as the usual 2 p.c. paste of the sulphate. Cupric sulphate impregnation for preserving or 'kyanising' timber has been superseded by creosote oils, since the former washed out of the wood. 'Microsol,' sold as a soluble disinfectant for stables and drains, contained 75 p.c. of copper sulphate with sulphocarbolate and some free sulphur dioxide.

Mercury.—Mercuric chloride, 'corrosive sublimate,' has long been recognised as one of the most powerful of disinfectants, and a 1 per 1000 solution was the earliest standard for comparisons. Apart from cost, points limiting its utility to special purposes are: (1) the poisonous effect on higher animals and plants; (2) its precipitation by so large a number of substances, such as hard water, alkalis, and numerous salts, metals, sulphides, and many organic bodies, causing its action to be liable to great variations and inconveniences. It will often form a pellicle over organisms without killing them, and it is inapplicable to the disinfection of sputum, excreta, and the like, from its producing a coagulum which prevents further penetration. Sodium or ammonium chloride is sometimes added to increase the stability of the aqueous solution, but considerably diminishes the germicidal power. The Local Government Board recommended for disinfecting purposes: HgCl_2 $\frac{1}{2}$ oz., HCl 1 fluid oz., aniline blue 5 grs. (a colouring for safety), water 3 gallons (1 in 962).

Krönig and Paul in 1897 showed that mercury salts followed a general rule that the germicidal power depends on the metallic ion, and is in proportion to the degree of ionisation, so that a 1 in 500 solution of HgCl_2 is much less than twice as active as 1 in 1000: moreover, the chloride is more active (in equivalent solutions) than the bromide, and 4 times more active than the cyanide, which is almost non-ionised. Solutions of the *oxycyanide* are used in surgery, are distinctly *alkaline*, and only slightly precipitate albumen; a strength of 1 in 1500 is antiseptic, does not readily attack instruments, and is not irritant. *Mercuric iodide*, dissolved in potassium iodide, is a powerful disinfectant, and is made

up as 'iodic hydrarg.' It is less affected by albuminoids and less irritant than the chloride, and is incorporated in a disinfectant soap. *Mercury-zinc cyanide*, 'Lister's antiseptic,' has the disadvantage of being of variable composition. A great number of organic mercurial compounds, introduced into medicine and surgery, trace their main effect to an antiseptic or germicidal action. 'Sublamin,' mercuric-ethylenediamine sulphate (43 p.c. Hg), is easily soluble in water, is much less irritant than mercuric chloride, does not coagulate albuminous solutions nor precipitate soap, and is a valuable hand-disinfectant.¹ 'Protectyl' contains about 96 p.c. water, 1 p.c. salicylic acid, 0.2 p.c. mercury, and about 3 p.c. gelatin.

Silver nitrate stands next to mercuric chloride in germicidal power, and has similar limitations in its use, with the additional one of being precipitated by chlorides. The writer found that 1 in 1000 killed *B. coli* and *S. py. aureus* in 24 hours, but a small quantity of chloride or organic matter prevented the effect. Among other silver salts are the citrate, 'Itrol,' recommended as a non-irritant antiseptic dusting for wounds (Pharm. Zentr. 38, 460); 'Actol,' the lactate, for antiseptic injections; 'Tachiol' silver fluoride, easily soluble, and a powerful non-toxic bactericide specially useful for the urinary tract (1 in 1000 to 1 in 5000). Chiefly with the object of avoiding irritant action, incompatibility with chlorides, and coagulation of albuminoids, a large number of organic preparations of silver have been introduced, such as 'argentamine' (ethylenediamine-silver-phosphate), and the proteid compounds 'argonine' (casein), 'argyrol' (gluten), 'largin' (albumen), and 'protargol' (protein). A report to the British Med. Assoc. in 1906 gives the time in minutes required to kill *S. py. aureus* by the preparations used as: silver nitrate ($\frac{1}{2}$ to 2 p.c.), 2 to 5; protargol (2 to 4 p.c.), 3 to 5; largin (10 p.c.), 2 to 5; argonine (5 p.c.), 3 to 6; whilst argyrol and 'collargol' (colloidal silver, J. Soc. Chem. Ind. 1903, 315) had very little bactericidal power (Lancet, 1907, i. 675). Many of these are destructive to gonococci and to ophthalmic disease organisms.

Osmic acid was found by Koch and Klein to be powerfully bactericidal: it is very poisonous and a strong oxidiser. The former stated that an extremely dilute solution of *potassium auricyanide*, 1 part $\text{Au}(\text{CN})_3$ in 2 millions, checked the growth of *B. tuberculosis*.

Chick and Martin (J. of Hyg. 1908, 634) observe that for spores, metallic salts rank highest as germicides; with mercuric chloride, the reduction of efficiency caused by blood serum is much greater than with phenol.

Compounds related to the alcohols. It has long been known that 'wood spirit,' crude methyl alcohol, in a dilution as low as about 5 p.c., can kill insects and most micro-organisms, and preserve perishable organic materials owing to the tar products that it naturally contains. The alcohols, by themselves, are only efficient in a very much higher strength by coagulating albumen and (when absolute) by withdrawing water. Wirgin (Zeitsch. Hyg. 1904, 46, 149)

has tested methyl, ethyl, butyl, and amyl alcohols with anthrax spores, and *S. py. aureus*, and concludes that the disinfecting power is low, that it increases with the molecular weight, and that there is scarcely any action on dry spores. It has been suggested to add alcohol vapour in steam disinfection, but Seige (Chem. Zentr. 1902, 1, 130) finds no advantage. Hand-disinfection with alcohol is not reliable (Goerner; Harrington, Boston M. J. May 21, 1903), although Hansen found that epidermal bacteria, especially in suppurating eczema, are, when moist, destroyed in one minute by absolute, and in most cases by 50-60 p.c. alcohol (Centr. Bakt. 1907, 466). *Glycerol* in strong solutions (25 p.c. and upwards), is antiseptic, but in weaker ones it rather promotes the growth of bacteria. *Allyl isothiocyanate*, mustard oil, has figured in a number of patents, and is capable of killing many organisms, but not economically.

Formaldehyde is found in commerce as the 40 p.c. solution 'formalin' or 'formol'; it is antiseptic and germicidal, and is official in the German, Austrian, Belgian, United States, and Japanese pharmacopœias. Formalin, diluted 10 times, is used for embalming and for preserving bodies for dissection and museum specimens, but for antiseptics generally, a much weaker solution is efficient. The Board of Agriculture state in their Journal of Dec. 1906, that from 2 years' experiments at Kew, they have found that fruit of all kinds immersed for 10 minutes in a solution of 3 pints formalin to 10 gallons water (= $1\frac{1}{2}$ p.c. CH_2O), then allowed to drain and dry, keeps 10 to 21 days longer than when untreated; and that one lot of liquid can be used for a number of batches. The writer and Dr. Foulerton have proved that 1 in 50,000 of formaldehyde (= 1 in 20,000 of formalin) suffices to keep milk sweet for 24 hours, even in warm weather, without injury to health (Pub. Health, May, 1899; Lancet, 1899, 1427, 1571). Apparently because experiments with larger doses showed effects on nutrition, the British Dept. Committee on Preservatives, in 1901, recommended 'that the use of formaldehyde or formalin or preparations thereof in foods or drinks be absolutely prohibited.' And yet its agency in the preservation of food is as ancient as that of salt. The disinfectant and preservative power of wood-smoke is in part due to formaldehyde, which is present on the surface of smoked provisions,¹ and was found by Trillat in amounts varying from $\frac{1}{10000}$ to $\frac{1}{100000}$ of the weight of the substance consumed, in the smoke of carbonaceous combustibles, especially wood and cellulose. In tobacco smoke, he found 0.05 to 0.12 p.c., and in soot from house chimneys, 0.28 to 0.35 p.c. as paraformaldehyde. Typhoid and cholera organisms were killed by products from the combustion of 2 grams of sugar passed into a 12 litre vessel, and by burning 4 kilos. of sugar in a room of 100 cub. metres 'even very resistant organisms were destroyed.' (Rouguier has made this the basis of Fr. Pat. 360476, 1905.) With straw, the best results were obtained by burning it in a heap of alternate dry and wet layers: using 18 kilos. of

¹ Schrauth assigns a high disinfecting value to the sodium salt of hydroxymercury-benzoic acid (J. Soc. Chem. Ind. 1910, 1328; 1911, 382).

¹ Perrier finds $\frac{1}{10000}$ to $\frac{1}{100000}$ in bacon, ham, sausages, and herrings; remarks that a strict regulation against formaldehyde would forbid these foods; and contends that a limit should be fixed instead of prohibition.

straw in a room of 140 cub. metres (4944 cub. feet), *B. coli* and *diphtheria* were destroyed after contact with the smoke for 12 hours; the room temperature rose to 35°, and up to 2 grams of formaldehyde were generated per kilo. of straw (Compt. rend. 138, 1613; 139, 742; 140, 797; 141, 215; 150, 339). This explains some old methods of disinfection, which Trillat still recommends for emergencies, but admits they are inferior to the use of pure formaldehyde in solution or vapour.

H. Will (Zeitsch. Brauw. 1905, 28, 330, 347) gives formalin a very high place among brewery disinfectants. He notices, like other brewers (Kiuzel; Slater and Rideal, Lancet, April 21, 1894), that it is more powerful against bacteria than against yeasts and mould fungi. Limits recorded as preventing development are: sarcine and bacteria, 0.003 to 0.031 p.c.; yeasts, 0.007 to 0.062 p.c.; moulds, 0.031 to 0.125 p.c.

Advantages in formaldehyde disinfection are: (1) that it can be easily applied in the state of gas or vapour for fumigation; in the liquid condition as spray, wash, dipping, or in higher dilutions as an antiseptic, or in the solid form as its polymers, compounds, or mixtures; (2) that unlike mercuric chloride and many other agents, it is not thrown out of action by albuminous matter or by most chemicals; (3) that it is effective in strengths which are not irritant or poisonous, and do not injure fabrics or metals. At quarantine stations, large quantities of bulbs, roots, nuts, fruits, &c., coming from plague or cholera-infected regions are disinfected by immersion in a 5 p.c. solution of formalin, which does not injure the food value and much retards decay. In the Linley process, meat is treated with formaldehyde vapour, '1 oz. formalin per cub. foot of space in the chamber,' the gas after a time removed by a fan, and the meat frozen for shipment. A report to the Local Government Board, in 1909, by Buchanan and Schryver, on Formaldehyde Preservation of Meats (Food Report, No. 9), states that the gas commonly penetrates for about 20 mm. under a thin layer of connective tissue, that the amount absorbed often reaches 1 in 3500, that it is reduced or removed by boiling or roasting, but that grilling seems to make it penetrate further.

In surgery, formaldehyde and its preparations have been of wide service. Salter (Guy's Hosp. Gaz. Oct. 1896) states that it rapidly kills the fungus of ringworm. As pigment and spray (1 or 2 p.c. formalin), it has been successful in diphtheria: in such strength, it quickly kills other non-sporing organisms, including, according to E. Blake, the 'staphylococcus of eczema.' In most cases, $\frac{1}{2}$ p.c. solution is sufficient. 'Lysoform' is a liquid potash soap containing formaldehyde, suitable for operations and for instrument and hand disinfection. The alkali promotes the effect and penetration; Geronzi found that the addition of 5 p.c. of sodium carbonate to the 5 p.c. formalin which he successfully used for obstinate ear disease increased the tolerance and enhanced the germicidal power (Arch. Ital. di Otolgia, 1903).

Formaldehyde antiseptic powders for dressing are: 'Amyloform' (starch); 'Proteol' (casein); 'Steriform' and 'Sterisol' (lactose); 'Glutol' (gelatin). These, especially the last, when

moistened as in a wound, slowly regenerate formaldehyde. Formalised gelatine is now largely used with success instead of surgical collodions. *Formamint tablets*, 'for infectious diseases and as a prophylactic,' are said to contain 0.01 gram of CH_2O in each, combined with milk sugar (Eng. Pat. 2672, 1906; Pharm. J. 1907, ii. 838). M. Jones states that with *B. diphtheria* the R. W. coefficient is only 0.01 as against 0.30 for cyllin pastilles.

Paraform, paraformaldehyde, trioxymethylene, or 'triformal,' is a solid polymer, only slightly soluble in cold water, and dissociated into CH_2O gas on heating. It was introduced as an internal antiseptic and for disinfecting instruments, and said to be as active as β -naphthol, but its chief use is for evolving formaldehyde either alone or in mixture, for which a large number of methods have been proposed, many of them patented. Mixtures with Na, Ba, or Sr peroxide, when brought into contact with water, yield formaldehyde and hydrogen peroxide: it is stated that 'Autan' contains 1 part of paraform to 2 of BaO_2 (Lancet, 1908, i. 139), and that 50 grams mixed with water kills all organisms in a cubic metre of air bubbled through it (Fr. Pat. 366605, 1906).

Room disinfection with formaldehyde cannot be economically effected by simply evaporating the solution; under ordinary circumstances, only a portion of the substance is volatilised, the remainder polymerising and remaining behind as a solid, while reliable disinfection requires a definite large volume of gas to be produced in a short time. For this object, very numerous methods and apparatus have been devised, which may be grouped as follows:—

A. Direct production of CH_2O gas, by passing methyl alcohol vapour and air over hot surfaces of platinum (Hofmann) or partly oxidised copper (Loew). The various lamps on this principle have had the faults, among others, that the oxidation is incomplete and inconstant. Kenwood, however, found in trials with a lamp using platinised asbestos, that sufficient formaldehyde can be generated from $1\frac{1}{2}$ litres of methyl alcohol to disinfect a room of 2000 cub. feet.

B. Heating the solution (formalin) under pressure. Trillat observed that this almost entirely prevented polymerisation, especially if a neutral mineral salt, such as calcium chloride, was added to raise the boiling-point. In his *autoclave*, he uses 'formochloral' (formalin with 10 p.c. of CaCl_2) in the proportion of about 1 lb. to 1500 cub. feet. When the pressure has reached 35–40 lbs. (135°–140°), the gas is injected into the closed room through a copper jet passing through the key-hole, at such a rate that the pressure is maintained. By this method, Kenwood obtained sterilisation of diphtheria swabs, and the writer with various articles infected with *B. typhosus*, *diphtheria coli*, *S. py. aureus*, and anthrax spores, found that in 24 hours all were sterilised, whilst fabrics, furniture, metals, and leather were not injured. With the Thursfield disinfectant, evolving steam and formaldehyde vapour, the writer found that, per cubic metre of room space, $7\frac{1}{2}$ c.c. of formalin vapourised with not less than 30 c.c. of water was sufficient for killing anthrax spores in 6 hours, but the disinfectant had little penetrating

power, especially through wet material (J. R. San. Inst. 1903, 508).

C. Formalin, mixed with glycerol, is distilled at nearly the ordinary pressure, as in the Trenner-Lee, Lentz, and Lingner apparatus. The latter, according to the Russian National Health Society's Journ. 1900, was mainly instrumental in extinguishing the plague at Astrachan, in 1899. Klein (report of 1902), by 3 hours' exposure in a sealed room with the Lingner generator, sterilised anthrax spores and tubercular sputum. Houston and Newman also report favourably (Practitioner, Sept. 1902).

An important point to notice is that in method (B), the CH_2O is chiefly liberated at the beginning of the operation, in (C) at the end, mixed in the latter case with steam and glycerol spray, which deposits as a film on the surfaces, and assists in the penetration and disinfectant action.

D. Formaldehyde and acetone are used in a complicated process of Fournier's, in which ammonia is also introduced (Eng. Pat. 10348 of 1908: he has a number of other allied patents).

E. Combined disinfection with SO_2 and formaldehyde has often been proposed, since both have a reducing action and therefore should not interfere with one another. Guasco and Jerome assert that it is more effectual than either substance alone, and their French patent, 379998 of 1906, claims admixture with 'sulphurous gases' as preventing polymerisation.

F. Evolution by mixing with other chemicals. Dehydrating agents disengage very little CH_2O gas from formalin, since most of it polymerises. With quicklime, the writer has only obtained 8 p.c. of the theoretical yield (cf. Eng. Pat. 8259, 1899; Fr. Pat. 323041, 1902; and U.S. Pat. 790468, 1905). Carteret observes (Compt. rend. 1908, 146, 819) that 1 part formaldehyde and 2 parts bleaching powder added to 3 parts water evolve 70 p.c. of the theoretical yield of CH_2O and no Cl, while the heat gradually rises to 108° (D. R. P. 217944 of 1908). Potassium permanganate behaves similarly, generating great heat, with a variable loss of substance by oxidation: U.S. Pat. 885223 relates to a mixture of this kind. The action of peroxides has been already mentioned.

G. The simplest process is heating paraform by a small flame (avoiding ignition), when it melts and is resolved into CH_2O . The 'Alformant,' or Schering lamp, uses 1-gram tablets placed in a perforated cup, and it is directed to use 10 tablets per 1000 cub. feet with 6 hours' exposure. The writer found that this quantity killed *B. coli*, *typhosus*, *diphtheria*, and *S. py. aureus* in 20-24 hours, and that double the quantity in the same time killed moist, but not always dry anthrax spores. He recommended spraying with $\frac{1}{2}$ p.c. solution of formalin before using the lamp, as the gas is evolved with insufficient moisture. The latter defect is remedied in the 'hydroformant' lamp, in which 12 ozs. of water in an annular vessel is simultaneously evaporated. Rosenau considers this method of generating CH_2O useful for the disinfection of closets and small enclosures of less than 100 cub. feet, with not less than 12 and preferably 24 hours' exposure, and not less than 2 ozs. of paraform per 1000 c. feet (about 2 grams

per cub. metre). Klein, Houston, and Gordon's report to the London County Council, in 1902, records that with 23 grams of paraform per 1000 c. feet, *B. typhosus*, *diphtheria*, *pyocyaneus*, and *S. py. aureus* were killed in 5 hours, but not anthrax spores nor (with certainty) tuberculous in sputum. It will be noticed that the time is not even that given in the directions issued with the lamp, and the humidity and temperature of the room are not stated. Allan, Newman, and Cribb had previously obtained generally satisfactory results with 10 grams paraform per 1000 cub. feet, under moist conditions (Brit. Med. J. Aug. 13, 1898). Kenwood's experiments pointed to an average of 25 grams per 1000 cub. feet being necessary. Werner and Bonhoff (Berl. Klin. Woch. 1904) find that tubercular sputum is certainly disinfected by 5 grams per cub. metre (141 grams per 1000 cub. feet) acting for 7 hours, which is double the quantity Flugge first recommended. In Breslau a large number of formaldehyde disinfections are carried out for scarlet fever and measles, and the disease has in no case recurred in the same room.

Method (G), as the writer stated in 1897, should always be a double one: (1) spraying lightly and evenly with a $\frac{1}{2}$ p.c. solution of formaldehyde (2 ozs. formalin per gallon), this strength being sufficient, and not needing special precautions of masking or gloves; (2) fumigating with 10 to 20 grams paraform per 1000 cub. feet and 24 hours' contact. With larger rooms than usual, it is better to use two or more lamps than to put an extra number of tablets into one lamp.

Spraying with the solution should, in fact, be the invariable practice except with the large CH_2O generators, which are capable of filling the room also with steam and spray. When spraying is used alone, there is a danger of not penetrating into crevices, and the solution must be of higher strength; Dr. Mackenzie's extensive experience in the disinfection of houses and hospital wards, proved that 1 p.c. CH_2O (4 ozs. formalin per gallon) is attended with success: he adds 5 ozs. glycerol per gallon of formalin to prevent too-rapid drying. Thresh and Sowden in 3 to 4 hours sterilised *diphtheria*, *typhosus*, *cholera*, *pyog. aureus*, and *prodigiosus* with $\frac{1}{2}$ p.c. CH_2O , but *pyocyaneus* (on whitewash) only with 2 p.c.; they, therefore, recommend the latter strength.

Where the space has to be occupied soon afterwards, any residual formaldehyde can be neutralised by volatilising ammonia, which forms the inodorous solid hexamethylenetetramine $\text{C}_6\text{H}_{12}\text{N}_4$. This substance retains some antibacterial properties: under the name of *Urotropine*, it is a serviceable antiseptic in cystic affections, and is administered to typhoid convalescents to destroy the bacilli of the disease, which, for a long period, continue to be discharged in the urine. As an alternative, since the drug may act unfavourably on the patient, or as an additional precaution, the urine can be sterilised externally with 1 in 1000 of sulphuric acid. Urotropine is the basis of a large number of antiseptic preparations, such as 'Helmitol' (Chem. Zeit. 1901, 25, 1045; Z. Klin. Med. 38, 4, 5, 6).

Disinfection of excreta is attained by mixing

with 3 to 5 p.c. of formalin and keeping in a closed vessel for at least an hour. Rosenau states that faeces are rendered sterile at the end of 10 minutes by an equal volume of a 4 p.c. solution of formalin. Houston prescribes 1 to 2 pints (according to bulk) of 5 p.c. formalin, acting for at least an hour (Practitioner, Sept. 1902).

Formaldehyde, as an insecticide, is much inferior to SO_2 , although Brough (J. Mass. B. of H. March, 1898, 51) observed, in his disinfections with the former gas, that all the flies were invariably killed, and generally the bed-bugs. It is an excellent deodorant.

No acidity is produced by continuous spraying or distillation of formaldehyde, therefore it is not readily converted into formic acid in this way.

Formic acid.—We have discussed the germicidal action of acids generally in an earlier section of this article. Formic acid has this power to a considerable extent, and is a strong antiseptic. Kitasato's results, as summarised by Horrocks, gave acetic acid a slightly higher activity in nutrient media, stating that with *B. typhosus* the amounts p.c. in cases of (1) growth, (2) growth restrained, (3) no growth, were respectively: formic acid, 0.22, 0.278, and 0.356; acetic acid, 0.2, 0.225, and 0.3; with *Sp. cholerae*, formic, 0.11, 0.167, 0.22; acetic, 0.1, 0.153, 0.2. But very different results are obtained in water and most organic solutions. The writer has found that *typhosus* is killed by 0.5 p.c. of formic acid in less than 15 minutes and by 0.1 p.c. in about 30 minutes; and in 1907 he made the R.W. typhosus coefficient of formic acid many times higher than that of acetic. He also found the preservative action to be higher: with vegetable substances, 1 p.c. of formic acid was equal in effect to 5 p.c. of acetic (time of trial, 2 months). Raw fish were mounted in 0.53 p.c. formic, in 5 p.c. acetic, and in 0.3 p.c. boric acids, heated for 20 minutes to 80°, and the jar closed with cotton wool; in a week, the last was brownish, disintegrated, and uneatable, though not distinctly putrid; while the first two kept sweet and of natural characters for 3 months. Experiments with bread-pulp infected with a mixed mould-growth proved that 0.1 p.c. of formic acid entirely inhibits the growth for several days, even under the most favourable conditions of culture. But in the destruction of the spores, formic acid is less effective than formaldehyde. Lebbin (Chem. Zeit. 1906, 30, 1009) effectively preserved different classes of foods by 0.15 p.c. of formic acid, and others have proved that in the quantities mentioned above it is physiologically harmless; the taste is more pleasant than acetic acid, and the odour is not noticeable. B. H. Smith (J. Amer. Chem. Soc. 1907, 1236) preserved vegetables with formic, with salicylic and with benzoic acid, in unprotected jars. Under conditions in which the untreated samples became sour and mouldy in 2 days, 0.1 p.c. formic acid preserved them for 7 days, 0.3 p.c. for 12 to 18 days, 0.5 p.c. for 25 days, 0.7 p.c. and 1 p.c. for 45 to over 85 days, and 2 p.c. for over 85 days. He states that 0.1 p.c. of benzoic acid kept his sample for 85 days, whilst with the same quantity of salicylic acid it was sour in 4 days. In ordinary preserving practice, as

we have seen, the articles would have remained good for the longer time with the smaller quantities of formic acid, which, even if it must be applied in a somewhat higher proportion, is from physiological and physical reasons preferable to salicylic or benzoic. The chief formic acid preservatives used in commerce, mainly for fruit preparations, are 'Werderol' and 'Fructol' (10–14 p.c. formic acid, '1–1½ p.c. of the liquid to be added'); and 'Alacet' (made synthetically from CO and NaOH at the Nitritfabrik, Köpenick, about 50 to 60 p.c. formic acid, 'use 0.3 p.c. of the liquid'). The result in the three cases would be about 0.14–0.18 p.c. of the acid. In an investigation of these articles by Croner and Seligmann (Zeitsch. f. Hyg. 1907, 56, 387), they find that inhibition of moulds, yeasts, and acid-forming organisms begins at 0.15 p.c. formic acid, that sterilisation is effected in 24 hours by 0.2 p.c., and in 10 to 30 minutes by 1 p.c.

Only the free acid is active against organisms, although the salts do not favour the growths as do the alkaline acetates. Sodium formate helps the solubility of many antiseptics without lessening their power, therefore figures as an adjunct in a number of patents.

Acetic acid is one of the most anciently used of preservatives; 'aromatic vinegar,' a more or less concentrated acid containing essential oils, had a partially-justified reputation against infection. The writer finds that *B. coli* is killed by 5 p.c. H_A in 5 minutes, by 2.5 p.c. in 15 minutes, while with 0.5 and 0.1 p.c. it is alive after 40 minutes. *Pyrolineous acid*, or crude wood vinegar, owes its antiseptic power chiefly to the presence of creosote and formaldehyde.

Acetyl peroxide and benzoyl-acetyl peroxide are stated by Freer and Novy (Amer. Chem. J. 1902, 27, [3] 161) to be strongly germicidal, since solutions corresponding to 0.037–0.074 p.c. of the former, or 0.056–0.112 p.c. of the latter, = 0.005–0.01 p.c. of active oxygen, destroyed within a minute all known disease-producing bacteria, and even spores of *B. mesentericus*, which are not killed by 5 p.c. phenol; whilst H₂O₂ solution containing 0.05 p.c. of active O was without action on many bacteria even in 60 minutes. Benzoyl peroxide had no oxidising action, and was without effect on bacteria. A solution of acetyl peroxide was introduced under the name 'acetozone,' but the title is now applied to a more convenient and stable mixture of the benzoyl-acetyl compound with infusorial earth, said to be useful in typhoid, dysentery, and cholera (Lancet, 1904, ii. 1160; Brit. Med. J. 1907, i. 634).

Propionic acid has been tested comparatively by Duggan (Amer. Chem. J. 7, 62) with the highly resistant *B. subtilis*. He gives as the strengths necessary for killing: formic acid, 7 p.c.; acetic acid, 9 p.c.; propionic acid, 12 p.c. (numbers proportional to the molecular weights). According to A. C. Jordan (Practitioner, Sept. 1902, 297), 0.1 p.c. of *butyric acid* in broth tubes infected with vigorous *B. coli* or *typhosus* caused them to remain sterile; *S. pyog. aureus* required 0.2 p.c. *Valeric acid* is a feeble antiseptic, but has been introduced along with a little creosote, as an internal antiseptic called 'geosote.'

Oleic acid, the fats, 'Lanolin,' &c., have no

antiseptic power in themselves, but when applied to the skin may prevent infection by the exclusion of germs. Vicario, however, observed that the fatty matters sometimes already contain germs, and Baldas (Giorn. R. S. Ital. d' Igiene, Feb. 1901) proved that *B. coli* and *typhosus*, *S. pyog. aureus* and *albus*, retained their virulence in oils for 2 months; therefore ointment bases require to be sterilised by heating to 100°, or preferably to 120°, as various bacilli survive in oil far longer than in aqueous solution. In fatty media antiseptics and disinfectants, as a rule, are much less active than in water, hence the ineffectiveness of carbolised oil as shown by Koch and Breslauer. Lanoline and cold cream contain water, so can enable agents in aqueous solution to come in contact with micro-organisms. Some metallic oleates are parasitic: cupric oleate in ringworm and favus (Lancet, 1907, i. 510); mercuric oleate for pediculi; zinc oleate is said to cure chronic eczema.

Vegetable acids like tartaric, citric, and malic have the general power of inhibiting bacteria which prefer a neutral to an acid medium, but their effect is much less than that of mineral acids, and, as is well known, their solutions quickly become mouldy in warm weather. Citric acid was formerly recommended for sterilising water: Dr. Christmas in 1892 stated that cholera organisms were killed by 0.08 p.c. and typhoid by 0.10 p.c. Kitasato's figures for tartaric, citric, and malic acids added to neutral media containing *typhosus* are in p.c.'s: growth, 0.338; growth restrained, 0.384; no growth, 0.476. Succinic acid is slightly antiseptic. 'Alphogen' or 'Alphozone,' succinyl peroxide, is said to be a powerful germicide (Brit. Med. J. 1905, i. 1150; Lancet, 1905, i. 367).

Benzoic acid is strongly antiseptic in solution and vapour, and to a rather less degree in its soluble salts. It dissolves in about 400 parts of cold water, and the saturated solution kills *B. typhosus* in a few minutes. When molecular proportions, i.e. sodium benzoate 0.026 p.c., potassium benzoate 0.029 p.c., benzoic acid 0.022 p.c., are separately mixed with milk, the writer observes that all retard the souring, the acid more than its salts, but the effect comes to an end sooner than with inorganic salts like the fluorides, since benzoic acid is itself decomposed by some organisms. Not being poisonous, it has been much used as a food preservative, particularly in countries where salicylic acid was forbidden. Following a report of the Referee Board of the U.S. Board of Agric. that doses of benzoates under 0.5 gram per day were not injurious to health, and that even 4 grams per day did not act as a poison, the U.S. Board, in Pamphlet 104, 1909, have announced that they will make no objection to the use of sodium benzoate in food, provided it is plainly labelled on each package, both as to presence and quantity. The taste and odour are difficult to mask. It has long been used as an antiseptic in surgery, e.g. in 'Friar's Balsam' (tinet. benzoini co). *Benzoic aldehyde* is official in the U.S. Pharmacopœia, and in the form of commercial oil of bitter almonds owes its parasiticide power in ointments mainly to the hydrocyanic acid it contains, which, of course, neces-

sitates care in use. *Benzoyl-sulphonic-imide*, 'Saccharin' or 'Gluside,' has some preservative power, and has been given internally to stop decomposition of urine in cystitis, but its use for sweetening is less on account of this power than because it is itself unfermentable.

Salicylic acid.—The saturated aqueous solution contains 1 in 500: tested with *typhosus*, *pyog.*, *aureus*, and *anthrax*, Westcott found that in 3 hours only the former was killed. As a food preservative, it is about equal to benzoic, their relative activities varying under different circumstances. Its physiological effect is more distinct than that of boric or formic acid or formaldehyde in the small quantities required, but there is no clear evidence that it causes injury to adults if the amount is limited. The British Depart. Committee's suggested restriction is that it 'be not used in a greater proportion than 1 grain per pint in liquid food and 1 grain per lb. in solid food,' or 0.0114 and 0.014 p.c. respectively, which practically would amount to a prohibition, since moulds and ferments are only reliably inhibited by 0.1 p.c., the amount commonly employed, though often exceeded. Addition of the acid to foods is forbidden in France, Austria, and some other countries. Traces are present in a large number of fruits (Analyst, 1903, 149). 'Salol' is phenyl salicylate, an internal antiseptic which is decomposed in the duodenum into phenol and salicylic acid. According to Lowenthal, when mixed with pancreatic juice, it rapidly kills *Sp. cholerae* (Compt. rend. 107, 1169). 'Salophen,' *p*-aminophenyl acetyl salicylate, is said to have a rather stronger antiseptic power (Practitioner, March, 1907). A large number of derivatives of salicylic acid have been introduced, and many of them patented.

Cinnamic acid, at 2 p.c., prevents the growth of bacteria, and at 4 p.c. destroys them. It is contained in Peru and storax balsams, which are parasiticide in skin diseases. Fr. Pat. 371091 preserves butter by enclosing it in a wrapper impregnated with cinnamic acid, which 'prevents butyric fermentation.' *Acetyl-o-coumaric acid*, 'Tylnarin,' is another internal antiseptic, said to have a R.W. coefficient of 4.5.

Tannin is antiseptic to proteids through its property of forming with them insoluble compounds such as leather, but none of the tannin extracts have even the power to preserve their own solutions.

Hydrocarbons, essential oils, and camphors.—Petroleum, mainly consisting of hydrocarbons of the paraffin series, has long been a well-known insecticide, and is mentioned by Marco Polo in the 13th century as used to kill acari in mange. It has been stated that articles are disinfected by dry-cleaning with petroleum-benzine, or by benzene. Farrel and Howles (J. Soc. Dyers, 1908, 24, 109, 166), however, find that acting on infected threads for 6½ hours, neither benzene (C₆H₆) nor petroleum-benzine killed *typhosus*, whereas carbon tetrachloride killed it in 30 minutes, whilst 'benzine soap,' dissolved in benzene, has no germicidal power.

Perfumes, chiefly composed of terpenes and their oxidised products (e.g. the camphors, menthol, thymol, and eucalyptol), have a limited sanitary value. All of them are very sparingly soluble in water, but impart to it a more or less

antiseptic effect. Early estimates of their power have not been concordant, chiefly owing to their having been tried variously in aqueous or alcoholic solution, or in suspension. A saturated solution of *thymol* in water (0.3 p.c.) arrests fermentation and putrefaction. Peppermint (containing *menthol* and menthane) has had a high reputation, and a number of recipes for 'plague water,' have it as a basis. The use of hops in brewing partly rests on the power of the essential oil to check fermentation. 'Terebene,' made by the action of H_2SO_4 on turpentine, was once reputed as a disinfectant, but now hardly figures except as terebene soap. Among other artificial products from turpentine are *terpin hydrate* (said by Colpi to arrest the growth of tubercle bacilli in 0.25 p.c. strength), and *terpineol* (anthrax is stated to be killed by 1 p.c., and staphylococci by 10 p.c. in 60 minutes; (H. Marx, *v. infra*; also D. R. P. 207576, 1906)).

Camphor is much spoken of as a personal prophylactic, but there cannot be sufficient of the vapour to sterilise the air. It is an ingredient in many remedies for cholera and diarrhoea, and in several 'block disinfectants' such as 'Sanoscent,' 'Camphortar,' &c. *Eucalyptus globulus* and other species which have long been famous as antimalarial, are largely planted on the Continent in marshy districts. The essential oil is decidedly germicidal, and has been given with some success in typhoid, and also against tape- and threadworm.

Pinol is a liquid of similar character from *Pinus pumilo*. H. Marx has investigated the action of various perfumes on anthrax and *S. pyog. aureus* (Centr. Bakt. 1903, [1] 33, 74). Kobert (Chem. Zentr. 1907, i. 419) finds that the terpenes have, by themselves, in general only a weak antiseptic action. The proportions needed for sterilising exceed the solubility in water, and can only be reached by a spirituous solution or an emulsion.

But it has been recognised, since Schönbein pointed out the fact about 1840, that essential oils have a disinfectant power conferred on them by their slow oxidation in the presence of air and moisture, whereby ozone is produced; that as long as air and oil are present, the ozone is continually regenerated and absorbed, forming oxidising and antiseptic products, which dissolve in the water, along with peroxide of hydrogen. This was the principle of the 'Sanitas' patent 274, 1876.

Aromatic nitro-compounds, such as nitrobenzene, have often been proposed as disinfectants, but are precluded by their odours, poisonous action, and sparing solubility. Trinitrophenol, 'picric acid,' is rapidly fatal in saturated solution (about 1 p.c.) to bacteria and spores, but causes yellow stains, is irritant and very poisonous. Cotton wool, soaked in the solution, is used very successfully in the aseptic treatment of burns; hence it is recommended by H.M. Inspector of Explosives to keep handy for this purpose. Potassium dinitro-ortho-cresol, 'Antinonin,' 1 in 400, is destructive to all common injurious parasites, and does not injure plants.

Aniline is open to the same objection as nitrobenzene. A number of aniline dyes are germicidal, owing to their power of penetrating and combining with living tissue. This action

is very variable, but it is stated that 1 p.c. prevents development of organisms, whilst 1 in 500 to 4000 retards their growth. Methyl violet or 'pyoktanin,' gentian violet, certain auramines, safranin, methylene and toluidine blue have been used in surgery and in malaria. Malachite green, injected into the blood, kills *trypanosoma* in 48 hours (Brit. Med. J. 1904, ii. 1449, 1645; Deutsche Med. Woch. Leipzig, 1906, 21, 463). Methylene blue, with atropine and benzoic acid, according to Lelean (Lancet, May 3, 1902), was the only drug he found of use against *Bilharzia*.

Naphthalene, Quinoline, Pyridine, and related bodies.—Naphthalene is feebly antiseptic, but not a disinfectant. It is useful by its odour to drive away domestic insects.

Beta-naphthol is official in the British (1898) and in a number of other Pharmacopœias, the dose in the former being 3 to 10 grains in a cachet for internal antiseptics, especially in typhoid and in cholera as a preventative. Its solubility in water is increased by boric acid. Schneider observes that naphthols dissolved in alkaline carbonates have greater disinfectant power than alkaline naphtholates; the former solutions contain naphthol in the free state. He states that staphylococci and typhoid are killed in a short time by 0.5 to 1.0 p.c. of β -naphthol alkaline carbonate solution (Zeitsch. Hyg. 1906, 52, 534).

Ointments containing 10 to 15 p.c. are efficient in scabies and psoriasis. 'Betol,' β -naphthol salicylate, is less soluble than naphthol, and is now seldom used. 'Alphol' is its analogue from α -naphthol, and is very similar. A number of easily soluble compounds have been introduced, such as the β -naphthol sulphonates, 'Asaprol' or 'Abrastol' (calcium), and 'Alummol' (aluminium). Helbing states that an aqueous solution of the latter, 1 in 250, prevents all growth of gonococci, pus cocci, and allied bacteria. Bechold (Zeitsch. angew. Chem. 1909, xxii. 2033) finds the odourless and non-poisonous halogen-substituted naphthols more powerful than any disinfectant except $HgCl_2$, and that tribromonaphthol kills staphylococci in dilutions of 1 in 250,000.

Pyridine is volatile, mixes freely with water, and is strongly insecticide, but has a very unpleasant odour, which has militated against its use in horticulture. Tobacco smoke, indeed, owes its powers, not to nicotine, which is almost entirely decomposed by the heat, but to the products pyridine and its homologues, which are formed. Tessinari destroyed the bacilli of cholera and pneumonia by tobacco smoke passed for 10 to 30 minutes through a tube containing infected nutrient gelatin. Wynter Blyth killed the bacillus of nasal catarrh by 1 p.c. solution of pyridine and its homologues (from bone oil), or by tobacco smoke. There is proof that smokers and workers in tobacco enjoy comparative immunity from epidemics, but pyridine inhalations (e.g. in asthma and whooping cough) require care, as it is a cardiac depressant. The above experiments confirm the general view that disinfectant preparations containing the basic constituents of coal tar are to be preferred to those which only include the phenols.

Tobacco juice, of course, contains nicotine, and in France is sold as an insecticide under an

official guarantee as to its nicotine strength. In England, a solution of the pure base in water is sometimes used as more definite. Richard's cakes for fumigation are nicotine and camphor: the writer found a sample in 1909 to contain 1.17 p.c. of nicotine and to be completely volatile at a gentle heat.

Chinosol is potassium-oxyquinoline-sulphonate, $C_9H_8NO \cdot OSO_3K$, a yellow powder easily soluble in water to an acid yellow solution, which does not stain, has only a slight aromatic odour, is permanent on keeping, is not poisonous, and does not coagulate albumen. It has been patented as a disinfectant, and more especially as an antiseptic. Klein compared its action on *S. pyog. aureus*, *B. coli* and *anthracis* with that of carbolic acid, and reports that a solution of 1 in 20 strength is required to kill *aureus* or *coli* in 5 minutes with certainty, whereas *chinosol* does this in a strength of 1 in 150. Anthrax spores are not appreciably affected in 48 hours by 5 to 6 p.c. carbolic, whereas *chinosol* of 1 p.c. acts germicidally on them in 5 minutes. In the writer's laboratory, *B. coli* was not sensibly affected after 4 hours by 1 in 1000 *chinosol*, whilst 1 in 2000 of $HgCl_2$ produced sterility under the same conditions in 15 minutes, so that it is difficult to explain the much higher powers that some observers have found for *chinosol*. Thresh and Sowden state that *chinosol* spray of not less than 1 p.c., is a reliable disinfectant (*J. San. Inst. Jan. 1903*). Houston did not succeed in killing *B. coli* in excreta by 1 in 75, and on linen by 1 in 62 (*Practitioner, 1902, 331*). On account of its acidity, it acts on iron and steel. Alkaline solutions interfere with its power: the writer showed that a soap containing 5 p.c. of *chinosol* was inferior to a 0.5 mercuric iodide soap. F. G. Müller reports encouraging results with *chinosol* in leprosy (*Zeitsch. Oest. Apoth. Ver. xxxv. 858*). 'Cresochin' (*Pharm. Centralhalle, xxxvii. 247*) is said to be a neutral sulphonate of quinoline and tricesol, which is recommended for disinfecting instruments, as it does not darken the steel.

Quinine, which has a quinoline nucleus, probably owes its action against fevers as much to its antiseptic power as to its effect on the nervous system.

A. Raal (*Pharm. Zeit. 1900, xlv. 569*) asserts that strongly fluorescent bodies much increase the action of sunlight on organisms, whilst they are almost inert in the dark. A 1 in 20,000 solution of acridine killed infusoria exposed to sunshine in 6 minutes; in the dark they survived for 24 hours. Similar results were noted with quinine sulphate and with eosin. The inference is that the effect is caused by the fluorescent rays. Fluoresceïn has been patented as an antiseptic by Turpin, chiefly for toilet preparations (*Fr. Pat. 346363, 1904*). The bromofluoresceïns, particularly eosin, are found to have greater power. He claims a large number of other phthaleïn compounds as disinfectants.

Certain faults of many antiseptics and disinfectants in the free state have led to an immense number of attempts to improve them by converting them into various derivatives. Although the effort to produce new proprietary substances, has given rise to a multitude of often

misleading titles, many of these preparations have been proved to have utility. The modifications may be generally classified as follows:—

1. *Metallic salts*.—Compounds with the alkalis or earths are generally less active than the free substance. Other metals have been introduced, with the object of adding their special properties, as Al for astringency, Zn, Cu, Ag, and Hg for developing germicidal effect; but it must be remembered that a combination of this kind, though it may have some lateral advantages, is commonly weaker than either agent singly. The same remark applies to the two next groups.

2. *Substituted compounds*.—Those with iodine are exceedingly numerous, including a large number which have been improvements on iodoform when it was unduly valued. Where organic radicles (basic like methyl or ethyl, acid like acetyl or benzoyl) are introduced, the physiological properties are usually entirely altered.

3. *Esters*, sulphonic, and other colligated compounds which, while less poisonous or irritant than the parent bodies, slowly yield the latter by gradual decomposition. Several of these have proved of great value.

Resorcinol, *m*-dihydroxybenzene, is a powerful medicinal antiseptic, and a 1 p.c. solution kills most organisms. 'Ander's lotion' contains 40 grains in 1 oz. water. 'Anusol' is a bismuth iodo-resorcin sulphonate. *Quinol* or hydroquinone, *p*-dihydroxybenzene, is said to be a stronger antiseptic than the last, and has been suggested for typhoid in doses of 3 to 8 grains. The ortho-compound, *catechol* or pyrocatechin, is also antiseptic. Duggan finds (*Amer. Chem. J. 7, 62*) that the amounts of the three isomerides required for preventing development of *B. subtilis* in broth are: ortho-20, meta-25, para-30; phenol being 20 and pyrogallol 15.

Guaiacol (methyl-catechol) and *creosol* (methyl-guaiacol) are the active ingredients in wood creosotes, and have been widely useful as antiseptics and parasitocides, especially in tuberculosis. Guaiacol has an antiseptic power (but not bactericidal—see Table) $2\frac{1}{2}$ times that of phenol, and a $\frac{1}{2}$ to 1 p.c. solution destroys *B. tuberculosis* in 2 hours (Marfori, *Ann. di Chim. 12, 3*). A one in 150 solution of (Morson's) creosote kills *pyog. aureus* and *typhosus* in 3 hours (Westcott). 'Little's Soluble Phenyle' contains wood creosote, and Corfield's experiments gave it a high value for wounds and against vermin. Kenwood and Hewlett (*J. R. San. Inst. 1906, 13*) make its R.W. coefficient 1.2.

Pyrogallol, tri-hydroxybenzene, is antiseptic, and a 3 p.c. solution kills most bacteria, particularly aerobes, but it stains, is unstable, and very poisonous.

For general purposes of disinfection, 'coal-tar' fluids, having as their chief active constituents bodies allied to phenols, are most extensively employed. They are usually dark syrupy liquids smelling of coal tar, and may be roughly divided into two classes: (1) those which on the addition of water form a more or less clear dilution; and (2) preparations miscible with water but producing an emulsion. The former usually consist of saponified tar-acids: the *liquor cresoli saponatus*, Ph. G., consisting of

equal parts of potash soap and crude cresol heated together, is of this nature. In the manufacture of these fluids, potash soap, glycerol, alcohol, and other agents are employed to aid the solubility in water. With the second group, the mostly insoluble, active ingredients are emulsified by the aid of soda, soaps, resin, neutral oils, or gelatin.

As already indicated, the proprietary articles of this nature bearing fancy names are very numerous. Since the Privy Council Orders of 1900 and 1902, the uncontrolled sale of liquids containing upwards of 3 p.c. carbolic acid or its homologues is prohibited, and the germicidal value of the more insoluble and higher boiling-point tar acids has been recognised. The generality of commercial disinfectant fluids are now practically free from carbolic acid, and, in comparison with the latter, are non-poisonous. These disinfectant preparations should not be employed to destroy resistant spores without prolonged exposure; according to the nature and amounts of active ingredients present, they are usually germicidal with non-sporulating organisms in dilutions far greater than is the case with absolute phenol. However, the strength of these proprietary articles varies considerably, and beyond the requirements of germicidal value specified in contracts with various authorities, there is at present, unfortunately, no legal control over the efficiency of disinfectants as sold to the public. There are instances of so-called disinfectants which enjoyed great popularity and even were advocated by the medical profession, yet possessed little or no germ-killing power under the conditions in which they would be employed.

Since the adoption of the R.W. test, there has been a steady rise in the efficiency of commercial disinfectants.

Testing of disinfectants.—Before 1881, when Koch introduced the use of pure cultures, tests depending upon the prevention of putrefactive changes in various organic infusions were mainly employed, and to a great extent the antiseptic or preservative value was noted rather than the actual germ-killing power (see first edition of this dictionary). Since then, an increasingly large number of investigators have worked upon practical methods of testing. With the phenolic disinfectants, valuations were made upon the total amount of tar acids present, but the widely differing activity of these bodies, which is also modified according to their physical condition on dilution (in solution, tricresol has only one-third the germicidal value of that in emulsion), has led to the general adoption of bacteriological tests.

In the *thread* method (Koch), silk threads are impregnated with the test organism, and exposed for a definite time to the action of the diluted agent, and then, after the removal of adhering disinfectant, sub-cultures are inoculated from the threads to determine the survival or death of the organism (v. Lancet, July 30, 1900). In place of threads, small garnets can be employed (Krönig and Paul), stones of uniform size being coated from cultures of the organism, and added directly to the disinfectant, sterility being determined by inoculating sub-cultures at intervals (Zeitsch. angew. Chem. 1901, xiv., xv.). The chief points to be con-

sidered are (1) time; (2) age of culture; (3) choice of medium, reaction of same; (4) temperature of incubation and (5) of disinfection; (6) variation in vital resistance of same species and (7) of different species; (8) proportion of culture to disinfectant. In order to facilitate the comparison of disinfectants; Rideal and Walker (J. R. San. Inst. 1903, 424) suggested their carbolic acid coefficient method as the basis for a standard process. In this test, which has been extensively adopted in England and abroad, the efficiency of the disinfectant is expressed in multiples of absolute phenol performing the same work. It is briefly as follows: add 5 drops of a 24 hours' blood-heat culture of the organism in broth to 5 c.c. of a particular dilution of the disinfectant in sterile distilled water; shake and take sub-cultures with a platinum loop every 2½ minutes up to 15 minutes; incubate sub-cultures at 37° for 48 hours. Allowing 30 seconds for each operation, four different dilutions of the disinfectant with one carbolic control are tested against the same culture and under strictly comparable conditions. For example:

	Minutes	2½	5	7½	10	12½	15
Disinfectant	1:500	+	—	—	—	—	—
"	1:550	+	+	—	—	—	—
"	1:600	+	+	+	—	—	—
"	1:700	+	+	+	+	+	—
Carbolic acid	1:110	+	+	+	+	—	—
Carbolic acid coefficient		550 = 5 110					

This test has for many years been officially used by the War Office, Admiralty, India Office and other Government departments at home and in the Colonies. It is impossible in any one test to include the greatly varying conditions of practical disinfection, but numerous modifications of the R.W. coefficient test have been suggested, mainly with the object of testing in the presence of considerable quantities of organic matter. Sterilised sea-water, urine, sewage, starch, and gelatine emulsions, nutrient broth and milk, have been incorporated with the diluting water—also testing with organisms in their natural environment, as with *coli* in sewage, in place of pure cultures. A sedimentation test for emulsified fluids allows a 1 p.c. solution to stand 24 hours before preparing final dilutions for testing (Lancet, Sept. 19, 1908). The 'Lister test' (C. J. Martin) is made in the presence of 3 p.c. of faeces, previously sterilised, dried, and powdered. Sims Woodhead and Ponder (J. Path. and Bact. 1909, 148) replace the inoculating loop by platinum spoons, used with a special sterilising apparatus, and extend the time to 30 minutes. A mean coefficient is taken for two values obtained at the beginning and end of the experiment with *B. coli* and sub-culturing into McConkey's bile-salt fluid. The Lancet (Nov. 1909) has suggested, in conjunction with the above method, a chemical analysis for the valuation of emulsified fluids as follows: 10 grams of disinfectant with 100 c.c. of water and 15 grams baryta, are heated for 30 minutes at 100° under a reflux condenser, then cooled and decanted through asbestos, washing with warm baryta water; the tar acids are extracted with ether from an aliquot portion of the filtrate, after adding calcium chloride and

acidifying with HCl, dried at 38°, weighed, and their bromine absorption determined. Neutral hydrocarbon oils are extracted from the baryta residue with acetone, and the insoluble soaps and resins treated with HCl and shaken out with ether. For estimation of water, 25 grams of the sample are acidified with 10 c.c. of 10 p.c. H₂SO₄ and shaken with 25 c.c. of white petroleum spirit, taking the volume less 10 c.c. of the aqueous layer after standing. In presence of the higher phenoloids, the weight of tar acids obtained is too low. The coefficients obtained for *B. coli* were found to be approximately one-third of the difference between the percentage of tar acids and the bromine value.

The germicidal power expressed in terms of carbolic acid with *B. typhosus* is shown for a number of disinfectant substances in the following table; while most of the figures are Rideal-Walker carbolic acid coefficients, some of the results have been obtained by modifications of the original test as noted, and these are obviously not comparable with the others.

Agent	Germicidal value	Observer
Absolute alcohol	less than 0.1	F. 1905
Acetic acid	0.6	R. 1907
Benzoic acid	about 5.0	R. 1910
Boric acid	less than 0.1	W. 1904
Bromine water	64	R. 1910
Cadmium chloride	1.55	R. 1911
Cadmium sulphate	1.0	R. 1911
Chinosol	0.15-0.30	Various observers
Chlorine water	28	R. 1910
Coppersulphate (calculated on CuSO ₄)	2.0	R. 1910
Cresylic acid commercial	3.7	R. 1908
Eucalyptol	1.2	L. 1904
Formaldehyde	0.55	R. 1907
Ditto	0.75	W. 1904
Formic acid	5.7	R. 1907
Guaiaicol	0.9	L. 1904
Hydrochloric acid	1.58	F. M. 1906 (with feces and urine)
Hypochlorites (calculated on 'available chlorine')	146-220	Various observers
Ditto with 50 p.c. urine	8	K. 1906
Iodine water	100	R. 1910
Iodine trichloride	94	R. 1909
Lactic acid	1.8	R. 1910
Mercuric chloride	400-3540	Various observers
Potassium permanganate	42	do.
Pyrogallic acid	0.22	M. W. B. 1906
Resorcin	0.30	do.
Silver nitrate	15.8	R. 1910
Sodium bisulphate	4.1	R. 1908
Zinc chloride	0.15	W. 1906

M. W. B., Meredith Wynter Blyth; F. M., Firth and Macfadyen; E., Major Fowler; K., Klein; L., Lodwidge; R., Rideal; W., Walker.

The extremely high values once given for mercuric chloride were due to the powerful inhibitory action of the traces carried over with the sub-cultures in the inoculations. S. R.

DISSOCIATION v. CHEMICAL AFFINITY.

DISTILLATION. The object of distillation is the separation of a volatile liquid from a non-volatile substance, such as pure water from sea-water, or more commonly the separation of two or more liquids of different volatility.

The apparatus required consists essentially of four parts: a still or boiler, A (Fig. 1), in which

FIG. 1.

the liquid is boiled; an upright tube or head, B; a condensing tube, C, sloping downwards and cooled by suitable means—a Liebig's condenser, L, through which a current of water is passed, being generally employed in the laboratory; lastly, a receiver, R, to collect the distilled liquid. The form of apparatus shown in Fig. 2 is convenient for many purposes; the still, the head, and the condensing tube are sealed together in one piece.

FIG. 2.

The still is usually heated by the flame of a Bunsen burner; for very volatile and inflammable liquids a water-bath is generally used, but the rate of distillation can be better regulated by a very small flame in contact with the bottom of the still; the Liebig's condenser is unnecessary for liquids which boil above 160° or 170° if the condensing tube is fairly long.

If the temperature at which the liquid boils is to be ascertained with accuracy—and this is generally the case in fractional distillation, especially in the final purification of a liquid—the following points should be attended to:—

1. The thermometer should be carefully calibrated, and it would be a great advantage if all thermometers were compared with an air thermometer, for different kinds of glass expand very differently when heated, and therefore two thermometers, constructed of different varieties of glass, will give different readings, especially at high temperatures.

2. The zero point of the thermometer should be redetermined from time to time. It is a good plan to heat the thermometer for several hours to about 300° or 360° before calibrating it; the subsequent changes of zero point, which otherwise might be considerable at high temperatures, are thereby greatly reduced (Crafts, Compt. rend. 95, 910; also several earlier papers). Thermometers treated in this manner may now be purchased.

3. All thermometers, except those which do not register temperatures higher than 60° or 70°, should contain nitrogen to prevent volatilisation of mercury in the heated stem; if the thermometer is provided with a small bulb at the top,

rise of pressure owing to compression of the gas in the thermometer is avoided.

4. The thermometer should, if possible, be so placed in the apparatus that not only the bulb but also the column of mercury in the stem is surrounded by the vapour of the boiling liquid; otherwise the following correction, which, at the best, is somewhat uncertain, must be applied:—

N = length of column of mercury in scale degrees not heated by vapour.

T = temperature of vapour (the approximate temperature directly read on the thermometer is usually sufficiently accurate).

t = mean temperature of column of mercury not heated by vapour. This temperature may be approximately ascertained by attaching a small thermometer to the other by means of thin indiarubber bands or wire, with its bulb at about the middle of the unheated column.

Correction: add 0.000143($T-t$) N .

The coefficient 0.00016 is usually employed, but Holtzmann pointed out that this is too high, and adopted the number 0.000135. Thorpe, however (Chem. Soc. Trans. 37, 159), has shown that the coefficient 0.000143 gives the best results.¹ The table for the correction of thermometer readings is taken from Thorpe's paper, and shown in next column.

For further information *v.* article on THERMOMETERS.

5. When the amount of liquid in the bulb is very small, the vapour is liable to be superheated by the flame, and unless the bulb of the thermometer is thoroughly moistened with condensed liquid, too high a temperature will be registered. If a very little cotton wool or, for temperatures above 230°, a little fibrous asbestos be wrapped round the bulb of the thermometer, it remains thoroughly moist, and with a pure liquid the thermometer registers a perfectly constant temperature until the last trace of liquid in the bulb has disappeared (Ramsay and Young, Chem. Soc. Trans. 47, 42).

6. The barometer should always be read, and corrected to 0°, and in a long distillation or in unsettled weather it should be read frequently, for the boiling-point varies greatly with the pressure. The observed boiling-point is corrected to that under normal pressure by means of the formula $\theta = c(760 - p)(273 + t)$, where θ is the correction in centigrade degrees to be added to the observed boiling-point, t° ; c is a constant; and p is the barometric pressure. For the majority of liquids the value of c may be taken, without serious error, to be 0.00012; but for water and the alcohols it is about 0.00010, and for a few liquefied gases it is considerably higher. A table of corrections was first given by Crafts (Ber. 20, 709). The values of c for a large number of substances have been collected and tabulated by Young (Chem. Soc. Trans. 81, 777; Fractional Distillation, 15).

¹ Rimbach (Ber. 22, 3072) has constructed tables of corrections by interpolation from experimental data up to 220° for two kinds of thermometer graduated in degrees, and up to 100° for thermometers graduated in tenths of a degree. All these thermometers were constructed of Jena glass, and from the results it would appear that the form of the thermometer, and doubtless also the nature of the glass, have a notable influence on the magnitude of the correction.

The various parts of the simple apparatus (Figs. 1 and 2) may require modification under certain circumstances.

The still.—For larger quantities of liquid, a tin or copper vessel is preferable to glass.

The head.—The modifications of this part

of the apparatus will be considered under *Fractional distillation*.

The condenser.—For very volatile liquids, the condensing tube must be cooled by ice or a freezing mixture (pounded ice and salt or ice and concentrated hydrochloric acid, &c.): In this case, a spiral or 'worm' tube should be used (Fig. 3). Condensation of moisture in the receiver is prevented by the drying tube *a*.

The receiver.—If a liquid boils at a very high temperature, or if it suffers decomposition at the ordinary boiling-point, it may be necessary to distil it under reduced pressure. For cases of simple distillation, the apparatus shown in Fig. 4 may be employed, but if the distillate is to be collected in separate portions, as in fractional distillation, the removal of the receiver would necessitate the admission of air into the apparatus and a fresh exhaustion after each change. This inconvenience may be obviated by the employment of stopcocks arranged in such a manner

FIG. 3.

that air may be admitted into the receiver and a fresh one put in its place while the distillation bulb remains exhausted (Thörner, Ber. 9, 1868; F. D. Brown, Chem. Soc. Trans. 35, 554; L. T. Thorne, Ber. 16, 1327 (Fig. 5); Lothar Meyer, *ibid.* 20, 1834). Or again, a series of receivers on a revolving stand placed under an exhausted bell-jar may be employed (Gorhoff

FIG. 4.

that air may be admitted into the receiver and a fresh one put in its place while the distillation bulb remains exhausted (Thörner, Ber. 9, 1868; F. D. Brown, Chem. Soc. Trans. 35, 554; L. T. Thorne, Ber. 16, 1327 (Fig. 5); Lothar Meyer, *ibid.* 20, 1834). Or again, a series of receivers on a revolving stand placed under an exhausted bell-jar may be employed (Gorhoff

FIG. 5.

and Kessler, Ber. 18, 1363; Brühl, *ibid.* 21, 3339 (Fig. 6)).

Many liquids absorb moisture from the air or are acted upon by oxygen, and in these cases special precautions must be taken, the moist air in the apparatus being expelled and replaced by dry air, carbon dioxide, nitrogen, or hydrogen; the receivers must also be protected by drying tubes. (For example, *v.* Thorpe, Chem. Soc. Trans. 47, 120; Young, *ibid.* 59, 923.)

Theory of distillation. Investigations of the vapour pressures of liquids have thrown much light on the subject of distillation. If a pure

liquid be confined in the space above the mercury in a barometer tube, it will evaporate until the pressure of its vapour—measured directly by the depression of the mercury column—has reached a definite amount, which, for a given substance, and, if liquid be still present, depends solely on the temperature. From the readings of pressure at various temperatures we may construct a curve to illustrate the relations of temperature to pressure for a given substance, but this curve has a twofold meaning, for it represents not only the vapour pressures at definite temperatures, but also the boiling-points of the liquid under definite pressures. Thus the vapour pressure of pure water at 100° is 760 mm. of mercury at 0°; and under a pressure of 760 mm. water boils at 100°. Again, the vapour pressure of water at 0° is 4.6 mm., and if the pressure in a distillation bulb containing water be reduced to 4.6 mm., the water will boil at 0°. The truth of this general statement was conclusively proved by Regnault (Mém. de l'Académie, 21 and 26).

Regnault also investigated the behaviour of a few mixed and heterogeneous liquids, which he

FIG. 6.

divided into three classes: (1) liquids which are quite or almost insoluble in each other; (2) liquids which are miscible only within certain limits; (3) liquids which mix in all proportions. Regnault employed both the statical and dynamical methods of investigation; that is to say, he determined, on the one hand, the vapour pressures of the liquids at various temperatures in the barometer tube, and, on the other hand, the boiling-points of the liquids under various pressures.

The behaviour of two liquids, A and B, when brought into contact with each other, must be affected (*a*) by the attraction of the like molecules; those of A for each other, and those of B for each other; and (*b*) by the mutual attraction of the molecules of A and B. If the attraction of the unlike molecules is relatively very slight, it may be expected that the liquids will be non-miscible, or nearly so, as in the case of benzene and water. If the attraction of the

unlike molecules is greater, but still relatively small, miscibility within limits may be expected, as, for example, with aniline and water. In such cases there is frequently slight expansion and slight absorption of heat on admixture. Comparing together various pairs of liquids, as the mutual attraction of the unlike molecules increases relatively to that of the like molecules, the following changes may be expected: (a) increasing and finally infinite miscibility; (b) slight expansion, diminishing to zero, and followed by increasing contraction; (c) diminishing absorption of heat, changing to increasing heat evolution. These changes do not, in many cases, run strictly *pari passu*, and among liquids which are miscible in all proportions, it is not unusual to find a small amount of contraction attended by a slight absorption of heat, as, for example, when a little water is added to normal propyl alcohol, but when certain compounds, such as chlorobenzene and bromobenzene, which are chemically closely related, are mixed together, there is no appreciable change of volume or temperature. For such substances it is probable that the different molecular attractions, A for A, B for B, and A for B, are very nearly equal, and that the relation suggested by Galitzine (Wied. Ann. 41, 770; and by D. Berthelot, *Compt. rend.* 126, 1703), namely, that $a_{A,B} = \sqrt{a_A \cdot a_B}$, holds good, where $a_{A,B}$ represents the attraction of the unlike molecules, and a_A and a_B the respective attractions of the like molecules.

It would appear, then, that there are two very simple cases: I. that in which the liquids are non-miscible; II. that of two infinitely miscible and closely related liquids which show no heat or volume change on admixture.

I. It was found by Regnault that when two non-miscible liquids are placed together over the mercury in a barometer tube, the observed vapour pressure is equal to the sum of the vapour pressures of the two liquids when heated separately to the same temperature. It is only necessary that both substances should be present in sufficient quantity, and that the tube should be shaken or sufficient time allowed for the evaporation of the heavier liquid. The liquids evaporate independently of each other, and Dalton's law of partial pressures is therefore applicable to the distillation of non-miscible liquids. Each vapour behaves to the other as an indifferent gas, and the boiling-point of each liquid depends on the partial pressure of its own vapour. The temperature is necessarily the same for both liquids, and the total pressure, if the distillation is carried out in the ordinary manner, is equal to that of the atmosphere. The boiling-point is, therefore, that temperature at which the sum of the vapour pressures of the components is equal to the atmospheric pressure. For example, at 90.23° the vapour pressure of water is 530.1 mm.; and that of chlorobenzene is 210.1 mm.; total, 740.2 mm.; and it was found that when chlorobenzene and water were distilled together under a barometric pressure of 740.2 mm., the temperature varied only between 90.25° and 90.35°, until there was scarcely any chlorobenzene left in the residue, when it rose rapidly to 100°. The boiling-

point of a pair of non-miscible liquids is necessarily lower than that of the more volatile component, and may be far lower than that of the less volatile.

The process of distillation with steam is very frequently employed in the case of substances of high boiling-point, which are insoluble or only slightly soluble in water, such as aniline or nitrobenzene. (For the application of steam distillation to the preparation of ethereal oils, v. von Rechenberg, *Theorie der Gewinnung und Trennung der ätherischen Oel durch Destillation*, Schimmel & Co. 1910.)

The composition of the vapour—and therefore of the distillate—from two non-miscible liquids, like the vapour pressure and boiling-point, is independent of the relative amounts of the components, provided that both are present in sufficient quantity and that evaporation can take place freely. Calling the vapour densities D_A and D_B , and the vapour pressures at t° p_A and p_B , there will be, in a litre of the mixed vapour, 1 litre of A at t° and p_A mm., and 1 litre of B at t° and p_B mm. The weights of vapour will therefore be:

$$\frac{0.0899 \times D_A \times 273 \times p_A}{(273+t) \times 760} \text{ and } \frac{0.0899 \times D_B \times 273 \times p_B}{(273+t) \times 760}$$

respectively, and the relative weights will be $\frac{D_A \times p_A}{D_B \times p_B}$ (Naumann, *Ber.* 10, 1421, 1819, 2014, 2099; Brown, *Chem. Soc. Trans.* 35, 547).

The vapour density of chlorobenzene is 56.2, and that of water is 9; and at 90.23° the relative weights of vapour will be

$$\frac{m'_A \cdot 56.2 \times 210.1}{m'_B \cdot 9 \times 530.1} = 2.475,$$

and the percentage weight of chlorobenzene will be 71.2. In the actual experiment to which reference has been made, the percentage of chlorobenzene in the distillate was found to be 71.4. Both boiling-point and vapour composition agree well with the calculated values.

II. The vapour pressure of a mixture of two infinitely miscible liquids which are chemically closely related to each other, or, probably, for which $a_{A,B} = \sqrt{a_A \cdot a_B}$, is given by the formula $100p = Mp_A + (100-M)p_B$, where M is the molecular percentage of A, and p, p_A , and p_B are the vapour pressures of the mixture and of A and B respectively, at the same temperature, t° . In other words, the relation between vapour pressure and molecular composition is represented by a straight line (Van der Waals, *Proc. Roy. Acad. Amsterdam*, 3, 170; Young, *Chem. Soc. Trans.* 81, 768; Young and Fortey, *ibid.* 83, 45; Zawidski, *Zeitsch. physikal. Chem.* 35, 129). The relation has been found to hold accurately for chlorobenzene and bromobenzene, and with very slight error for other pairs of closely related liquids.

In order to calculate the boiling-points of all mixtures of two such liquids under a given pressure, p, the vapour pressures of each must be known at all temperatures between their respective boiling-points under that pressure. The percentage molecular composition of mixtures which would exert the vapour pressure

p must then be calculated at a series of temperatures between these limits by means of the formula $M = 100 \frac{p_B - p}{p_B - p_A}$. Lastly, the values of M must be plotted against the temperatures, when the curve drawn through the points will give the required relation between boiling-point and molecular composition. In the cases examined, the agreement between the observed and calculated results is quite satisfactory.

The relation between the composition of a liquid mixture and that of its vapour (distillate) has been the subject of many experimental investigations (Brown, Chem. Soc. Trans. 35, 547; 39, 304; Leffeldt, Phil. Mag. (v.) 46, 42; Zawidski, Zeitsch. physikal. Chem. 35, 129; Carveth, J. Phys. Chem. 3, 193; Winkelmann, Wied. Ann. 39, 1; Linebarger, J. Amer. Chem. Soc. 17, 615; Gahl, Zeitsch. physikal. Chem. 33, 179; Rosanoff, Lamb, and Breithut, *ibid.* 66, 349; Rosanoff and Easley, J. Amer. Chem. Soc. 31, 953); for a description of which (up to the year 1903, *v. Young's Fractional Distillation*, 71-113). Unfortunately, however, it is only in a very few cases that the mixtures investigated consisted of closely related liquids. In the discussion of their results, Leffeldt and Zawidski made use of formulæ which they derived from a general equation proposed independently by Duhem and by Margulès, and it is to be noted that both formulæ, in the simplest cases, can be reduced to one originally given by

Brown, $\frac{m'_A}{m'_B} = c \frac{m_A}{m_B}$, where m'_A and m'_B are the relative weights of the two substances in the vapour, m_A and m_B the relative weights in the liquid, and c is a constant. From Zawidski's

formula it would follow that $c = \frac{p_A}{p_B}$. So far as experimental evidence is available, it would appear that Brown's formula is applicable to mixtures of liquids for which $a_{A,B} = \sqrt{a_A a_B}$, and that for closely related liquids $c = \frac{p_A}{p_B}$.

When the components of a liquid mixture are not chemically closely related, the relation between vapour pressure and molecular composition is not, as a rule, represented by a straight line, but by a curve, and, in all probability, the form of the curve depends on the relation between $a_{A,B}$ and $\sqrt{a_A a_B}$, as shown in Fig. 7. That is to say, when

$$a_{A,B} < \sqrt{a_A a_B}, 100p > Mp_A + (100 - M)p_B,$$

and vice versa.

The greater the difference between $a_{A,B}$ and $\sqrt{a_A a_B}$ the greater will be the curvature; and it will be seen that, for any given values of p_A and p_B , if the deviation from straightness exceeds a certain limit, there must be a point of maximum or minimum pressure on the curve. It is obvious, also, that the smaller the difference between p_A and p_B , the smaller will be the deviation required to give a maximum or minimum pressure. If $a_{A,B}$ is so much smaller than $\sqrt{a_A a_B}$ that the two liquids are only partially miscible, the maximum pressure will not be represented by a single point, but by a horizontal line forming part of the curve.

The influence of chemical relationship is

well seen by the behaviour of the monhydric aliphatic alcohols towards water. These alcohols may be regarded as derivatives of water, formed by the replacement of a hydrogen atom by the group C_nH_{2n+1} ; the smaller the alkyl group, the closer is the relationship of the alcohol to water. At the ordinary temperature methyl alcohol is miscible with water in all proportions, as also

FIG. 7.

are ethyl and propyl alcohols; normal butyl and isobutyl alcohol are only partially miscible with water; and the solubility of the higher alcohols in water diminishes with rise of molecular weight, cetyl alcohol, for example, being practically insoluble. The volume and heat changes on admixture with water similarly indicate that the attraction of the unlike molecules diminishes as the molecular weight of the alcohol increases. Lastly, the deviation of the vapour pressure curves from straightness increases (Konowalow, Wied. Ann. 14, 34), as may be seen from Fig. 8.

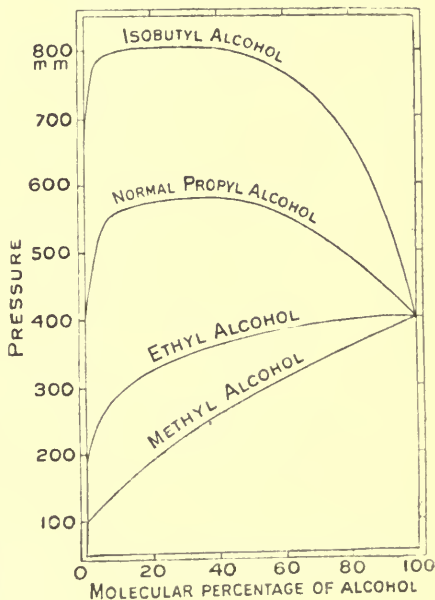

FIG. 8.

(The temperatures are such that the vapour pressure of each pure alcohol is 400 mm.)

The boiling-points of liquids which are not closely related cannot, as a rule, be calculated by means of the formula $M = 100 \frac{p_B - p}{p_B - p_A}$. If, as is usually the case, the vapour pressures of the mixtures are higher than are given by the

formula $100p = Mp_A + (100 - M)p_B$, the observed boiling-points will be lower than the calculated; if the vapour pressures are lower, the boiling-points will be higher. Moreover, when there is a point of maximum pressure on the curve which shows the relation between vapour pressure and molecular composition, there must be a point of minimum temperature on the boiling-point—molecular composition curve, the composition of the mixture which exerts a maximum vapour pressure, p , at t° being the same as that of the mixture which has the minimum boiling-point, t° , under the pressure p . So, also, two substances capable of forming a mixture of minimum vapour pressure can also form a mixture of maximum boiling-point.

Such mixtures of either minimum or maximum boiling-point, when distilled, boil at a constant temperature without change of composition, like pure substances, and they have frequently been mistaken for chemical compounds. The composition, however, depends on the pressure, which would not be the case with a definite compound; and, moreover, mixtures of minimum boiling-point are formed owing to the relatively small attraction of the unlike molecules for each other. A very striking example of the influence of pressure on the composition of the mixture of constant boiling-point has recently been observed by Wade in the case of ethyl alcohol and water. Under normal pressure the mixture of minimum boiling-point contains 4.43 p.c. of water. At higher pressures the percentage of water is slightly higher; at lower pressures it is smaller, and it is remarkable that the diminution in the percentage of water becomes more and more rapid as the pressure falls, so that below 80 mm. no mixture of minimum boiling-point is formed at all.

In the case of three liquids, if each of the three possible pairs is able to form a mixture of minimum boiling-point, it may happen that a particular mixture of all three liquids will boil constantly at a lower temperature than will any of the pairs or single liquids. Thus benzene and water form such ternary mixtures of minimum boiling-point with ethyl, *n*-propyl, isopropyl, and tertiary butyl alcohols (Young, Chem. Soc. Trans. 81, 707; Fortey and Young, *ibid.* 81, 739).

A table of mixtures of constant boiling-point is given in Young's Fractional Distillation, 67-69. Other mixtures have since been discovered by Wade (Chem. Soc. Trans. 85, 938; 87, 1656; *v.* also 95, 1842).

The composition of the vapour from a mixture of liquids which are not closely related, cannot, as a rule, be calculated from the vapour pressures of the components and the composition of the liquid, but for purposes of interpolation the formulæ of Leffeldt or Zawidski may be found useful (*l.c.*).

Fractional distillation. It has been stated that Brown's formula, $\frac{m'_A}{m'_B} = c \frac{m_A}{m_B}$, is applicable to mixtures of all closely related liquids so far investigated, and that, in all probability, $c = \frac{p_A}{p_B}$. The value of c is necessarily such that the vapour is richer than the liquid in the more volatile component. The first portion of

distillate obtained by condensation of the vapour will, therefore, be richer, and the residual liquid will be slightly poorer in that component. Continuing the distillation, the vapour evolved from the residual liquid will again be richer than the liquid in contact with it in the more volatile component, though poorer than the first portion of vapour. If successive portions of vapour be condensed, the percentage of the more volatile component in the distillates or *fractions* will steadily diminish, until, if the constant c differs greatly from unity, the residue will consist of the less volatile liquid in a pure or very nearly pure state. As the distillation proceeds, the temperature will, therefore, rise until, if c has a high value, the boiling-point of the less volatile component is reached.

If the fractions obtained in the first distillation were redistilled, each of them could be separated into smaller fractions, the first richer and the last poorer in the more volatile component, and by a process of systematic fractional distillation it should, theoretically, be possible to effect a separation of both components.

A mathematical and experimental investigation (Barrell, Thomas, and Young, Phil. Mag. (v.) 37, 8) of the behaviour on distillation of mixed liquids which follow Brown's law, showed that with two components it is the liquid of higher boiling-point which is the easier to separate; and that if there are three or more components boiling at fairly equal intervals of temperature, the substances of intermediate boiling-point are the most difficult to separate, and the least volatile substance is the easiest.

The method employed for the fractional distillation of a mixture of two liquids can best be explained by taking a concrete example. A mixture of 100 grams of benzene (b.p. 80.2°) and 100 grams of toluene (b.p. 110.6°) was slowly distilled, and the distillate was collected in a convenient number of fractions, the receivers being changed when the boiling-point reached certain definite previously arranged temperatures, the actual readings being corrected for barometric pressure and for errors in the thermometer scale. The results of the first four fractionations, and also of the ninth, are given in Table I, next page.

In the first distillation the temperature rose almost at once to 86° (corr.), and the first portion of distillate was therefore collected in receiver 4. On the other hand, the temperature reached 110.6° before the whole of the liquid had come over; the residue, therefore, consisted of pure toluene.

The distillate in receiver 4 was now placed in a smaller flask and distilled, fractions being collected in receivers 2, 3, and 4. When the temperature reached 89.2°, the flame was removed, and the contents of receiver 5 were added to the residue in the still. The distillation was recommenced, and fractions were collected in receivers 3, 4, and 5, the flame being removed when the temperature reached 92.2°. The distillation was continued in a similar manner until, after addition of the contents of receiver 12, the temperature rose to 110.6°, when the residue of pure toluene was added to that from the first fractionation. The third and fourth fractionations were carried out like

TABLE I.

Number of receiver	Final temperature (corrected)= t	Weight of fraction = ΔW				t	ΔW
		I.	II.	III.	IV.		
Pure benzene	°	—	—	—	—	80.2	10.20
1	81.2	—	—	12.95	31.55	80.3	45.00
2	83.2	—	3.80	24.80	23.90	80.6	17.55
3	86.2	—	33.85	22.75	16.20	81.4	7.20
4	89.2	9.75	22.30	13.50	9.55	83.5	4.50
5	92.2	51.80	19.65	11.80	8.00	88.0	3.30
6	95.4	28.85	13.60	9.15	5.80	95.4	2.75
7	98.6	21.20	12.95	7.30	5.35	102.8	2.60
8	101.6	12.80	9.05	6.75	4.65	107.3	2.85
9	104.6	11.45	8.90	6.30	3.85	109.4	3.15

11	109.6	13.45	9.60	8.95	7.40	110.5	7.00
12	110.6	24.90	30.75	33.05	30.50	110.6	5.75
Pure toluene	(110.6)	10.90	22.95	31.35	42.10	(110.6)	72.10

the second. In the subsequent fractionations the temperature ranges of the middle fractions were gradually increased and those of the lowest and highest fractions diminished. It was not until the ninth fractionation that pure benzene began to be collected. Eventually 81.4 grams of pure benzene and 88.8 grams of pure toluene were recovered.

Full details of the systematic fractional distillation of mixtures of two liquids and three liquids, and of more complex mixtures, are given in 'Fractional Distillation,' 114-143.

If the components of a mixture are not closely related, the composition of the vapour cannot, as a rule, be calculated by Brown's formula, but even in such cases the percentage of the more volatile component in the vapour will be greater than in the liquid, and the separation by fractional distillation is theoretically possible, unless the deviation of the vapour pressure-composition curve from straightness is so great that a mixture of maximum or minimum vapour pressure is formed.

For mixtures to which Brown's law is applicable, it may be stated quite generally that the greater the difference between the boiling-points of the compounds, the more readily can a separation be effected by fractional distillation, but for other mixtures the form of the curve representing the relation between boiling-point and molecular composition, if known, must be taken into account. If the

FIG. 9.

curve for two components were of the form a (Fig. 9), the substance of higher boiling-point

could be separated very easily, but the more volatile component only with great difficulty, if at all. On the other hand, if the curve were of the form b , nearly horizontal at the higher temperature, the more volatile component would be comparatively easy, and the less volatile difficult to separate. The first case is frequently met with, the second seldom. With curves of the form c and d (Fig. 10) it would not,

FIG. 10.

under any conditions, be possible to separate both components by distillation of any given mixture, but it would be possible to separate the mixture of minimum or maximum boiling-point from that component which was in excess. In a case represented by curve c , where the minimum temperature corresponds to the molecular composition q , the distillation might proceed in either of three ways: (1) If the liquid mixture had the composition q , it would distil unchanged in composition at the constant minimum temperature; (2) if the molecular percentage of A were less than q , the liquid would tend to separate into two components, the more volatile of which would be the mixture

of minimum boiling-point, and the less volatile the substance B; (3) if the molecular percentage of A were greater than q , the components separable by distillation would be, first, the mixture of minimum boiling-point, and, second, the liquid A. A well-known case of this kind is that of normal propyl alcohol and water; the boiling-points under normal pressure are: water, 100° ; *n*-propyl alcohol, 97.2° ; mixture of minimum b.p. 87.7° . This mixture contains 43.2 molecules p.c. of the alcohol; it was described for many years as a hydrate of propyl alcohol. If the curve had the form *d*, the mixture would distil like a pure liquid if it had the composition r , or it would tend to separate into two components, the first being either A or B, according as the molecular percentage of A in the original mixture was greater or less

FIG. 11.

than r , and the second the mixture of maximum boiling-point. Formic acid and water behave in this manner, as shown by Roscoe (Chem. Soc. Trans. 13, 146; 15, 270). Boiling-points: water, 100° ; formic acid, 99.9° ; mixture of maximum b.p., 107.1° ; molecular percentage of acid in mixture, 56.7° .

If, as with ethyl alcohol and water (Fig. 11), the mixture of constant boiling-point distils at nearly the same temperature as one of the two pure liquids, it is impossible to separate that liquid in a pure state by distillation. In this case, as the curve is exceedingly flat at the lower temperature (Noyes and Warfel, J. Amer. Chem. Soc. 23, 463), it is practically impossible to separate the mixture of minimum boiling-point (containing 4.43 p.c. by weight of water) in a pure state even when water is in excess, although it is quite easy to separate pure water from dilute spirit.

The correct interpretation of the results of the fractional distillation of a complex mixture may be rendered very difficult by the following causes: (1) the presence of two components boiling at nearly the same temperature; (2) the presence of one or more components in relatively very small quantity; (3) the formation of mixtures of constant boiling-point. It is only by plotting the total weights of distillate against the temperatures, or by dividing the weight of each fraction, Δw , by its temperature range and tabulating the ratios $\Delta w/\Delta t$, that the

results are likely to be understood, and in any case, the existence of a mixture of constant boiling-point may not be discovered, and it may be difficult to decide whether a distillate collected at a practically constant temperature consists of a single pure substance or of two liquids boiling at nearly the same temperature.

All the above difficulties are met with in the fractional distillation of petroleum, which contains homologous and isomeric paraffins, polymethylenes and their alkyl derivatives (naphthenes) and aromatic hydrocarbons, Russian petroleum being relatively rich, and American petroleum poor in naphthenes and aromatic hydrocarbons. When American petroleum was carefully distilled, it appeared at first as though the distillate coming over between the ordinary temperature and 40° contained only a single component, boiling at about 33° ; but by systematic fractional distillation with a very efficient still-head, it became evident (Fig. 12) that two components, *isopentane*, b.p. 27.95° , and normal pentane, b.p. 36.2° , were present (Young, Chem. Soc. Trans. 71, 440). Again, in the early fractionations there appeared to be no indication of the presence of any component boiling between 40° and 60° , but by tabulating the values of $\Delta w/\Delta t$, it was seen that a very small quantity of a liquid boiling at about 50° was present, and a distillate coming over almost constantly at 49.5° was eventually obtained. A chemical and physical investigation of this distillate showed, however, that it was a mixture of pentamethylene and a hexane of low boiling-point. The presence of benzene in American petroleum is indicated by the formation of dinitrobenzene, when the distillate from, say, 60° to 80° is treated with nitric and sulphuric acids (Schorlemmer, Annalen, 127, 311). But when the petroleum was carefully fractionated, it was found that the small fraction coming over at about 80° yielded no dinitrobenzene, the greater part being obtained from the fractions below 70° . This anomaly is explained by the fact that benzene forms a mixture of constant

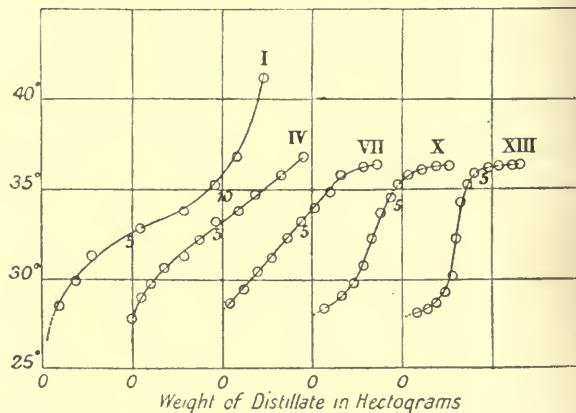

FIG. 12.

boiling-point with *n*-hexane, coming over at almost the same temperature as the paraffin. The amount of benzene being relatively small,

the whole of it distils over at the low temperature. In Russian petroleum the percentage of benzene is so much greater that some of it comes over at its true boiling-point, 80-2° (Young, Chem. Soc. Trans. 73, 905).

(For a detailed discussion of the interpretation of the results of the fractionation of complex mixtures, v. Fractional Distillation, chap. 19.)

Improved still-heads. It would be quite impossible to effect really difficult separations by means of the ordinary apparatus employed for distillation, and various modifications of the still-head have been devised in order to increase its efficiency. Even when the separation is an easy one, much time and material may be saved by the employment of efficient still-heads. Great progress was made in the improvement of the still-head in commerce—notably for the better separation of alcohol from weak spirit—before any advance was made in the laboratory. It will, however, be more convenient to consider first those forms of apparatus which are suitable for laboratory purposes.

In choosing or constructing a still-head, the first point to be considered is its efficiency in separating the components of a mixture. It frequently happens, however, that the quantity of liquid available is small, and it is therefore important that the quantity of condensed liquid in the still-head at any moment shall be as small as possible. If the residual liquid is of value, it is also of importance that the condensed liquid in the still-head shall all return to the still after the source of heat is removed.

In comparing the efficiency and usefulness of different still-heads, it is necessary always to distil a mixture of the same composition; and the rate of distillation must always be the same, because the efficiency of any still-head is greatly diminished by increasing the rate. In the comparisons mentioned in this article, equal weights of pure benzene and pure toluene were employed, and the distillate was collected at the rate of one drop per second. Unless otherwise stated, 50 grams of the mixture were distilled.

Of all possible forms, the plain vertical still-head is the least efficient. During distillation, as the vapour rises up the cylindrical tube, the outer part of it comes in contact with the condensed liquid flowing down the sides of the tube. Since the tube is constantly losing heat by radiation and by conduction to the surrounding air, this liquid is constantly cooled and fresh condensation constantly goes on, the outermost layer of vapour probably condensing almost completely with little change of composition. The central portion of vapour rises rapidly up the tube, and can only reach the liquid by diffusion or by convection currents, and much of it may pass through the still-head without reaching the liquid at all; the condensed liquid, on the other hand, flows rapidly back to the still. In order, however, that a satisfactory separation of the components may take place, as much of the vapour as possible should come in contact with the hot condensed liquid, so that equilibrium, as regards composition, may be brought about all through the tube.

The efficiency of a plain vertical still-head is,

roughly, proportional to its length. For tubes of equal length the efficiency is lowest when the internal diameter is about 14 mm. On the other hand, the quantity of liquid and vapour in the still-head increases regularly with the width of the tube; it is therefore better to use very narrow rather than very wide tubing.

Better contact between liquid and vapour, and therefore greater efficiency, is ensured by sloping the middle part of the tube, the extremities being kept vertical, and the efficiency is further improved by bending the sloping portion so as to form a spiral. In Young's 'rod and disc' still-head (Fig. 13), the downflow of part of the condensed liquid is greatly retarded by the discs on the central glass rod, and this liquid is protected from the cooling action of the air; at the same time, eddies and cross-currents are produced in the vapour. The increase in efficiency caused by the introduction of the easily constructed rod with discs is very marked. Wurtz (Ann. Chim. Phys. iii. 42, 129) recommended a vertical tube with a series of bulbs blown on it, and Young has shown that the efficiency is somewhat increased and the amount of liquid in the still-head is greatly diminished Fig. 13.

by blowing pear-shaped instead of spherical bulbs on the tube (Fig. 14). The 'rod and disc' and 'pear' still-heads are specially suitable for liquids of high boiling-point.

Greater efficiency, combined with diminished condensation of liquid in the still-head, is attained in Young's 'evaporator' column, one section of which is shown in Fig. 15. The

Fig. 14.

Fig. 15.

vapour rises up the inner tube, passes down between the inner and middle tubes, and up again between the middle and outer tubes, and so reaches the section above. The liquid condensed in the upper part of the still-head falls in drops from the depression at the top of the section on to the flattened top of the inverted middle tube, and spreads itself over its surface, falling again in drops from the bottom of this tube. The temperature of the vapour passing

through the inner tube of any section being higher than the boiling-point of the condensed liquid falling on to the inverted tube, re-evaporation takes place to some extent, and, if there is much difference between the boiling-points of the components of the mixture being distilled, ebullition may actually occur. The quantity of condensed liquid in the still-head is thereby greatly reduced. The 'evaporator' still-head is specially suitable for accurate work where great efficiency is required (Chem. Soc. Trans. 75, 679).

The 'Hempel' still-head (Zeitsch. anal. Chem. 20, 502) consists simply of a wide vertical tube, filled with glass beads of special construction, and constricted below to prevent the beads from falling out. A short, narrower vertical tube with side delivery tube is fitted by means of a cork into the wider tube. The advantages of the Hempel apparatus are simplicity and efficiency, but the amount of liquid in the still-head is excessive.

The results obtained with various still-heads are given in Table II.

TABLE II.

Nature of still-head or dephlegmator	Plain vertical, 5.1 mm. diameter	Plain vertical 14.0 mm. diameter	Plain vertical 25.7 mm. diameter	'Rod and disc', 14 mm. diameter	'Pear'	'Evaporator'	'Evaporator'	'Evaporator'	'Hempel', with 200 beads	Glinisky	Le Bel-Henninger	Young and Thomas	Young and Thomas

In many of the still-heads employed on the large scale, for example in the Coffey still (Fig. 28), the condensed liquid is caused, by means of suitable obstructions, to collect into shallow pools, and the ascending vapour has to force its way through these pools; very good contact is thus brought about between vapour and liquid at definite intervals. The excess of liquid is carried back from pool to pool, and finally to the still by suitable trapped reflux tubes. It is convenient to reserve the term 'dephlegmator' for this class of still-head. The 'Le Bel-Henninger' (Fig. 16) and the 'Glinisky' (Fig. 17) dephlegmators have been very frequently employed for laboratory work, but they do not give good results when small quantities of liquid are distilled; the dephlegmators of Brown (Chem. Soc. Trans. 37, 49) (Fig. 18) and of Young and Thomas (*ibid.* 75, 679) follow the principle of the Coffey still more closely, and are much better in this respect.

In a comparison of the Glinisky, Le Bel-

Henninger, and Young and Thomas dephlegmators, each with three sections, it was found that when 400 grams of the mixture of benzene and toluene were distilled, there was not a great difference in efficiency, but the Glinisky was the least satisfactory. With 50 grams of the mixture the differences (Table II.) were quite noticeable, and with 25 grams they were greatly accentuated. With the Glinisky column the highest temperature reached was only 107.6°, and the residue, when distilled from a very small bulb, came over between 102.2° and 110.4°. No pure toluene was therefore obtained, and the residue left in the still was distinctly less pure than the last portion of distillate collected. With the Le Bel-Henninger column the highest temperature was only 107.35°, and the residue began to boil at 105.7°; with the Young and Thomas column the temperature just reached 110.6°, and the residue

¹ Unnecessarily long.

began to boil at 110.4°. The 'rod and disc,' the 'pear,' and the 'evaporator' still-heads gave better results when only 25 grams of the mixture were distilled, the residue in each case consisting of pure toluene. These results show that for small quantities of liquid the Young and Thomas dephlegmator gives much better results than the Glinisky or Le Bel-Henninger, but that none of them is so satisfactory as the other still-heads.

FIG. 16.

FIG. 17.

FIG. 18.

In order that a dephlegmator may give the best results, the following requirements should be fulfilled: 1. It should be possible to greatly increase the number of sections without seriously increasing the fragility of the apparatus. 2. As the amount of condensed liquid flowing back at any level is greatest at the bottom and least at the top, it follows that, in order to form a pool, more complete obstruction is required at the top of the column than at the bottom. 3. Since the amount of condensed liquid in the still-head should be as small as possible consistently with efficiency, the reflux tubes should not be wider—in that part which is filled with liquid during distillation—than is necessary to carry back the liquid freely, and the traps should be no deeper than is required to prevent the ascending vapour from forcing its way through them. On the other hand, the upper part of the reflux tubes should be wide, so as to facilitate the entrance of the liquid. 4. There should be a rapid flow of condensed liquid through the reflux tubes, otherwise the change in composition of the liquid in these tubes will lag behind that of the distillate. 5. There should be a reflux tube connecting each section with the one below it, so that the change in composition may be regular from top to bottom of the column. In this respect the Glinisky dephlegmator is entirely wrong in principle. 6. When the distillation is completed, the residual liquid should return as completely as possible from the still-head to the still. In this respect the dephlegmators as a class are less satisfactory than the other still-heads.

By surrounding the still-head with water or any other liquid, the temperature of which is kept as little above the boiling-point of the more volatile component as will allow of vapour passing through, a considerable improvement in

the separation is effected. The temperature of the bath, however, requires very careful regulation if the boiling-points of the components are near together, or if one component is present in large excess, for in either case a fall of a fraction of a degree would cause complete condensation of the vapour, while a slight rise of temperature would prevent any condensation from taking place, and there would be no fractionation whatever. In constructing a regulated temperature still-head, it is advisable to bend the tube into the form of a spiral, because its effective length may thus be greatly increased without unduly adding to the height of the bath, and also because the spiral form is more efficient than the vertical. This class of still-head was first recommended by Warren (Annalen, Suppl. 4, 51). A better apparatus was described by Brown (Chem. Soc. Trans. 37, 49; 39, 517) (Fig. 19). A combination of a regulated temperature still-head and dephlegmator was employed by Young and Thomas (*ibid.* 71, 440) for the separation of normal and *iso*-pentane from petroleum.

Experiments to test the relative efficiency of these various forms of apparatus have been made by Kreis (Annalen, 224, 259; Claudon, Bull. Soc. chim. 42, 613; Brown, Chem. Soc. Trans. 37, 49; Young, *ibid.* 75, 679; Fractional Distillation, chaps. 10, 11, and 14).

Continuous distillation of wort has long been carried out on the large scale by means of the Coffey still (Fig. 28). In 1902 Carveth (*J. Phys. Chem.* 6, 253) and Lord Rayleigh (*Phil. Mag.* vi. 4, 521) independently suggested apparatus intended for use in the laboratory. The liquid to be distilled (or its vapour) is introduced continuously into the middle part of a long spiral or other still-head, the lower part of which is prevented, by means of a liquid or vapour-bath, from cooling below the boiling-point of the less volatile of the two components, while the temperature of the upper part is prevented, by means of a liquid bath, from rising above the boiling-point of the more volatile component. Lord Rayleigh obtained good results in the distillation of weak spirit. It is probable that the method might be made applicable to the distillation of mixtures of three components (Fractional Distillation, 189).

As many of the stills used in the arts are described under the headings ALCOHOL, BENZENE, PARAFFIN, &c., it will be unnecessary here to give a minute description of all of them, but an account of the principles underlying the different methods will not be out of place.

The still is usually made of copper or some other metal, but for special purposes other materials must be employed. Thus for the distillation of sulphuric acid, vessels of glass or platinum are used; for nitric acid, cast iron is found to be the best material; stoneware or glass stills are employed for bromine and iodine; and so on.

FIG. 19.

The still may be heated by the free flame of a furnace or by steam. Fig. 20 shows an

FIG. 20.

arrangement for heating a still with steam, which may be above the atmospheric pressure.

When only a rough separation of the constituents of a complex mixture is required, as in the preliminary distillation of coal tar, dephlegmators or rectifiers are not employed, but the vapours pass directly from the still to the condenser.

For the better separation of the components of a mixture, modified still-heads are employed. A simple apparatus, devised by Mansfeld for the distillation of tar oils, is shown in Fig. 21; the vapours are partially condensed in the still-head

FIG. 21.

A, which is cooled by water, and the condensed liquid flows back into the still B, the purified vapour passing on to the condenser C.

A more perfect separation is effected by Coupier's apparatus (Fig. 22). In addition to the column A, there is a series of bulbs, B, B, placed in a cistern containing brine, which may be heated by steam by means of the pipe C. The vapour—of benzene, for example—partially freed from less volatile substances in the column, is further purified by partial condensation in the bulbs, the condensed liquid flowing back by the tubes D, D into the column, while the purified vapour passes on to the condenser by the pipe E.

A very similar arrangement is seen in the French column apparatus (Fig. 23). The liquid is heated by a steam coil in A; the vapour is

partially purified in the rectifier B; it is further freed from the less volatile components in the

FIG. 22.

condensing apparatus C, and finally reaches the condenser D.

FIG. 23.

In Savalle's apparatus also the vapours pass first through a dephlegmator or analysing column, then through a surface or multitubular condenser, which is provided with a water supply, so regulated that its temperature is about that of the boiling-point of the liquid required; the liquid condensed in the regulated-temperature still-head returns to the dephlegmator, and the purified vapour passes on to the cold condenser.

In most of the still-heads employed on the large scale, the vapour first passes through a dephlegmator, the construction of which varies considerably in different cases. Dubrunfaut's dephlegmator, employed in the French column apparatus, is shown in Fig. 24. Two others, devised by Savalle, are represented in Figs. 25 and 26.

FIG. 24.

In the Egrot dephlegmator an arrangement somewhat similar to the dome (Fig. 24) is used, but a large number of these domes are

Fig. 25.

Fig. 26.

placed in each tray, and the condensed liquid is made to follow a zigzag course from the circumference to the centre of each tray.

The principle of the still-head in the Pistorius still is quite different. The vapour, entering a section (Fig. 27) of the still-head, is deflected from centre to circumference by the flat dome; it then passes back to the centre above the dome, and is partially condensed by the water in the shallow vessel above.

A simple and efficient still-head has been described by Foucar (Eng. Pat. 19999

of 1908). The column consists essentially of a helical septum which traverses the annular space between two concentric cylinders. The vapour

Fig. 27.

from the still passes up the long spiral passage before reaching the condenser. The inner cylinder can, if desired, be used as a thermostat, the column then acting as a regulated-temperature still-head.

A. Hirsch (J. Ind. Eng. Chem. 1910, 2, 409)

Fig. 28.

recommends the use of a differential condenser in the still-head, in the form of a spiral of metal tubing, through which a current of water of regulated initial and final temperature is caused to flow. The apparatus works easily and well so long as the temperature of the vapour leaving the still-head is considerably lower than that of the vapour entering it; but the difficulty of regulation increases greatly as this temperature-difference diminishes.

For work on the large scale Hirsch recom-

mends the introduction of a differential condenser between the lower and upper parts of a rectifying column.

In England, the Coffey still is largely used; it differs considerably from those described, inasmuch as there is no large boiler, and the heat is supplied, not from an outer fire or steam-jacket, but by the condensation of steam in the wort; moreover, the process is continuous. The essential parts of the apparatus are shown in Fig. 28. The wort is pumped from a reservoir, A,

up the pipe B, and passes down the zigzag pipe CC, where it is heated by the ascending vapours, then up the pipe D, from which it is discharged into the column E. It is prevented from falling through the perforated plates of the column or analyser by the ascending vapours, but falls through the pipes F, F, from one plate to another until it reaches the bottom, when it is allowed to escape. Meanwhile, steam is passed into the analyser X by the pipe H, and causes the wort to boil, so that by the time it has reached the bottom it is completely deprived of alcohol. The ascending vapours force their way through the perforated plates of the analyser, a portion of the aqueous vapour being condensed by each washing, and the descending wort being thereby heated. On reaching the top of the column, the concentrated alcoholic vapour passes down the pipe K into the rectifier, and there ascends through similar perforated plates; but in the rectifier it is not washed by wort, but by the weak alcohol formed by the previous condensation of vapour. This dilute alcohol, on reaching the bottom of the rectifier, flows off into a reservoir, from which it is pumped into the top of the analyser, where it mixes with the descending wort. In the upper part of the rectifier there are simply shelves, which compel the vapour to take the same zigzag course as the pipe which conveys the wort downwards. The purified and concentrated vapour then passes through the pipe L to the condenser. S. Y.

DISTYRENE $C_{16}H_{14}$. Produced by heating styrene (*q.v.*) with hydrochloric acid at 170° (Erlenmeyer, *Annalen*, 135, 122). Also, together with distyrene acid and carbon dioxide, by prolonged boiling of cinnamic acid with diluted sulphuric acid (Fittig, *Ber.* 12, 1739-1744; Erdmann, *Annalen*, 216, 179-199).

A colourless optically inactive oil, with a blue fluorescence, which gradually disappears; sp.gr. 1.016 at 15° ; b.p. 311° . On prolonged boiling yields toluene, isopropylbenzene, and some styrene; whereas *metastyrene*, produced from styrene on keeping, or heating in sealed tubes at 200° (Kovalevsky, *Annalen*, 120, 66), or with aqueous sodium bisulphite at 110° (Miller, *ibid.* 189, 341), passes almost quantitatively into styrene at 320° (Stobbe and Posnjak, *ibid.* 371, 259-286).

Distyrene yields benzoic acid on oxidation with chromic acid; and a crystalline dibromide $C_{16}H_{12}Br_2$ (m.p. 102°) on brominating in carbon disulphide solution.

According to Stobbe and Posnjak (*Annalen*, 371, 287-302), distyrene is $\alpha\gamma$ -diphenyl- Δ^2 -butene $C_6H_5-CH=CH-CH(CH_3)-C_6H_5$.

Distyrene disulphonic acid (dicinnamene disulphonic acid) $C_{16}H_{14}(SO_3H)_2$, described by Lange as obtained on heating γ -truxillic acid with sulphuric acid (*Ber.* 27, 1410-1415), is therefore not a derivative of distyrene.

Solid distyrene; m.p. 124° ; obtained by distilling cinnamic acid or its calcium salt (Engler and Leist, *Ber.* 6, 256; Miller, *Annalen*, 189, 340), and by passing $C_6H_5-C_2H_3Br_2$ over red-hot lime (Radziszewski, *Ber.* 6, 494), has been shown by Erlenmeyer (*Annalen*, 372, 249-251) to be stilbene.

DITA BARK. *Saween* (Ph. J. Trans. [3] 7, 110). The bark of *Alstonia scholaris* (R. Br.),

an apocynaceous tree found in India, the Philippines, Eastern Australia, and tropical Africa (*Ber.* 11, 2234).

According to Harnack (*ibid.* 11, 2004; Chem Soc. Trans. [2] 36, 332), it contains only one base, *ditaïne*, a basic glucoside, having the composition $C_{22}H_{36}N_2O_4$; but Hesse (*Annalen*, 203, 144; *Ber.* 13, 1750; *Pharm. J.* [3] 11, 251, 331) found in it three bodies *ditaïne*, $C_{16}H_{19}NO_2$; *echitamine* (echitammium hydroxide), $C_{22}H_{28}N_2O_4 \cdot H_2O$, melting with decomposition at 106° (this base is identical with Harnack's *ditaïne*) and *echitenine* $C_{20}H_{27}NO_4$, a brown amorphous mass, melting above 120° , soluble in chloroform, alcohol, and ether. It dissolves in nitric acid with the production of a purple-red colour which quickly passes through green into yellow.

The milky juice of this tree has the same properties as guttapercha; when inspissated it softens in boiling water; is soluble in turpentine and chloroform, and receives and retains impressions. A decoction of the bark is used as an astringent tonic.

DITAÏNE *v.* DITA BARK.

DITTANY. The root of *Dictamnus albus* (Linn.) (ord. *Rutaceæ*), which is a native of the south of Europe. It contains a volatile oil, and also resin, bitter extractive matter, and gum; and was formerly employed in medicine, especially for the treatment of epilepsy (Aldis, *Lond. Med. Gaz.* 19, 142).

'*Cretan Dittany*' is the common name for *Origanum dictamnus* (Linn.), a native of the Levant.

DIURETIN. A compound of sodium theobromine and sodium salicylate (*v.* SYNTHETIC DRUGS).

DIVI-DIVI. Divi-divi consists of the dried pods of the *Cesalpinia coriaria* (Willd.), a tree 20-30 feet high, found in the West Indies and Central America. The pods are about 3 inches long and $\frac{3}{4}$ inch broad, are very thin, and frequently resemble in shape the letter S. From 40 to 45 p.c. of tannin is present, which consists of ellagittannin and probably also gallotannin. Extracts of this material have a somewhat unfortunate tendency to ferment, with simultaneous development of a deep-red colouring matter; but this can be prevented to some extent by the use of antiseptics. Divi-divi is largely imported for the preparation of leather, and is also employed for black dyeing, but its use is far more limited in this latter respect than myrabolans. A. G. P.

DOCIMACY or **DOCIMASY:** (*Docimasia*, Fr.) Originally the act or art of examining by test (*δοκιμασία*, a test), applied in metallurgy to experiments made to determine the nature and purity of a metal; in pharmacy, to the testing of medicines and poisons; in medical jurisprudence, to the different proofs to which the lungs of a new-born child are subjected, for the purpose of ascertaining whether it was born alive or dead (Dunglison). Usually employed in chemistry as synonymous with assaying.

n-DODECANEDICARBOXYLIC ACID

Prepared by hydrolysing the diethyl ester obtained by the electrolysis of an aqueous solution of the monoethyl ester of suberic acid

(Brown and Walker, *Annalen*, 261, 123); or by the oxidation of chaulmoogric acid, obtained from chaulmoogra seeds (Barrowcliffe and Power, *Chem. Soc. Trans.* 1907, 568); m.p. 123°.

DODECATOIC ACIDS $C_{12}H_{24}O_2$.

1. *Lauric acid*, found by Marsson in laurel fat, a glyceride obtained from *Laurus nobilis* (Linn.) (Marsson, *Annalen*, 41, 330); also present in cocoa-nut oil (Görgey, *ibid.* 66, 295), in pichurin beans, in Dika bread, and in the fruit of *Cyrtodaphne sebifera* (Oudemans, *Zeitsch. Chem.* 1867, 256); m.p. 43-5; sp.gr. 0.883/20° and 0.875/43-6°; b.p. 225.5° (100 mm.).

2. *Hordeic acid* is found among the products of the distillation of dried barley with dilute sulphuric acid; forms crystalline plates; m.p. 60° (Beckmann, *J.* 1855, 513).

DOG-TOOTH SPAR. The scalenohedral form of calc spar (*v.* CALCITE or CALCSPAR).

DOLOMITE. A native carbonate of calcium and magnesium, named after D. G. Dolomieu (1750-1801), a French geologist. The mineral, in its typical form, contains equal molecules of the two carbonates, corresponding to 54.34 p.c. of $CaCO_3$ and 45.66 p.c. of $MgCO_3$. This variety is sometimes termed *normal dolomite*. Rammelsberg recognises two other varieties, occurring less frequently than the normal type, and containing respectively $3CaCO_3, 2MgCO_3$ and $2CaCO_3, MgCO_3$. But as the two carbonates are isomorphous, they occur associated in very variable proportions, and many of the massive dolomites are merely limestones more or less magnesian.

Dolomite crystallises in the rhombohedral system, and, unlike calcite, it commonly assumes the primitive rhombohedron ($106^\circ 15'$); the forms are remarkable for presenting curved faces, while lenticular and saddle-shaped crystals are not unusual. Further, the degree of symmetry is not the same; etched figures and the occurrence of certain rare faces show that the crystals are rhombohedral with parallel-faced hemihedrism (the crystal class being the same as for diopside and phenacite). Dolomite is slightly harder and denser than calcite; its *H.* being 3.5-4.5, and its sp.gr. 2.85-2.95. This sp.gr. is slightly higher than that calculated on the assumption of an isomorphous mixture of calcite and magnesite. This difference, together with the difference in the type of symmetry, indicates that normal dolomite is a double salt; and that crystals containing other proportions of calcium and magnesium carbonates must consist of isomorphous mixtures of dolomite with calcite or magnesite, or of the two latter alone.

The lustre of dolomite is often nacreous, especially in those varieties which contain a small proportion of $FeCO_3$, whence they are known as *pearl spar*. If the proportion of $FeCO_3$ increases, the mineral assumes, on weathering, a brownish tint, and is sometimes termed *brown spar*. $MnCO_3$ is often present to a slight extent, and imparts a faint pink tinge. Most varieties of dolomite show little or no effervescence with cold hydrochloric acid, but when powdered readily dissolve in the warm acid. Dolomite is soluble in water containing carbonic acid. The analyses of some of the dolomite springs in the Franconian Jura, by Gorup-Besanez, lead to the conclusion that

natural waters acting on a normal dolomite may dissolve it, and redeposit the mineral without decomposition. According to Bischof's experiments, the action of carbonated water on an imperfect dolomite or dolomitic limestone, is to dissolve out the $CaCO_3$, the rock becoming relatively richer in $MgCO_3$ until a true dolomite is left; such a result, however, was not obtained by Gorup-Besanez (*Annalen*, 8, Suppl. 1871, 230).

Some of the finest crystals of dolomite occur at Traversella in Piedmont; while in this country the best examples are obtained from the Laxey Mine in the Isle of Man, from Derbyshire, Alston Moor, and Leadhills in Lanarkshire. A variety of asparagus-green colour, from Miemo in Tuscany, is termed *miemite*; it contains, according to Rammelsberg, 57.91 p.c. of $CaCO_3$; 38.97 of $MgCO_3$; 1.74 of $FeCO_3$; and 0.57 of $MnCO_3$. A compact snow-white variety from Gurhof in Lower Austria, has been distinguished as *gurhofite*.

Dolomite occurs not only as a mineral, but as a rock. Crypto-crystalline, granular, and compact varieties form mountain-masses of great magnitude, especially in the Eastern Alps, where they are largely developed in the Triassic series, and form the characteristic jagged-peaked mountains known as 'the Dolomites.' Sterry Hunt has shown that a large proportion of the Canadian limestones should be classed as dolomites, and even where the rock is a normal limestone it is commonly veined with dolomite, while the fossils also are more or less magnesian; this is notably the case with the Trenton limestone of Ottawa, belonging to the Lower Silurian formation.

In this country magnesian limestone is developed on a large scale, especially in the Permian series, corresponding with the *Zechstein*, or Upper Dyas, of German geologists.

The outcrop of the magnesian limestone stretches from the mouth of the Tyne, through Durham and eastern Yorkshire, to the plain of the Trent near Nottingham. Certain beds near Sunderland are remarkable for presenting concretionary varieties, which assume globular and botryoidal forms, with a radiating structure, varying in size from a marble to a cannon-ball; while near Marsden there occurs a laminated variety, notable for yielding thin slabs which display flexibility. The massive and granular varieties have been largely quarried for ages as a building stone, the principal quarries being near Anston in Yorkshire, Bolsover in Derbyshire, and Mansfield Woodhouse in Nottinghamshire. The best stone is of a warm creamy tint, easily worked, and, when well selected, extremely durable, the most durable kind being that which presents a crystalline texture and contains the two carbonates in molecular proportions, so as to form a normal dolomite. Southwell Cathedral, York Minster, and Ripon Cathedral offer good examples of the use of this stone; and the perfection with which the Norman carving at Southwell had been preserved led to the selection of Bolsover dolomite as the stone for the new Houses of Parliament. According to Daniell, who analysed the Bolsover stone for the Commissioners appointed to make the selection, it contains 51.1 p.c. of $CaCO_3$, 40.2 of $MgCO_3$, 1.8 of Fe_2O_3 and Al_2O_3 , 3.6 of SiO_2 ,

and 3·3 of H_2O , &c. While this stone is, under ordinary circumstances, very durable, so large a quantity was required for the Houses that much of it was of inferior quality, and this has not proved satisfactory; other localities than those originally selected were laid under contribution, and stone was thus introduced which has yielded to the disintegrating influences of a London atmosphere.

A rock known as *dolomitic conglomerate* occurs in the South-West of England and in South Wales, and appears to be an old beach deposit of Keuper age. It consists chiefly of pebbles and angular fragments of carboniferous limestone, united by a cement more or less magnesian, and coloured with oxide of iron. The rock is quarried for burning, is used locally as a building stone, and, when polished, forms a handsome marble.

If magnesian limestone be calcined below a red heat, the carbonate of magnesium suffers decomposition, while the calcium carbonate is but slightly affected. On slaking the product, the caustic magnesia forms a definite hydrate, which is said to unite with the unaltered carbonate of calcium to produce a cement that offers considerable resistance to the action of water. Magnesian limestone, if argillaceous, though only to a small extent, has the reputation of forming good hydraulic cement; but some authorities allege that after a time the magnesian cements suffer alteration whereby their durability is greatly impaired. If dolomite be perfectly calcined, the product may be used for taking casts, since it 'sets' with water, like gypsum, though but very slowly.

Calcined dolomite is extensively employed as a lining for the converters used in the basic method of steel manufacture invented by Thomas and Gilchrist. The calcination is effected in either cupolas or regenerative kilns. After 9 hours' burning, the stone, though still hard, is found to have lost about half its volume and half its weight. This 'shrunk dolomite' is crushed, mixed with gas tar as a vehicle, and moulded into bricks, which are then heated until the tar is burnt off, when they are ready for use in the converter.

Dolomite treated with sulphuric acid yields the sulphates of calcium and magnesium, the two salts being readily separated by the greater solubility of the latter; hence magnesian limestone has been largely employed as a source of Epsom salts.

The origin of dolomite has given rise to much discussion, and probably more than one natural mode of formation must be recognised. While the frequent occurrence of dolomite with rock-salt and gypsum, and the paucity of associated fossils, suggest that it has been formed in inland waters, there are difficulties in the way of admitting its formation by direct precipitation. Sterry Hunt suggests that Na_2CO_3 , resulting from the decomposition of soda-bearing minerals, like certain felspars, might be carried by fresh waters to the sea, and, on meeting with $CaCl_2$ and $MgCl_2$, decomposition would ensue, with formation of $NaCl$ and $CaCO_3$ and $MgCO_3$. To account for the association of dolomite with gypsum, he assumes a reaction between $CaCO_3$ and $MgSO_4$, whereby $CaSO_4$ and $MgCO_3$ would be formed, and the latter might associate itself with

fresh $CaCO_3$ to form the double carbonate. Most dolomite seams, however, to have been formed by the alteration of limestone. Water holding carbonate of magnesium in solution may cause the dolomitisation of a limestone through which it happens to percolate. The replacement of a molecule of $CaCO_3$ by one of $MgCO_3$, so as to form a dolomite, is accompanied by a diminution of volume to the extent of 12 or 13 p.c.; and it is characteristic of many dolomites to possess a cavernous structure. Elie de Beaumont suggested that this is due to the shrinkage consequent on dolomitisation; while von Morlot found by direct observation that the cavities in such a rock amounted to 12·9 p.c. of its bulk. It must be remembered that most limestones of organic origin, such as coral limestones, are more or less magnesian, and Richthofen and others hold that many of the Tyrolese dolomites are altered coral-reefs. It was formerly supposed that the dolomites of Tyrol were limestones which had been metamorphosed by heated magnesian vapour emitted from eruptive rocks; and Durocher found that by heating fragments of limestone with $MgCl_2$ they became partially dolomitised. It is much more probable, however, that the alteration has been effected by the magnesium salts in sea-water. (v. J. W. Judd and C. G. Cullis, *The Atoll of Funafuti* (Roy. Soc. London, 1904); E. W. Skeats, *Quart. J. Geol. Soc.* 1905, 61, 97; E. Philippi, *Jahrb. Min.* 1907, *Festband*, 297; G. Linck, *Zts. Deutsch. Geol. Ges.*, 1909, 61, 230; v. CALCIUM and MAGNESIUM.)

F. W. R.

DOMYKITE. A copper arsenide Cu_3As , corresponding to copper 71·7 and arsenic 28·3 p.c. It occurs in reniform, botryoidal, and compact masses, of white or grey colour, with metallic lustre, rapidly tarnishing. $H. = 3-3\cdot5$; sp.gr. 7-7·5. Readily fusible before the blowpipe, with emission of arsenical vapours. Soluble in nitric acid, but not in hydrochloric acid. It is found at Coquimbo and Copiapo in Chile, at Cerro las Paracatas in Mexico, and at Zwickau in Saxony.

Several other arsenides of copper, more or less like domykite, are known. The *Algodonite* of F. Field is Cu_2As , and occurs at the Algodones Mine, near Coquimbo. *Whitneyite*, from Houghton Co., Michigan, U.S., described by F. A. Genth, is Cu_2As ; and D. Forbes's *Darwinite*, named after Charles Darwin, is a similar mineral from near Copiapo. *Condurrite*, from Condurrow Mine, Cornwall, appears to be a mixture of arsenide of copper with various oxidised products derived from the alteration of tennanite or some kindred species. The names *Keveenanite*, *Mohawkite*, and *Ledouxite* have recently been applied to various copper arsenides from Michigan, in which the copper is in part replaced by nickel and cobalt. L. J. S.

DORMIOL v. SYNTHETIC DRUGS.

DOSS. Japanese name for a dyewood from an evergreen tree *Ilex Mertensii* (Maxim.), found in the Ogasawara and Okinawa Islands. Contains a dyestuff, *dossetin* $C_{15}H_9O_5$, crystallising in yellow needles; m.p. 271°-272° (Ito, *J. Soc. Chem. Ind.* 1908, 440).

DOUBLE SCARLET, BRILLIANT SCARLET v. AZO-COLOURING MATTERS.

DRAGON'S BLOOD. A resin used as a red pigment (v. PIGMENTS; also RESINS).

DRIERS (in the United States also termed 'Japans') is the trade term for those metallic oxides, chiefly oxides of lead and manganese (litharge, red lead, manganese dioxide) or their inorganic salts, which were formerly used exclusively in the process of oil boiling as 'driers.' More recently acetate, oxalate, and borate of manganese have been employed. Since metallic salts of rosin acid have the same property, such salts are also manufactured as 'driers.' They are obtained either by precipitating rosin soap solutions with solutions of metallic salts, or by fusing together a metallic oxide with colophony. Hence these are distinguished in commerce as 'precipitated' driers, and 'fused' driers. The latter are readily discriminated from the former by their not containing any moisture. Metallic salts of linseed oil fatty acids are now used as driers; they can be prepared either by precipitation or by the dry process, hence both 'precipitated' manganese linoleate, 'precipitated' lead linoleate, and 'fused' manganese linoleate, &c., are obtainable. The driers prepared from linseed oil fatty acids, as also from rosin (colophony), are soluble in oil of turpentine, ether, chloroform, and linseed oil itself. Hence they are also termed in commerce 'soluble driers.' Solutions of these driers in linseed oil or in turpentine oil, or in a mixture of both, are obtainable in commerce under the name 'liquid driers,' 'terebene,' and other fancy names.

The function of these driers appears to be to absorb oxygen from the air and transfer it on to the linseed oil, thus accelerating its drying to a flexible film when exposed to the air. On this assumption, the fact that litharge and manganese dioxide act as driers will be best explained by stating that at the high temperature at which linseed oil is 'boiled,' the oxides saponify the linseed oil, forming therewith lead or manganese soaps, which then act in their turn in the manner indicated above. The following are the analytical data obtained by the author in the examination of a drier:—

	Per cent.
Ash	18.6
Fatty and rosin acids	83.4

The more detailed examination gave the following result:—

	Per cent.
Lead oxide	10.99
Manganous oxide	6.79
Iron peroxide	0.47
Calcium oxide	0.56
Rosin acids	38.32
Oxidised acids	4.24
Other fatty acids	40.86

It should, however, be understood that the results furnished by chemical analysis alone are not sufficient to supply the data on which to base an opinion as to the properties which a drier will impart to the oil. The colour and drying power of the boiled oil to be prepared and other conditions greatly influence the choice and the quantity of a drier to be employed on a large scale.

J. L.

DROP GUM or GAMBOGE v. **PIGMENTS.**
DROSERA WHITTAKERI. The *Drosera Whittakeri* is to be found in Australia, and grows plentifully on the hills near Adelaide. This plant

is provided with a tuber, which consists of an inner solid but soft nucleus full of reddish sap or juice, and an outer series of easily detached thin, and more or less dry, layers of an almost black material. Between these layers are to be found small quantities of a brilliant red colouring matter, the amount varying in tubers of different size and age, but apparently more plentiful in the older plants (Rennie, Chem. Soc. Trans. 1887, 51, 371; 1893, 63, 1083).

The colouring matter is extracted from the tubers by means of hot alcohol, the solution evaporated, and the residue, containing a little alcohol, is then mixed with some water and allowed to stand. The product is dried, sublimed, and the brilliant vermilion powder, which contains two substances, is fractionally crystallised from boiling alcohol or acetic acid.

The more sparingly soluble compound $C_{11}H_9O_5$, forms red plates, melting at 192° – 193° , dissolves in alkaline solutions with a deep-red violet colour, and gives a triacetyl derivative, $C_{11}H_9O_5(C_2H_3O)_3$, m.p. 153° – 154° .

The monosodium compound $C_{11}H_9O_5Na, 2H_2O$ gives dark reddish-brown needles, the disodium compound, $C_{11}H_9O_5Na_2, H_2O$, brown needles, and the calcium compound $(C_{11}H_9O_5)_2Ca, 3H_2O$, dark-brown crystals.

By treatment with stannous chloride or hydrochloric acid, this substance, $C_{11}H_9O_5$, yields a reduction product $C_{11}H_{10}O_5$, in yellow needles, m.p. 215° – 217° . When dry, this is stable in air, but if left in contact with alcohol or water, it soon becomes red owing to oxidation. According to Rennie, it is probable that the original colouring matter is a trihydroxymethyl-naphthoquinone, in which case the substance $C_{11}H_{10}O_5$ will consist of the corresponding hydroquinone derivative. The more readily soluble compound contained in the tubers possesses the formula $C_{11}H_9O_4$. It crystallises in red needles, m.p. 174° – 175° ; dissolves in alkaline solutions with a deep-red colouration; and gives a diacetyl derivative $C_{11}H_9O_4(C_2H_3O)_2$, in yellow needles, m.p. 107° – 110° . A. G. P.

DRUMINE. An alkaloid stated to be present in *Euphorbia Drummondii* (Ogston, Brit. Med. Jour. 1887, 451).

DRY CLEANING. French or chemical cleaning, *Nettoyage à Sec*. A process of removing dirt, grease, &c., from fabrics by solvents other than water, such as petroleum benzene, coal-tar benzene, carbon tetrachloride, &c. The substitution of such liquids for water seems to have been first made in France during the middle of the last century by the application of 'camphene,' a terpene used at that period for illuminating purposes.

The process was introduced into the United Kingdom, in 1866, by Messrs. Pullar & Sons, who greatly developed it, employing machinery to a large extent in place of the hand labour formerly used.

The solvents mainly used at the present time are 'benzines,' usually obtained from American and Borneo petroleum, of sp.gr. 0.78; boiling between 80° and 120° . The benzols employed are what are known commercially as 90's and 50's. They may contain sensible quantities of carbon disulphide, thiophen, and possibly other sulphur products, which are apt to impart a disagreeable smell to the fabric. Carbon

tetrachloride, on account of its relatively high price, is only used to a limited extent. It has the great advantage over the hydrocarbons that it is unflammable, and can be employed in particular cases where the use either of benzene or of benzol is inadmissible. (For a method of valuing benzene for the purpose of the dry cleaner, *v. Trotman, J. Soc. Chem. Ind. 1906.*)

Thiophen in benzol may be detected by the isatin and sulphuric acid reaction (*v. THIOPHEN. (Cf. Schwalbe, Chem. Zeit. 1905.)*)

Carbon disulphide may be detected by the formation of a precipitate with phenylhydrazine, and determined quantitatively by conversion into potassium xanthate by means of alcoholic potash (*v. CARBON DISULPHIDE.*)

An admixture of paraffin hydrocarbons with the benzol may be recognised by nitrating the sample with nitrosulphuric acid and subsequent steam distillation.

The carbon tetrachloride employed for degreasing should be free from hydrochloric acid or traces of free chlorine. It should also contain no chloroform or phosgene gas, which are apt to act deleteriously upon the workpeople.

Special soaps, soluble in benzene, are employed in dry cleaning. They not only assist the degreasing, but diminish the risk of fire. The soaps consist of practically anhydrous oleates or stearates of potash or soda made by melting together oleic acid and soap, or by dissolving the alkali in methylated spirit, and adding to the solution the requisite quantity of oleic acid or melted stearic acid. Strong ammonia solution may be employed instead of potash or soda.

(For a description of the methods and machinery employed in modern processes of dry cleaning, and of the apparatus for the recovery and purification of the solvents used, *v. Dyeing and Cleaning*, by F. J. Farrell, Griffin & Co., Ltd. 1910.)

DULCAMARA. *Bittersweet, Woody nightshade. (Douce amère, Fr.; Bittersüss, Ger.)* The young branches of the *Solanum dulcamara* (Linn.), a climbing plant with purple flowers and red berries inhabiting the British Islands and most parts of Europe (Woodville, *Med. Bot.* 33; Benth. *a. Trim.* 190). The drug appears to be going out of use, but in the form of decoction it is sometimes administered as a remedy in rheumatism and certain skin diseases.

The investigations of Pfaff (*Mat. Med.* 6, 506), Desfosse (*J. Pharm. Chim.* 6, 414), Pelletier (*ibid.* 6, 416), and others went to show that bittersweet contained a glucoside 'dulcamarin,' 'picroglycion,' or 'dulcarin,' and also a compound believed to be the alkaloid 'solanine' (*cf. Meissonier, Annalen*, 1, 368). Continuing an inquiry of Wittstein's (*Vierteljahrs. pr. Pharm.* 1, 364, 495), Geissler has shown (*Arch. Pharm.* [3] 6, 1010) that dulcamara contains a definite compound, *dulcamarin* $C_{22}H_{34}O_{10}$, together with a substance resembling solanine, which, however, does not yield sugar when heated with dilute acids. The dulcamarin of Geissler is a slightly yellow, inodorous, amorphous powder having a strong bitter taste followed by sweetness. It is soluble in water and alcohol, but insoluble in ether, chloroform, and benzene. It forms a lead salt $C_{22}H_{32}PbO_{10} \cdot 5H_2O$. With dilute

sulphuric acid it breaks down into *glucose* and *dulcamarelin* $C_{16}H_{26}O_6$; thus

Dulcamarelin is resinous, and forms the lead salt $C_{16}H_{24}PbO_6$.

An examination of *Solanum dulcamara* by Davis (*Pharm. J.* [iv.] 15, 160) has revealed, in addition to dulcamarin, the presence of *solanine* $C_{42}H_{75}O_{12}N$, m.p. 235°; *solanidine* $C_{41}H_{71}O_{12}N$, m.p. 205°; and *solanin*

DYEING. The art of dyeing consists in imparting colour to the substance of various materials, usually textile fabrics, in such a manner that it is not readily removed or altered by those influences to which the dyed material is subsequently exposed. *Tinting* is essentially the same as dyeing, but the term is applied to the production of light shades only. In *staining*, the colour is not so permanently fixed as in dyeing, but in all these processes the colouring substance is presented to the material in a dissolved condition. In textile *printing*, the colour is applied to portions of the material only, thus producing a pattern, but in other respects, many printing operations are, as regards principle, similar to dyeing. In *painting*, on the other hand, a more or less opaque pigment is applied to the material by means of adhesives, thus partially or entirely obscuring the true surface.

Dyeing is of chief importance in connection with the textile industries, but many other materials are coloured by dyeing processes, such, for example, as leather, feathers, horn, ivory, bone, straw, and wood.

The various materials above enumerated show remarkable differences in behaviour towards any particular dyestuff. Wool, silk, leather, feathers, horn, and animal skin products in general, behave somewhat similarly towards colouring matters, but the dyeing properties of cotton, linen, and other vegetable products are quite different.

Differences quite as marked are to be noted in the behaviour of various colouring matters towards one and the same material, and thus, in dyeing operations, the nature both of the material to be dyed and of the colouring matter employed, have to be taken into account.

The theory of dyeing. The precise cause or causes of the different behaviour of the textile fibres in dyeing is still a matter of acute discussion; but there is little doubt that the chemical nature and physical condition of the fibre and of the dyestuff all play their part in the complicated phenomena of dyeing.

The earliest theory with regard to the

fixation of dyes was that the action is purely mechanical, and it is still urged by many that rarely in dyeing processes is there direct evidence of chemical combination between fibre and dye-stuff. Both bodies, as a rule, retain their individual chemical and physical properties unchanged, and the dye can frequently be removed from a fibre by means of alcohol or other solvent.

In its earliest form, the mechanical theory was put forward by Helot and d'Apligny in 1780. (The Art of Dyeing Wool, Silk, and Cotton, being a translation of Helot's L'Art de la Teinture des Laines (1734); and d'Apligny's L'Art de la Teinture des fils de Coton (1776).) They assumed that the particles of colouring matter became embedded in the minute pores permeating the fibre substance. Crum (Chem. Soc. Trans. 16, 404) strongly supported this theory, while Müller-Jacobs (J. Soc. Dyers, 1885, 63) expressed much the same idea in attributing the fixation of dyes to membranous diffusion. It has, however, been shown by several investigators that dyeing processes do not obey the general laws of osmosis. v. Georgievics (J. Soc. Chem. Ind. 1895, 149) considers dyeing is chiefly due to surface attraction. Witt (Färber-Zeit. 1890) put forward a modification of the mechanical theory. He regards the fibres as solid solvents in which the dyestuff dissolves, the latter being withdrawn from its aqueous solution in the same way as, e.g., ether will extract many substances from their aqueous solution. The degree to which a dye-bath can be exhausted will then depend upon the relative solubility of the dyestuff in the acid or neutral dye liquor and in the fibre substance at the temperature used. Krafft (Ber. 1899, 1608) attributes dyeing phenomena to a separation of the dyestuff upon the fibre in a colloidal state, and this view has been supported by Biltz (*ibid.* 1904, 1766), Linder and Picton (Chem. Soc. Trans. 1905, 1931), and Dreaper (J. Soc. Chem. Ind. 1905, 223).

The chemical theory of dyeing was originally put forward by Macquer and Bergman in opposition to the mechanical theory of Helot and d'Apligny, and has received much experimental support from Persoz, Berthollet, Chevreul, Kühnmann, Vignon, Knecht, and many others. It is mainly based on the following facts: wool and silk fibres contain amino-acids, and thus possess strongly marked acidic and basic functions. Cellulose, the essential constituent of the vegetable fibres, is chemically much less active, and dyes much less readily than wool and silk, but under certain conditions it exhibits weakly acidic functions. All dyestuffs (with few exceptions) possess either acidic or basic properties, or are in the form of salts, which dissociate in the dye-bath; and chemical combination between fibre and dyestuff would thus, *primâ facie*, be expected. Moreover, *lanuginic* and *sericinic acids*, which are produced respectively by the hydrolysis of wool and silk, precipitate both acid and basic dyes from their aqueous solution (Knecht and Appleyard, J. Soc. Dyers, 1889, 72).

A full discussion of the evidence for and against the mechanical and chemical theories of dyeing cannot be here entered upon, but a general review indicates that the attempt to cover all dyeing phenomena by any one simple explanation must fail, and that many factors are concerned, the relative importance of which varies

in different cases. In the dyeing of wool or silk, with acid or basic dyes, it may be taken as established that chemical combination occurs, but prior to this some hydrolysis of the fibre, and more or less complete ionisation of the dye-stuff takes place. Surface concentration of the dye on the fibre probably also occurs, and the coagulation and precipitation of the dissociated colloidal dyestuff may also play a part. This is rendered more probable by the recent observation that the temperature of maximum absorption of dye does not (in the cases investigated) correspond with that of maximum fixation (Dreaper, Trans. Faraday Soc. 1910, pt. i. Haldane-Gee and Harrison, *ibid.*); the former possibly coinciding with the point of maximum coagulation and precipitation, and the latter indicating the point of maximum degree of chemical combination. Whether the superficially precipitated dye penetrates the fibre by osmosis or by 'solid solution' is mainly a question of definition of terms.

In the case of the dyeing of vegetable fibres, the same factors probably operate, but their relative importance is not the same, the physical factors—precipitation, surface attraction, and osmosis—predominating over the effect of direct chemical action.

Classification of colouring matters. It has already been pointed out that dyestuffs vary in their behaviour. If, e.g., separate pieces of wool are boiled in solutions of (a) logwood, (b) indigo, (c) magenta, and (d) picric acid, the following results are obtained: (a) the wool acquires a brown stain; (b) the wool remains undyed, the indigo floating about in an insoluble condition; (c) the wool is dyed a magenta colour; and (d) the wool is dyed a full yellow. If the experiment is repeated on wool which has been previously mordanted with potassium dichromate, the result will be that in (a) the wool is dyed black, whereas in (b), (c), and (d), similar results are obtained as in the previous experiments. Logwood, therefore, must be applied in conjunction with potassium dichromate or some similar substance, *i.e.* with a mordant; whereas magenta and picric acid dye without such aid, and indigo requires a special process, the nature of which is not indicated by the results of the above-described experiments.

Colouring matters may be divided into three groups on the lines indicated above, viz.: (1) those which must be applied in conjunction with a mordant; (2) those which dye direct from their solutions; and (3) those requiring special processes.

This classification is practically identical with that of Bancroft (Philosophy of Permanent Colours, i. 118, London, 1794), who, upwards of a hundred years ago, divided colouring matters into *substantive dyes* and *adjective dyes*; the former class comprising those which dye directly from their solutions, and the latter being composed of those dyes which require mordants. Nietski (Färber-Zeit. 1889-90, 8) uses the terms *direct dyes* and *mordant dyes* in exactly the same sense, and both Bancroft's and Nietski's terms are still in use. Hummel (The Dyeing of Textile Fabrics, 1st ed. 1885, 147) also classifies dyestuffs into two groups: *monogenetic dyes* being such as are capable of producing one colour only, while *polygenetic dyes* produce distinct colours

with different mordants. The members of the first group are *coloured bodies*, and these merely require to be fixed upon the fibre, whereas the *colouring principles* comprising the second group only develop a colour when combined with a mordant.

It will be seen that these three systems of classification closely correspond, the terms *substantive dyes*, *direct dyes*, and *monogenetic dyes* being almost synonymous, as are *adjective dyes*, *mordant dyes*, and *polygenetic dyes*. It should, however, be pointed out that none of these classifications is absolute; magenta, for example, is a direct dye as applied to wool, but requires a mordant when used for cotton.

A distinct method of grouping dyestuffs is that of Benedikt (The Chemistry of the Coal-tar Colours, 1886, 29), who distinguishes between *colour acids*, *colour bases*, and *neutral colouring matters*. Both colour acids and colour bases are fixed on the fibre in the form of salts, but whereas in the colour acids the essential colour-producing group resides in the acid portion of the compound, in the colour bases the reverse is the case. Alizarin red, dyed on wool, is a salt of which alumina forms the basic and alizarin the acid constituent. Alizarin is therefore a *colour acid*. Similarly, the red pigment formed on dyeing tannin-mordanted cotton with magenta is a combination of rosaniline base with tannic acid. Magenta is therefore a *colour base*. Indigo and many other vat dyes are *neutral colouring matters*.

All the above schemes of classification are defective, both from the points of view of the practical dyer and the chemist. As regards practical application, the large number of dyestuffs now on the market may, however, be satisfactorily classified into the following groups: (1) *mordant dyes*; (2) *acid-mordant dyes*; (3) *acid dyes*; (4) *direct dyes*; (5) *basic dyes*; (6) *sulphide dyes*; (7) *vat dyes*; (8) *ingrain dyes*.

The classification of dyes according to chemical constitution is based upon the existence, in all members of each class, of a certain group of atoms, upon the integrity of which their colouring power depends. This is termed the *chromophorous group*, the theory being first put forward by O. N. Witt, in 1876. The introduction of such a chromophor into a suitable colourless compound is accompanied by the development of colour, e.g. benzene (C_6H_6) is colourless, but azobenzene ($C_6H_5-N=N-C_6H_5$) is orange-coloured. Many substances, however, such as azobenzene, although strongly coloured, are devoid of dyeing power. Such bodies are termed *chromogens*, and in order to convert them into useful dyes, the introduction of a salt-forming group is necessary; these groups, in this connection, being termed *auxochromous groups*. Thus, whilst azobenzene is not a dyestuff, both *amino-azobenzene* and *hydroxy-azobenzene* are useful dyes. In these compounds, the azo-group ($-N=N-$) is the *chromophor*, and the amino- or hydroxyl-group is the *auxochrome*.

The presence of both a chromophor and an auxochrome does not, however, necessarily indicate that a substance is a useful dye. For example, *trinitroaniline*, $C_6H_3(NO_2)_3NH_2$ contains the chromophor (NO_2) and the salt-forming auxochrome group (NH_2); but it is not a use-

ful dyestuff, because the basic character of the auxochrome is neutralised by the strongly acidic chromophor. On the other hand, trinitrophenol $C_6H_2(NO_2)_3OH$, is the useful dyestuff picric acid.

Those dyestuffs which do not contain a salt-forming auxochrome cannot be applied by ordinary dyeing processes, and the fact that a special process is required, e.g. for indigo, is not primarily due to its insolubility, but to its neutral character.

The scheme of classification, based on the chromophor, distinguishes the following groups:—

Group	Chromophor	Typical dyes
1. iso-Nitroso or oxime	$\begin{array}{l} >C-O \\ \\ >C-N-OH \end{array}$	Resorcin green, dioxine, gambine.
2. Nitro-	$-NO_2$	Picric acid, naphthol yellow.
3. Azo-	$-N=N-$	(a) <i>Basic</i> —chrysoidine, Bismarck brown, Janus red (b) <i>Acid</i> —azo- oranges and scarlets, naphthol black, diamond black. (c) <i>Direct</i> —benzopurpurin, diamine colours, direct blacks.
4. Triphenyl-methane		Magenta, methyl violet, Victoria blue, patent blue, malachite green.
5. Oxyketone		The alizarin dyes.
6. Pyronine		Rhodamine, eosins, violamine.
7. Acridine		Acridine yellow, orange, and scarlet.
8. Oxazine		Meldola's blue, gallocyanin, Capri blue.
9. Thiazine		Methylene blue, thiocarmine.
10. Azines		Safranines and indulines.
11. Miscellaneous.		

This classification of dyestuffs into chemical groups is of importance in the identification and testing of dyestuffs, as the constitution of the compound determines its behaviour towards reagents. It is not, however, a convenient one as regards the practical application of the dyestuffs.

Essential properties of a dyestuff. In order to rank as a useful dye, a substance must possess certain essential features. A *direct dye* must not only possess a colour of considerable intensity and permanence, but must also be capable of easy fixation on textile fibres without injury to fibre or dyestuff. For example, both vermilion and azo-scarlet possess a brilliant colour, but the former is not a dyestuff, because it cannot be applied or produced by dyeing processes. A *mordant dye*, on the other hand, need not possess a strong colour, and may, in fact, be colourless. It must, however, be capable of producing strongly coloured and insoluble colour-lakes in combination with suitable mordants. *Vat dyes*—e.g. indigo—are, as a rule,

quite insoluble in water, and therefore cannot be applied by an ordinary process. The essential feature of this group is that their reduction products are soluble in alkaline solutions, and on this fact the method of application depends.

In order to constitute a dyestuff a body must, therefore, either be strongly coloured in itself or be capable of producing coloured lakes. It must also be of such a character that it can be fixed upon textile material from an aqueous solution, and it must produce a colour which possesses sufficient permanency and resistance to washing and other influences.

Operations preliminary to dyeing processes. In any dyeing operation, the chief bodies concerned are the fibre to be dyed and the dyestuff. In their natural condition, all textile fibres contain impurities which not only detract from their appearance, but prevent their being satisfactorily dyed. The removal of these impurities is the object of the washing, scouring, and bleaching processes which the crude fibres undergo.

A great bulk of manufactured textile material, chiefly cotton and linen, is used in the undyed condition, but wool and silk are usually dyed.

Dyeing processes. Dyeing may take place at various stages of the manufacture of textiles. '*Piece dyeing*' is generally employed when a plain-coloured material is required, being the most economical and convenient process. If a coloured pattern is required, the material must be dyed before weaving, and the process may then be carried out on the raw wool or cotton ('*wool dyeing*,' '*cotton dyeing*'), at an intermediate process ('*sliver*' or '*slubbing dyeing*') or upon the spun yarn ('*yarn dyeing*,' '*hank dyeing*,' '*cop dyeing*,' '*warp dyeing*').

Wool is dyed in all these forms; silk, almost exclusively in the form of yarn; and cotton, chiefly as warps, cops, or pieces.

The dyeing of wool. Wool may be dyed with a greater range of colouring matters than any other textile fibre. All the various classes of colouring matters enumerated in the classification based on practical application (see p. 282) are used in the dyeing of wool; the most important groups being the *mordant*, the *acid-mordant*, the *acid* and the *direct* dyes, as well as the *vat dye*, indigo. In boiling solutions, the affinity of wool for dyestuffs is generally greater than that of silk, but at temperatures below 60° the relative affinity is frequently reversed. By a suitable selection of dyestuffs and control of the process, it is therefore possible to dye the wool and silk in a woven fabric to different shades, or to produce a uniform colour on the two fibres. As a general rule, dyeing processes which produce good results on wool are entirely unsuited for cotton, and it is an easy matter to dye one of the two fibres when present in a mixed fabric and leave the other practically unstained. If both fibres are to be dyed the same or different colours, two distinct processes are, as a rule, required.

Different varieties of wool behave differently in dyeing, the finer wools, such as merino, requiring a larger amount of dyestuff to produce a given shade than the coarser qualities, e.g. Lincoln wool. The absorption of dye is, however, by no means entirely governed by the diameter of the fibre, e.g. fine silky mohair is very difficult to dye, probably on account of the

close texture of the external scales. Fibres taken from different portions of the same fleece also vary somewhat in dyeing properties; and wool taken from the skin of animals slaughtered for meat, or from diseased animals, also differs as regards its affinity for dyes. All these differences are shown to a much greater extent with some dyestuffs than with others.

The affinity of wool for certain dyestuffs may be increased by suitable treatment with acids, alkalis, or oxidising agents (bleaching powder or hydrogen peroxide solution), or may be diminished by a treatment with tannic acid solution and in other ways. Various colours may thus be produced by a '*piece-dyeing*' process by weaving together untreated wool and wool treated with one or other of the above-mentioned reagents.

The behaviour of wool towards solutions of metallic salts governs the use of these bodies as mordants. When boiled in solutions of salts which are neutral to litmus (e.g. sodium chloride), no change takes place; but when boiled in solutions of salts of the heavy metals having an acid character (e.g. sodium dichromate), a decomposition of the salt takes place, and an insoluble basic salt or a hydrated oxide is fixed upon the fibre.

The dyeing of silk. In general behaviour towards colouring matters, silk resembles wool, but, as a rule, dyes are fixed on silk in a less permanent manner than on wool. The dyeing of silk appears to depend, to a greater extent, on absorption, and to a less extent on chemical action. The *acid*, *basic*, and *direct* dyes are chiefly used on silk, but other classes, e.g. the *mordant* and *vat* dyes, are also employed, though they tend to detract somewhat from the brilliant lustre and suppleness on which the beauty of silk depends. The maximum absorption of dyes by silk usually takes place at 60°–80°, and not at 100° as in the case of wool.

The so-called '*dry dyeing*' process sometimes employed for silk consists in the use of benzene or other volatile liquid as a solvent for the colouring matter in place of water. The usual dyestuff-salts are not soluble in benzene, but the fatty acid compounds or resinates of basic dyes are readily soluble.

The mordanting of silk with metallic salts is usually carried out in cold concentrated solutions of basic salts, chiefly basic aluminium sulphate for colours, and basic ferric sulphate or ferrous acetate for blacks.

The production of black upon silk is a matter of great importance, and is almost a trade to itself. The silk is first immersed in a solution of chestnut extract or other tannin matter, and then in a solution of basic ferrous acetate (pyrolignite of iron) or ferric sulphate ('nitrate of iron'). By successive alternate treatments in these liquors, the silk may be weighted to the extent of 400 p.c. It is then dyed with logwood extract. There are a number of alternative processes for the black dyeing of silk.

Wild silks, of which *Tussur* is the chief variety, are much more difficult to dye than ordinary silk, the fine fibrillæ of which the fibre is composed being very impervious. The band-like flat surface of the fibre also reflects the light in such a manner that a white shiny

appearance may be produced instead of a rich, intense colour or black.

Artificial silks, consisting essentially of cellulose, are more allied to cotton than to silk as regards dyeing properties. Those varieties produced from collodion dye more readily with the basic dyes than do cotton or the artificial silks obtained from cuprammonium or zinc chloride solutions.

The dyeing of cotton. Cotton is dyed chiefly in the form of hanks or warps, less frequently as piece goods. The dyeing of cotton on the spool, cop or beam is, however, rapidly extending.

The dyeing properties of cotton differ greatly from those of wool, and therefore the processes and materials used also differ. Until the discovery of Congo red in 1884, there were three dyestuffs only, which were capable of dyeing cotton directly from their aqueous solution—*turmeric*, *safflower*, and *annatto*—but there are now a large number of synthetic substantive dyes by means of which any desired shade can be obtained. The very numerous class of *acid dyes* which are of such great importance in wool and silk dyeing are inapplicable to cotton.

Cotton has no affinity for metallic salts, and therefore does not become mordanted by boiling in their solutions. Indirect methods have therefore to be adopted in applying the basic mordants required for the fixation of the mordant dyestuffs on cotton. This fibre exhibits a remarkable affinity for tannic acid, which is withdrawn from dilute solution and concentrated on the fibre to a considerable extent. The tannic acid may then serve for the fixation either of metallic mordants or of basic dyestuffs upon the fibre.

The *vat dyes for cotton* are now assuming a very prominent position, since, by their use, extremely fast colours are obtained.

The so-called *ingrain dyes* are used almost exclusively on cotton. The term is applied to designate a class of dyes which are produced *in situ* on the fibre by precipitation.

Mercerised cotton is virtually a distinct textile fibre; and whilst its dyeing properties are essentially the same as those of ordinary cotton, its treatment requires special precautions on account of its great affinity for the direct dyes.

The dyeing of linen. The behaviour of linen towards the respective classes of dyestuffs is similar to that of cotton, but it is more difficult to dye. The inferior dyeing affinity of linen is probably due to the different physical structure of the fibre.

The dyeing of jute. Although a cellulose derivative, jute differs from cotton and linen, both in its chemical composition and properties. As regards dyeing processes, it behaves, to a certain extent, like tannin-mordanted cotton, and may be dyed not only with the ordinary *direct*, but with the *basic* colouring matters without the aid of a mordant.

The dyeing of leather. Leather resembles wool in dyeing properties, but the difficulty of dyeing it in fast colours is increased by the necessity of using lukewarm liquors only, since boiling water destroys ordinary leather. Certain of the newer methods of producing leather, *e.g.* chrome tannage yield a product which will withstand boiling solutions. It is very im-

portant as regards the permanence of the leather (when used *e.g.* for bookbinding or furniture covering) that no mineral acid should be employed in the dyeing process. As a substitute, formic acid may be recommended. The *acid* and *basic* colouring matters are chiefly employed, the *mordant* dyes being used to a less extent.

The dyeing of feathers. The chief cause of difficulty in the dyeing of feathers is their natural water-resisting property. This is due partially to their ultimate physical structure, and partially to the natural grease present. The midrib is specially difficult to dye. Apart from these special difficulties, feathers behave in dyeing, like wool, and may be dyed with *acid*, *basic*, *direct*, or *mordant* dyes. Reds, browns, blues, and other colours are usually dyed with acid dyes, but the most satisfactory blacks are obtained by successive and repeated treatments with logwood extract, and ferrous sulphate with potassium binoxalate. Dyeing must proceed for a considerable period at the boil, in order to ensure penetration.

The dyeing of horn. Horn is dyed in strong solutions of *acid* dyes by steeping for a long period in the cold or slightly warm baths, which are acidified with acetic or formic acid. Since it contains sulphur, horn may be dyed brown by steeping in a solution of sodium plumbite, which results in the formation of lead sulphide. Black is also produced by alternate steepings in solutions of mercuric nitrate and potassium sulphide.

The dyeing of ivory. Both *acid* and *basic* dyes may be employed in the dyeing of ivory, the former being used with addition of acetic or formic acid in hot solutions. Alcoholic solutions of colouring matters may also be employed. Red is frequently dyed by the cochineal single-bath process used for wool.

Black is produced either by the logwood or iron or aniline black process, as used in cotton dyeing, or by means of silver nitrate.

The dyeing of wood. The method of dyeing wood in bulk is to boil or steam it to remove the resins, and then treat it in an apparatus similar to that employed in creosoting. The wood is placed in a closed vessel which is exhausted by a vacuum pump, and when the air has been sucked out from the pores as completely as possible, the hot dye liquor is admitted into the vessel and put under pressure by a force pump. The direct and basic dyes may be employed. Wood is usually dyed black by alternate treatments with logwood extract and sodium bichromate solution.

The dyeing of straw. Straw is largely dyed for use in the manufacture of hats and baskets. There are two commercial varieties, distinguished as *chip* and *straw*. Chip is readily dyed by means of the *direct cotton dyes* or the *sulphide dyes*, and many *basic* and *acid dyes* in neutral solution may also be employed. The process must be continued for 2 to 3 hours at the boil.

'Straw' is more difficult to dye than 'chip,' on account of the highly silicious character of the surface. The straw should be steeped for several hours in warm water before dyeing. Blacks are usually obtained with logwood and iron, but for colours the *direct cotton* and the *basic dyes* are chiefly used.

MATERIALS USED IN DYEING OPERATIONS.

A great variety of chemical substances are used in dyeing processes—acids, alkalis, oxidising and reducing agents, metallic salts, and a wide range of organic bodies. Two groups only need be here considered, viz.: (a) *mordants*, and (b) *colouring matters*.

Mordants. The function of a mordant is to chemically combine with the dyestuff employed, and fix the latter upon the fibre. It has already been mentioned that many colouring matters do not require the aid of mordants, but dye direct from their solutions. This applies to the *acid*, *direct*, *basic*, and *vat* dyes when used for wool and silk, and the *direct* and *vat* dyes when used for cotton. On the other hand, the *mordant* and *acid-mordant* dyes (as their name implies) demand the use of mordants on wool, as do the *mordant* and the *basic dyes* on cotton.

It is evident that the chemical properties of the dyestuff will govern the character of the mordant required for its fixation, and two types of mordants may thus be distinguished: (1) the *metallic* or *basic mordants*, used for the *mordant dyes*; and (2) the *acid mordants*, required in applying the *basic dyes* to cotton or other vegetable fibre.

Basic mordants are employed for fixing on animal and vegetable fibres those colouring matters which are of an acid character, i.e. either true acids or bodies containing hydroxyl-groups, of which the hydrogen is replaceable by metals. They are metallic salts, of which the most important are certain compounds of chromium, aluminium, iron, and tin.

Wool is mordanted by boiling it with dilute solutions of these metallic salts, usually with the addition of certain acids or acid salts, e.g. cream of tartar, sulphuric acid, formic acid, oxalic acid, &c. During this operation, the wool assists in the dissociation of the metallic salt, an insoluble basic salt being fixed within and upon the fibre, while a more acid salt remains in solution. The acids or acid salts, which are added along with the metallic salt, possibly assist the dissociation of the latter by forming more sensitive salts (tartrates, oxalates, &c.), and may be conveniently termed *assistants*.

As a rule, the mordanting operation precedes that of dyeing; not infrequently, however, the two operations take place simultaneously, and the dyeing is thus effected by the so-called 'single-bath' or 'one-dip' method, as, for example, in producing cochineal scarlet on wool. In such cases, the wool is boiled in a solution containing colouring matter, metallic salt, and assistant, in certain accurately determined relative proportions. Combination takes place between the colouring matter and the mordant, but the pigment which would otherwise be precipitated, is retained in solution by the liberated acid of the mordant or the assistant present, and is only gradually withdrawn from solution by the fibre, which thus becomes dyed.

In the case of the 'acid-mordant' dyestuffs, the application of the mordant follows that of the colouring matter.

Silk is mordanted in the same manner as wool, by boiling with metallic salt solutions; or, more usually, it is steeped for about 12 hours in cold solutions of the mordants previously

rendered more or less basic and sensitive. By subsequently washing with (calcareous) water, the metallic salt absorbed by the silk is dissociated, and an insoluble basic salt is precipitated within the fibre.

Cotton is mordanted with metallic salts by processes very different from those adopted for wool and silk, since it has not the property of causing the dissociation of the metallic salts when boiled in their solutions. The methods adopted also vary according to the form of the material, i.e. whether it be cotton wool, yarn, or cloth.

With calico, it is usual to impregnate the fabric with solutions of metallic *acetates*, then to dry it, and expose for several hours to a moist warm atmosphere. During this so-called 'ageing' process, dissociation of the salt takes place, acetic acid escapes, and a more or less basic salt remains fixed upon the fibre.

Sometimes the 'ageing' is replaced by a 'steaming process,' in which the fabric is exposed from $\frac{1}{2}$ to 1 hour to the action of high or low pressure steam in a closed chamber. This method is adopted by the printer of textile fabrics in the so-called 'steam style,' in which a mixture of colouring matter and metallic salt (usually acetate) is printed upon the fabric, which is then dried and steamed. The metallic salt is decomposed, a basic salt is precipitated upon the fibre, at the same time combining with the colouring matter and producing the coloured pigment. This method is analogous to the single-bath process of the woollen dyer.

Cotton may also be mordanted by impregnating it with a metallic salt solution, drying, and then passing through a solution of an alkaline substance to neutralise the acid and precipitate upon the fibre a basic salt or metallic oxide, e.g. ammonia, chalk, sodium carbonate, &c. Solutions of an alkali salt, the acid of which forms an insoluble compound with the base of the mordant, e.g. sodium phosphate, silicate, arsenate, &c., are also employed. All substances used in this manner for fixing the mordant upon the fibre are termed *fixing agents*.

In some cases of mordanting, the cotton is impregnated with the fixing agent first (e.g. tannic acid, sulphated oil, &c.), then dried and passed through the mordant solution afterwards, as for example, in Turkey-red dyeing.

Special methods of mordanting cotton are occasionally adopted, in accordance with the properties of the metallic salt employed. Stannic oxide, for example, may be fixed on cotton by passing the fabric through a solution of sodium stannate, and then through dilute sulphuric acid, and finally washing. Alumina is precipitated on the fibre by the mere exposure to air of cotton impregnated with sodium aluminate, in which case atmospheric carbonic acid is the active fixing agent.

The *chromium mordants* are of the first importance, since, with different colouring matters, they yield a considerable range of colours which are remarkable for their permanence. The most important chromium mordants are potassium and sodium dichromates, and they are more largely used as mordants in wool dyeing than any other metallic salts. In cotton dyeing they are not used as mordants, but are frequently employed as oxidising agents, e.g. to develop the colour in dyeing

catechu brown or aniline black, and are also used in producing chromate of lead yellow and orange. Chromium fluoride ($\text{CrF}_3 \cdot 4\text{H}_2\text{O}$) is also used to a limited extent as a mordant for wool. Other chromium salts employed as mordants, chiefly for cotton, are chrome alum and chromium acetate. Chrome alum is obtained in large quantities as a by-product during the manufacture of alizarin; chromium acetate is prepared by mixing together solutions of chrome alum and lead acetate.

Wool is mordanted with chromium by boiling for 1-1½ hours with 3 p.c. potassium (or sodium) dichromate. In many cases it is beneficial to add 1 p.c. sulphuric acid (sp.gr. 1.84) or 1.5 p.c. hydrochloric acid (sp.gr. 1.16), or 6 p.c. tartaric acid, or 1 to 2 p.c. formic acid, whereby fuller or brighter colours are ultimately obtained. When potassium dichromate alone is employed, partial decomposition of the salt occurs, accompanied by some reduction, the wool absorbing some chromic acid and chromium chromate as well as potassium dichromate. When an addition of sulphuric acid is made, the wool absorbs only chromic acid. In both cases the mordanted wool has a yellow or buff colour, and only in the dye-bath does the reduction to the real mordanting body, chromic oxide, take place within the fibre through the interaction of the colouring matter. When formic or tartaric acid is the assistant employed, the mordanted wool has a green colour, reduction of the chromic acid taking place already in the mordanting bath, and chromic hydrate being deposited within the wool. If large amounts of potassium dichromate are employed in mordanting, especially if sulphuric acid is also added to the bath, bad results may be obtained through the colouring matter being oxidised and destroyed by the excess of chromic acid present in the wool. This defect is known as 'over-chroming.' In certain cases, potassium dichromate may be usefully applied in the same bath with the colouring matter (e.g. with alizarin), or by an after process (e.g. in the case of camwood).

Silk is not usually mordanted with chromium. It becomes mordanted, however, if boiled with a solution of potassium dichromate and tartaric acid after the manner of wool, but not if potassium dichromate alone, or with the addition of sulphuric acid, is employed.

Cotton may be mordanted with chromium by impregnating it with a more or less concentrated solution of chrome alum, drying, and passing through a boiling solution of sodium carbonate (100 grams per litre) or caustic soda. Better results are obtained by the use of 'chromium mordant G. A. I.' or 'G. A. II.' (M. L. & B.), which are chromium chromates. Other satisfactory mordants for cotton are chromium bisulphite (Knecht) and sodium chromite (Koechlin). A method in vogue with the printer is to impregnate (pad) or print the cotton with a mixture of colouring matter and chromium acetate, dry and steam ('steam colours').

The chief aluminium mordants employed for wool are aluminium sulphate and alum. The best results are usually obtained by merely boiling the wool for 1-1½ hours with a solution of 8-10 p.c. of the aluminium salt, with the addition

of cream of tartar, in the proportion of 3 mols. to 1 mol. aluminium sulphate. Aluminium tartrate also gives excellent results, but it is cheaper to allow this salt to be formed in the mordanting bath itself in the manner described. With some colouring matters, oxalic acid or potassium binoxalate are to be preferred as assistants to cream of tartar.

Silk is mordanted by boiling with dilute aluminium sulphate solution, or by steeping 24 hours in a concentrated solution, and then washing in water, preferably calcareous.

The methods of mordanting cotton with aluminium are various. It may be impregnated with a more or less concentrated solution of alum or aluminium sulphate, dried, and then passed for a few minutes into a hot solution of sodium phosphate, arsenate, or silicate or ammonium carbonate. Or the cotton may be impregnated with a cold solution of neutralised sulphated oil, or of tannic acid, then dried, and steeped in a solution of aluminium acetate or basic aluminium sulphate. Another method consists in impregnating the cotton with a solution of sodium aluminate, drying and exposing to the air, or passing through a solution of ammonium chloride. Normal and basic aluminium acetates are also employed, the cotton being impregnated with their solutions, then dried, and exposed to a moist warm atmosphere ('ageing'), and finally passed through a hot solution of, e.g., sodium arsenate. The aluminium acetates employed are prepared by dissolving alumina hydrate in acetic acid, or by decomposing a solution of aluminium sulphate with calcium or lead acetate ('red liquor'). As a general rule, the more basic the aluminium salts are, the more readily do their solutions precipitate by heating or on dilution with water, and the larger is the quantity of alumina they yield to the fibre when used as mordants.

The chief iron mordants employed are ferrous sulphate and acetate, and ferric sulphate, acetate, and nitrate.

The ferrous acetate employed is made by dissolving scrap iron in pyroligneous acid. The 'pyrolignite of iron' or 'black iron liquor' thus obtained is preferable to that made by the mutual decomposition of ferrous sulphate and lead acetate solutions; it is less liable to oxidise because of the presence of tarry matter and reducing agents, e.g. pyrocatechol, &c. Ferric sulphate is prepared by heating a mixture of definite proportions of ferrous sulphate, sulphuric acid, and nitric acid. Although the last-mentioned substance is only used as an oxidising agent, the final preparation is generally termed by dyers 'nitrate of iron.' The so-called 'pure nitrate of iron' (ferric nitrate) is prepared by dissolving scrap iron in nitric acid.

Wool may be mordanted by boiling in a solution of 7 p.c. ferric sulphate [$\text{Fe}_2(\text{SO}_4)_3$] and 4 p.c. potassium binoxalate, but iron is now very little used as a mordant for wool.

Silk may be mordanted by steeping for about 12 hours in a cold solution of pyrolignite of iron (sp.gr. 1.025), and afterwards washing well. The most usual mordant, employed largely in black-silk dyeing, is the basic ferric sulphate $\text{Fe}_2(\text{SO}_4)_3(\text{OH})_2$. The silk is steeped in a somewhat concentrated solution of this salt (sp.gr.

1-25) for about 1 hour, then squeezed and well washed. The operations are repeated seven or eight times, after which the silk is boiled in an old soap-bath and finally washed. In this process, the very sensitive basic ferric sulphate absorbed by the fibre is decomposed during the several washings, a still more basic and insoluble salt being precipitated within the fibre.

Cotton is usually mordanted with iron by first impregnating it with a cold solution of tannin matter (e.g. myrobolans), and then, with or without drying, passing into a dilute solution of ferrous acetate, ferric sulphate, or nitrate (sp.gr. 1.01-1.02). The cotton may alternatively be impregnated with ferrous or ferric acetate, dried, and exposed to a moist warm atmosphere ('ageing'), and finally fixed by passing through a hot solution of, e.g., sodium phosphate.

Tin mordants are now rarely used, but if required the stannous salts are employed for wool and the stannic salts for cotton. The chief stannous mordant is stannous chloride or 'tin crystals.' It is frequently sold as a somewhat acid solution under the names of 'single muriate of tin' (sp.gr. 1.3), or 'double muriate of tin' (sp.gr. 1.6). The general name 'tin spirits' is given to a variety of solutions of tin in mixtures of hydrochloric, sulphuric and nitric acids.

Wool is mordanted by boiling in a solution containing 6 p.c. of the weight of wool of stannous chloride, and 6-10 p.c. cream of tartar. Large proportions of stannous chloride should be strictly avoided, otherwise the dyed wool feels harsh and its general properties are impaired.

Silk may be mordanted in the same manner as wool, or steeped several hours in a more or less concentrated solution of stannic chloride, and then well washed.

Cotton is mordanted with stannic oxide by impregnating the cotton with cold tannin solution (e.g. sumach) for 3 hours, then squeezing, and, with or usually without drying, steeping 1 hour in a dilute solution of stannic chloride (sp.gr. 1.02), and washing. Cotton thus mordanted was much used formerly for fixing mordant dyes—peachwood, logwood, &c., in which case the stannic oxide constituted the mordant, the tannic acid acting as fixing agent. Now that the basic coal-tar dyes are so much employed in dyeing cotton, although the same method of mordanting is employed, the rôles of the tin salt and tannic acid are reversed, for it is really the tannic acid which is the essential mordant, while the stannic chloride serves only as the fixing agent.

Acid mordants are employed for fixing basic colouring matters on cotton. They are not used for this purpose in wool and silk dyeing, since these fibres themselves act as acid mordants, and are dyed directly without the aid of any external mordant.

Tannic acid is the mordant *par excellence* for fixing the basic coal-tar colours on cotton. This fibre absorbs tannic acid from its cold solution, and if, when thus prepared, it is immersed in a solution of a basic colouring matter, the tannic acid combines with the colour base, a coloured lake is formed within the substance of the fibre, and the cotton becomes dyed. During the dyeing process, the acid originally in combination with the colour base is displaced, and since in the free state it interferes with the com-

plete formation of the colour lake, it is found beneficial to add a small proportion of sodium carbonate or acetate to the dye-bath. Since the tannates of colour bases are somewhat soluble, in excess of tannic acid or in alkaline solutions, it is necessary in practice to fix the tannic acid on the fibre, previous to dyeing, in the form of an insoluble metallic tannate. This is done by passing the tannic acid prepared cotton through a hot or cold solution of tartar emetic or stannic chloride; tannate of antimony or tin is thus fixed on the fibre, and these salts have as great an attraction for the colour base as free tannic acid has. Cotton thus mordanted and dyed is probably permeated with a very insoluble double tannate of antimony or tin and colour base, a triple compound which is insoluble in alkaline solutions, and therefore fast to washing with soap, &c.

The tannin mordants, chiefly used by the dyer, are gall nuts and sumach, for light colours; and myrobolans, divi-divi, quebracho, and chestnut extract, for dark colours.

As already pointed out, tannic acid is sometimes used as a *fixing agent* for tin, iron, or aluminium mordants, and since its iron compound is of a bluish-black colour, it sometimes serves as a useful *colouring matter*.

Tannic acid is not used as a mordant for wool, but for *silk* it is largely employed, partly for adding weight to the silk, and partly for the purpose of dyeing it black in conjunction with iron mordants. Its utility as a weighting agent is owing to the fact that under suitable conditions silk absorbs as much as 25 p.c. of its own weight of tannic acid from a hot solution, whereby the fibre gains not only in weight, but also in volume.

Fatty acids are used as mordants very much in the same way as tannic acid for fixing the basic coal-tar colours on cotton. They are, however, not attracted by cotton from their solutions, but they form insoluble lakes with the colour bases. The method of procedure is to impregnate the cotton with a more or less concentrated solution of their alkali salts, e.g. soap; after drying, the fabric is passed through, or preferably steeped in, a cold solution of aluminium sulphate, and washed. Although the fatty acid is thus fixed on the fibre as an insoluble aluminium soap, it is still capable of combining with the colour base when the cotton is passed into a solution of a basic colouring matter. Colours dyed by this method are brighter than, but not so fast to washing as those fixed by means of tannic acid.

Instead of ordinary soap, a more convenient fatty-acid mordant to employ is the so-called 'sulphated oil.' This is prepared by mixing two parts by weight of castor oil with about one part of sulphuric acid (sp.gr. 1.84), and allowing the mixture to stand for 24 hours. It is then washed with a strong solution of common salt to free it from excess of acid, and is finally neutralised with ammonia or caustic soda. The product of the action of the acid upon the oil is somewhat complex, but its practical utility depends upon the fact that it behaves like a fatty acid and gives an extremely soluble soap with alkalis. Ordinary castor-oil soap produced by boiling the oil with caustic soda is also very soluble, and may be used as a mordant.

Sulphated oil is frequently called 'Turkey-red oil,' 'alizarin oil,' and 'soluble oil,' since it is largely used in the modern short process of Turkey-red dyeing as the fixing agent for the necessary aluminium mordant, and it gives the characteristic brilliancy of colour obtained by the use of the oil preparations formerly employed. Monopole oil is a similar product.

Phenolic colouring principles, e.g. alizarin, and certain acid colouring matters derived from benzidine, stilbene, fluorene, &c. (the direct cotton dyes) can also be fixed on cotton, and serve as mordants for basic colouring matters, but they are only occasionally used for this purpose for the production of compound shades.

COLOURING MATTERS.

(For Classification, see p. 282.)

GENERAL METHODS OF APPLICATION.

CLASS I.—Mordant dyes. This group of dyestuffs includes the majority of the *natural dyes*, also the numerous class of *alizarin dyes*, a number of derivatives of *pyrogallol* and other *phenols*, and certain *quinone-oximes* or *nitroso-dyes*. The following are the chief members of the group: *mordant dyes of natural origin*—logwood; madder; cochineal; limewood and other 'soluble redwoods'; camwood and other 'insoluble redwoods'; fustic; weld; quercitron bark and flavin.

Synthetic mordant dyes.—Alizarin; anthrapurpurin, flavopurpurin, and purpurin; nitroalizarin (alizarin orange); alizarin maroon (aminoalizarin); alizarin bordeaux; anthracene brown; alizarin blues; alizarin cyanins; anthracene blues; alizarin greens; cerulein; anthracene yellow; mordant yellow, galloflavin, &c.; alizarin black; gallein; gallocyanin; caelestine blue; naphthol green, dark green, gambine, &c.

The mordant dyes are largely used in the dyeing of wool and in the dyeing and printing of cotton and silk. Generally speaking, they yield colours which are of great fastness to light, soaping, acids, alkalis, bleaching agents, &c. As regards cotton dyeing, they are now being replaced by the very fast vat dyes introduced within the past few years.

When a fabric, previously mordanted with a metallic salt, is dyed with a mordant dye, a chemical reaction takes place, resulting in the formation of a new compound which is the actual colouring substance; this compound being, at the same time, fixed upon the fibre, which thus becomes dyed. These *colour lakes* or *pigments* may, for the most part, be equally well produced by bringing together the mordant and the dyestuff under suitable conditions in the absence of the fibre. Many colour lakes of this class are indeed manufactured in bulk for use as painters' pigments, &c.

There are three methods by which mordant dyes may be applied: (1) the mordant may be first applied to the fibre, and afterwards the dyestuff in a separate operation ('mordanting and dyeing method'); (2) the order of application of mordant and dye may be reversed ('dyeing and saddening method'); or (3) the mordant and dyestuff may be applied simultaneously ('single-bath method'). All these methods are in use. If equally good results can be obtained, the 'single-bath' process is to be

preferred, but usually the 'mordanting and dyeing' process gives the maximum fastness.

The dyeing of wool with mordant dyes.—When potassium dichromate is employed as mordant, the 'mordanting and dyeing' process is usually preferable, because, in the 'single-bath' process, the acid necessarily added to dissolve the colour lake formed in the dye-bath, converts the mordant into such a powerful oxidising agent by liberating chromic acid, that most dyestuffs are injuriously affected. In the two-bath process, the wool should be thoroughly washed after mordanting. If this operation is omitted, a portion of the mordant passes from the wool into the dye-bath, and, combining with an equivalent amount of colouring matter, forms a precipitate which floats about in an insoluble condition. This not only leads to loss of dyestuff, but also tends, by superficial absorption, to cause the dye to 'rub off.' The dyeing process consists in boiling the wool for from 1 to 2 hours with the colouring matter in aqueous solution. The final washing, after dyeing, has for its object the removal of any colouring matter which is imperfectly fixed; but, however thorough the washing may be, there is usually a small amount of colouring matter present on the dyed wool, which has merely been absorbed without combining with the mordant. This free colouring matter will dissolve out or 'bleed,' during milling or scouring, because most mordant dyes are readily soluble in alkaline solutions. A slight supplementary mordanting ('afterchroming') is frequently given to fix this small amount of free dyestuff.

The 'dyeing and saddening' method is not much used with the true mordant dyestuffs, but is the chief process used in applying the *acid mordant dyes*. Since the ultimate intensity of colour depends chiefly upon the amount of dyestuff which is fixed in the first bath, whilst the colour is only developed by the mordant in the second bath, it is obviously more difficult to exactly match a pattern when this process is used than when the mordant is applied first.

In the 'single-bath' method of dyeing, the bath is prepared with the necessary amount of mordant and dyestuff with an addition of sufficient acid (usually oxalic or acetic acid) to dissolve the colour lake formed. This process is therefore only suitable when the colour lake is soluble in dilute acid, and this is particularly characteristic of the tin and aluminium colour lakes; although the single-bath process is also frequently applicable in the case of ferrous sulphate or chromium fluoride mordants.

The dyeing of silk with mordant dyes.—The mordant dyes are not very largely used on silk, chiefly because they detract somewhat from the lustre of the fibre. The degree of fastness of the acid dyes, if suitably selected, is, moreover, usually sufficient for the requirements of the silk dyer. The methods of mordanting have already been dealt with. Dyeing must take place at the boil for about an hour, and the silk is subsequently brightened by working in a warm dilute solution of acetic or tartaric acid, and dried without washing.

Dyeing of cotton with mordant dyes.—The 'mordanting and dyeing' method is generally used in cotton dyeing. Aluminium is the chief mordant employed, and, in conjunction with

alizarin, it yields the important Turkey-red dye. This is a complex compound containing an alizarin-aluminium-calcium lake in combination with oxidised fat acids. In the production of this colour, the cotton is first prepared with sulphated oil, then dried, mordanted with alum, and subsequently dyed with alizarin. The complete process involves a large number of operations, for the details of which manuals of dyeing must be consulted. The dyeing of Turkey red is a very ancient process, having been carried out centuries ago in India by the aid of milk (as fatty matter) and munjeet, the Indian madder plant. No alum was employed, but the plant with its earthy incrustations contained sufficient alumina to form the alumina lake. The art spread from the East through Persia to Turkey, and was first introduced into this country (Glasgow) in 1790. Madder has now been entirely replaced by synthetic alizarin in Turkey-red dyeing, and the substitution of sulphated oil for olive oil or soap has also greatly simplified the process.

Another important mordant dye on cotton is logwood black, which is obtained by dyeing with logwood on tannin-iron mordant. It is largely used in hank and warp dyeing. Catechu brown is produced by the 'dyeing and saddening' method, the cotton being first steeped in a strong solution of catechu, and subsequently treated with potassium dichromate. The latter acts essentially as an oxidising agent, producing the so-called *japonic acid* on the fibre.

A great variety of permanent and bright colours may be obtained with mordant dyes on cotton mordanted with chromium or aluminium, but they are not very largely used, fast colours being chiefly produced by means of the *sulphide*, *vat*, and *ingrain* dyes (Classes VI., VII., VIII.).

CLASS II.—Acid-mordant dyes. These dyes are suitable only for wool and silk, and are largely used on wool. They are now very numerous, and are chiefly azo-compounds containing salicylic acid or orthoaminophenol components. Some, however, are anthracene or pyrogallol derivatives. Unlike the mordant dyes, they usually contain sulphonic acid groups.

Many of the acid-mordant dyes may be employed as ordinary acid dyes, since a mordant is not essential to the development of their colour. Usually, however, such dyestuffs produce faster colours when applied in conjunction with a mordant.

An exhaustive list of acid-mordant dyestuffs cannot be given, but the following will serve as examples. They include dyes giving a complete range of colours. *Reds*: acid alizarin, anthracene, chrome, cloth and milling reds. *Oranges and yellows*: cloth oranges and yellows, alizarin yellows (certain marks are mordant dyes), chrome yellows, milling orange and yellow, diamond and mordant yellow. *Greens*: acid alizarin, chrome, diamond and milling greens. *Blues*: acid alizarin, brilliant alizarin and chrome blues; alizarin sapphire; cyananthrol; chromotropes (chromotropes dye red as acid dyes). *Violets*: alizarin heliotropes; anthraquinone and chrome violets; fast violet. *Blacks and greys*: acid alizarin, acid chrome, anthracene acid, anthracene chrome, chrome, chromotrope and diamond blacks. *Browns*:

acid alizarin, acid anthracene, chrome, cloth, diamond, and palatine browns; chromogen.

Dyeing of wool with acid-mordant dyestuffs.—The usual method of application of this class of dyestuffs is to prepare a bath containing the necessary amount of dyestuff along with 1 to 3 p.c. sulphuric or 3 to 5 p.c. acetic acid, and 5 to 10 p.c. sodium sulphate (Glauber's salt). After the solution has been brought gradually to the boiling-point, the boiling is continued until the colouring matter is entirely fixed, an additional amount of acid being added if necessary. Excess of acid, however, frequently retains the dyestuff in solution. The wool is then removed from the bath, the metallic salt is added, and the wool is again boiled in the bath for half an hour. In most cases, potassium dichromate, to the extent of one-half the weight of the dyestuff, is the mordant employed.

A modification of this process is used with the *metachrome* series of dyestuffs. The *metachrome mordant* is a mixture of yellow potassium chromate and ammonium sulphate. The bath is prepared with 3 to 5 p.c. of this mordant together with the dyestuff. A prolonged boiling is necessary, during which the ammonium salt is decomposed, ammonia being evolved and the liberated sulphuric acid gradually converts the chromate into dichromate and assists in the fixation of the dye and the formation of the colour lake.

The *anthracene chromate dyes* are applied in a bath containing colouring matter, dichromate, and sodium sulphate; this being another modification of the usual process.

The mercerol and autochrome dyes are also applied by special processes.

The acid-mordant dyes are of increasing importance in wool dyeing, but are little used on silk, and not at all on cotton.

CLASS III.—Acid dyestuffs. The acid dyes constitute by far the most numerous class of synthetic colouring matters. The chief chemical groups of acid dyes are *azo-dyes*, *nitro-compounds*, *sulphonated basic dyes*, and *phthaleins*; the greatest number being azo-dyes. The azo-dyes contain few greens, blues, and violets; but the reds, oranges, yellows, browns, and blacks are very numerous. The nitro-compounds are few in number and are all yellows, the chief being picric acid and naphthol yellow. The greater number of the sulphonated basic dyes, on the other hand, are greens, blues, and violets, but acid magenta belongs to this group. The resorcin or phthalein dyes are chiefly brilliant pinks or reds, the eosins being the most important group.

So extremely numerous are the acid dyes, and their names are so varied, that no useful purpose would be served by further enumeration of a small number of the products.

The dyeing of wool with acid dyes.—The commercial acid dyes are, in most cases, the sodium salts of sulphonic acids. The nitro-compounds, however, owe their acid character to the presence of nitro-groups in the molecule.

The simplest and most usual method of dyeing acid colours on wool is to prepare a bath containing the requisite amount of dyestuff with 1 to 4 p.c. of sulphuric acid and 10 to 20 p.c. of sodium sulphate (Glauber's salt). The wool is dyed in this solution for about an hour,

boiling for the greater part of the time. Some dyes require smaller, and some larger percentages of acid. The sodium sulphate exerts a levelling influence on the fixation of the dyestuff, probably by reason of the solvent action which it exerts, since acid dyes are readily removed ('stripped') from wool by boiling in a solution of sodium sulphate. Another reason is to be found in the retarding action which it exerts in the liberation of the free colour acid by the sulphuric acid. The equation, which may be expressed as: Colour salt + $H_2SO_4 \rightleftharpoons$ colour acid + Na_2SO_4 , is reversible.

Sodium bisulphate may be used in place of the sulphuric acid and sodium sulphate, or the sulphuric acid may be entirely replaced by acetic or formic acid.

In the case of dyestuffs which do not readily produce level colours on the fabric, the acid may be added to the bath, gradually in small portions at a time, or may be substituted by an ammonium salt, e.g. ammonium sulphate or acetate. The acid is then liberated very gradually as the ammonium salt is decomposed in the boiling bath, and the colouring matter is therefore converted very slowly from the condition of the soluble sodium salt to that of the more or less insoluble free sulphonic acid.

The dyeing of silk with acid dyes.—Acid dyes are very largely used in silk dyeing. They are applied in a bath containing a large quantity (up to 25 p.c. in volume) of 'boiled-off' liquor, the soapy solution of the silk gum obtained in the 'ungumming' of raw silk. The bath is rendered slightly acid by means of sulphuric, acetic, or formic acid. Dyeing usually takes place at 80°-90°, at which temperature silk has more affinity for acid dyes than in a boiling bath.

After dyeing, the silk is washed and is then 'brightened' by working in a dilute (sulphuric, acetic, or tartaric) acid solution and dried without washing.

The dyeing of cotton with acid dyes.—There is no satisfactory method of fixing the acid dyes upon vegetable fibres.

CLASS IV.—The direct dyes. The direct dyes have the special property of dyeing cotton without the aid of a mordant. Like the acid dyes, they are for the most part azo-compounds, but contain the chromophore $-N=N-$ twice in the molecule, and thus constitute the tetrazo-group of azo-dyes. They further resemble the acid dyes in that they are alkali salts of sulphonic acids, but as regards dyeing properties, they differ greatly from the simpler azo-acid dyes. Since the introduction, in 1884, of the first of the direct dyes, a very large number have been placed on the market, and the group contains dyes of all colours—reds, oranges, yellows, greens, blues, violets, browns, and blacks. As examples of these dyes may be mentioned the congo, benzo, diamine, mikado, titan, and hessian dyes.

Primuline is an example of a direct dye which is not an azo-compound. It contains the chromogen $\begin{array}{c} \diagup \\ S \\ \diagdown \\ N \\ \diagup \\ C \end{array}$.

Turmeric is the only important natural direct dye for cotton.

The direct dyes are applicable to all fibres, but are rarely used on silk. No satisfactory

explanation has been given of the fact that they readily dye cotton, whereas the acid dyes are entirely devoid of this property. The further fact that the direct dyes dye wool in a neutral, or even slightly alkaline bath, whereas the acid dyes require the addition of acid, also demands explanation.

The dyeing of wool with direct dyes.—These colouring matters are applied to wool in a neutral or feebly acid bath with or without the addition of sodium sulphate (Glauber's salt). In some cases, an after-treatment with a metallic salt gives improved fastness, the dyes then practically falling into the class of acid-mordant dyes.

As a class, the direct dyes on wool are much faster to milling than the ordinary acid dyes. When fixed on wool, they are also faster to acids, washing, and light than when dyed on cotton. In some cases, the colour produced by a direct dye on wool and cotton is identical, in other cases it differs considerably.

The dyeing of silk with direct dyes.—These dyes are not largely used on silk. They are applied in a similar manner to the acid dyes, but smaller amounts of 'boiled-off liquor' and acid are required.

The dyeing of cotton with direct dyes.—The application of the direct dyes to cotton is very simple. They are dyed either from a cold, lukewarm, or boiling solution, to which is added a small amount (up to 2 p.c.) of sodium carbonate, and an amount of a neutral salt (up to 20 grams NaCl or Na_2SO_4 per litre), which is governed by the solubility of the dyestuff employed. At low temperatures more concentrated solutions of colouring matter are required. Brighter colours are obtained by passing the dyed material through a solution of Turkey-red oil before drying or by adding this substance to the dye-bath.

Mercedised cotton has a much greater affinity than ordinary cotton for the direct dyes, and in dyeing this fibre special precautions are necessary to produce level colours.

Many of the direct dyes produce on cotton colours of great brilliance and richness, but they bleed out into hot water, and are still more readily attacked by soap. Most of them are also comparatively fugitive to light.

There are two processes by means of which the fastness properties of certain of the direct dyes can be improved.

1. *The diazotising and developing process.*—This process is applicable only in the case of those dyestuffs in which amino-groups constitute the auxochrome. The cotton is first dyed by the general process above described, then washed, and afterwards worked for a few moments in a cold dilute solution of nitrous acid (2 p.c. $NaNO_2$ and 4 p.c. H_2SO_4 on the weight of the cotton). This treatment diazotises the amino-groups. The cotton is then well washed in cold water and entered immediately into the developing bath, which contains a solution of a phenolic or amino-compound; sufficient alkali or acid respectively being added to bring the 'developer' into solution. The chief developers used are phenol, resorcinol, α - or β -naphthol, aminonaphthol, aminodiphenylamine, *m*-tolyl-enediamine, and certain of the naphthol sulphonic acids.

Primuline is applied by the process just described.

A modification of this method is known as the 'coupling process.' The cotton is first dyed with the direct dye, and, after rinsing, is worked in a diazotised solution of the 'coupler.' The chief body used as coupler is *p*-nitraniline. Ready prepared stable diazo-compounds of this class are sold under the names 'nitrazol,' 'azophor red,' and 'nitrosamine red.'

2. *After-treatment with metallic salts.*—In this process for improving the fastness of the direct dyes on cotton, the fibre is first dyed in the ordinary way, and then, after rinsing, is treated for half an hour in a warm acid solution of a suitable metallic salt. The salts chiefly employed are copper sulphate, potassium dichromate, and chromium fluoride; from 1 to 3 p.c. with addition of 2 to 4 p.c. of acetic acid being used. A mixture of the two first-mentioned salts is frequently used. This process is mainly employed in the case of blues, browns, and blacks. The chromium salts exert the chief influence in increasing the fastness to washing, and the copper salt the fastness to light.

This process is only applicable to the case of dyestuffs containing free OH or COOH groups.

Cotton dyed with direct dyes may be 'topped' with basic dyes, for which the direct dyes act as mordants.

CLASS V.—The basic dyes. This group of colouring matters is numerically smaller than the mordant, acid, or direct dyes. It includes, however, the most brilliant dyes known, rhodamine pink, auramine yellow, malachite green, methylene blue, and methyl violet being well-known examples.

The basic dyes are very diverse in their chemical constitution. Many are derivatives of di- or tri-phenylmethane (magenta, malachite green, methyl violet); others are azo-compounds (chrysoidine, Bismarck brown); some are azine-derivatives (safranin and induline); and others contain sulphur as an essential constituent (methylene blue).

The commercial basic dyes are usually hydrochlorides of the colour bases, but some are acetates, oxalates, sulphates, or zinc chloride double salts. They are characterised by great tinctorial power, 1 p.c. being usually sufficient to produce a full rich colour. As a class, they are not fast to light.

The dyeing of wool with basic dyes.—These dyes are little used on wool, the acid dyes being applied in an equally simple manner and producing faster colours. Wool has a strong affinity for basic dyes, and readily becomes dyed if immersed in their solutions. A small amount of sulphuric or acetic acid may usually be added with advantage. Certain of the basic dyes, e.g. Victoria blue, are very fast to milling when dyed on wool, and such are still employed.

The dyeing of silk with basic dyes.—Members of this group of colouring matters are largely used by the silk dyer when fastness to light is not important. The silk yarn is dyed at 60°–80° in the colour solution, to which may be added some 'boiled-off liquor' or neutral soap. After rinsing, the dyed silk is brightened in a dilute solution of acetic or tartaric acid.

The dyeing of cotton with basic dyes.—Cotton has little affinity for basic dyes, which, on this fibre, must therefore be applied in conjunction with a mordant, and since the dyestuffs of this

class are basic in character, the mordant must be of an acid nature.

Three types of acid mordants are available, viz.: tannin matters, fat acids, and colour acids.

1. *Tannin mordants.*—As mentioned in dealing with the mordants, cotton has a natural affinity for tannic acid, which it withdraws from solution. Since tannic acid forms lakes with the basic colouring matters, cotton thus prepared may be dyed with basic dyes, but the colours produced in this manner are not fast against washing. As previously explained, however, if after mordanting with tannin the cotton is treated with a salt of antimony, tin, or iron, an insoluble metallic tannate is formed on the fibre, which compound has the same affinity for basic dyes as tannic acid has. The fastness properties of the double tannate of colour base and metal are much superior to those of the simpler tannates of the colour bases.

For the production of pale or bright colours, commercial tannic acid, gall nuts, or sumac are the tannins employed. The cotton is saturated ('padded') with a solution of 2° to 3°Tw. strength, or steeped for 2 to 3 hours in a solution containing 2 to 5 p.c. tannic acid or 10 to 30 p.c. ground gall nuts or sumac; the amount being calculated on the weight of cotton. The yarn or fabric after squeezing is then at once passed into a 'fixing bath' containing 0.5 to 3 p.c. of tartar emetic or an equivalent amount of antimony oxalate or fluoride. After well washing, the cotton is dyed with 0.1 to 1 p.c. of basic dye.

Additions of acetic acid to the tannin bath, ammonium chloride and chalk to the fixing bath, and dilute acid to the dye-bath, are frequently made. The mordanting and fixing baths may be used for several successive lots of material.

If the brightest possible shades are not required, some cheaper tannin matter (myrobalans or quebracho) may be employed, and stannic chloride may replace tartar emetic as fixing agent. For dark shades, ferrous acetate ('black iron liquor') is used as fixing agent, the blue-black tannate of iron producing a composite colour with the basic dyestuff.

2. *Fatty mordants.*—If Turkey-red oil or soap is used as mordant, the colour produced with a given basic colour is brighter, but less fast than when tannin mordant is used.

The fat acids are fixed on the cotton as metallic salts, usually aluminium salts; the fibre being first saturated with a solution containing 1 lb. of sulphated oil or soap per litre, then dried and passed into a solution of aluminium acetate ('red liquor') at about 8°Tw.

3. *Colour acids as mordants.*—Mention has already been made of the fact that the direct dyes act as mordants towards the basic dyes, compound shades being thus obtained. Mordant, sulphide, and acid dyes also possess the property of attracting basic dyes, but these combinations are not much employed.

The dyeing of jute with basic dyes.—Although jute is a vegetable fibre, it does not consist of free cellulose, but of a bastose-cellulose compound, *corehorobastose* (Cross and Bevan). The dyeing properties of this substance differ materially from those of cellulose, jute, in fact, behaving in a very similar manner to tannin-mordanted cotton, and dyeing direct with basic dyes.

CLASS VI.—The sulphide dyes. The number

and importance of this group of dyes has extended greatly during the past few years. They are chiefly employed for the production of fast blacks on cotton and other vegetable fibres, but fast blues, greens, browns, and yellows may also be obtained. They come into the market in the form of powders, which are usually insoluble in water, but soluble in solutions of sodium sulphide. They are also rendered soluble by other reducing agents, *e.g.* sodium hydrosulphite or glucose in alkaline solution.

The sulphide dyes are commercially known under the following names: sulphur, sulphur thioene, thionol, thional, thioxine, cross-dye immedial, katigen, kryogen, pyrogen, pyrol rexoll, eclipse, vidal, or auralon dyes. They are produced by melting together under suitable conditions aromatic nitro-, amino-, or imino-compounds with sulphur and sodium sulphide. The constitution of the sulphide dyes is not known, but the commercial products are probably mixtures of polymers or homologues and not homogeneous bodies. They contain free sulphur in amount varying from 1 to as much as 12 p.c. (Gardner and Hodgson, *J. Soc. Chem. Ind.* 1910, 672), and also contain very variable amounts of sodium sulphide and polysulphides.

The dyeing of wool with sulphide dyes.—Wool is rarely dyed with sulphide dyes, on account of the injurious action of sodium sulphide on the fibre. The wool may be protected to some extent against this action by the addition to the dye-bath of glucose, tannic acid, or ammonium salts. A previous treatment of the fibre with formaldehyde has also been recommended (R. Kann, *Eng. Pat.* 3492, 1903), but this reduces the affinity of the wool for these dyestuffs.

The dyeing of silk with sulphide dyes.—Fast blacks, blues, and browns may be obtained on silk by the following process: The sulphide dyestuff, together with the necessary amount of sodium sulphide, and twice as much glucose as sulphide, is boiled in water until the dyestuff is dissolved. This solution is added to the boiling dye-bath already containing 1 gram soda ash, 3 c.c. Turkey-red oil, and 5 to 10 grams sodium sulphate per litre. The silk is dyed below the surface of the liquor for an hour, then rinsed, soaped, and brightened with acetic acid. Faster shades are obtained if the dyed silk is subsequently treated in a boiling solution containing 2 to 4 p.c. potassium dichromate and 3 to 6 p.c. acetic acid.

The dyeing of cotton with sulphide dyes.—This group of dyestuffs is now of the greatest importance in cotton dyeing for the production of fast blacks, and to a less extent, fast blues, greens, browns, &c. The necessary ingredients in the dye-bath, in addition to the dyestuff, are sodium sulphide, sodium sulphate, or other neutral salt, and an alkali, usually sodium carbonate. The actual and relative amounts of these substances vary considerably with different dyestuffs, depending upon the ease with which the colouring matter employed undergoes reduction and the solubility of the reduced product. An addition of Turkey-red oil, monopol oil, or glue, tends to produce more level and brighter shades; glucose aids the reduction. Dyeing takes place just below the boil, and it is usually desirable to keep the cotton completely immersed during the operation, in order to prevent

irregular oxidation. The baths are used in a very concentrated condition, with the result that such a small proportion of the dyestuff is withdrawn, that for reasons of economy 'standing baths' are employed, that is, the baths are used continuously and replenished with dyestuff, &c., as required. The dyeing takes place in iron vessels, copper being rigidly excluded, on account of the ease with which it is attacked by sodium sulphide.

Some of the sulphide dyes do not require any treatment subsequent to dyeing other than exposure to air, but with many dyes of the group an after-treatment greatly improves their fastness to light and other influences. The chief object of the after-treatment is to ensure the complete oxidation of the colouring matter; and, as oxidising agents, chromium salts, or hydrogen peroxide are used. Steaming the material in presence of air is employed in the case of immedial blue.

After-treatment with potassium dichromate and acetic acid is now usually practised, since the use of copper salts has proved to be dangerous in regard to the subsequent tendering of the fibre on account of their catalytic action in inducing acid formation (Gardner and Hodgson, *J. Soc. Chem. Ind.* 1910, 676).

The tendering of cotton dyed with sulphide blacks has greatly retarded the use of these dyestuffs. The defect does not usually develop for some weeks or months after the material has been dyed, and it has been shown to be due to the slow formation of sulphuric acid on the fibre. The development of acid arises mainly from the oxidation of free sulphur present on the dyed fibre, but even in the absence of free sulphur, acid development may take place by decomposition and oxidation of the colour molecule.

The risk of tendering, during storage, of cotton dyed with sulphide blacks is entirely eliminated by a final treatment of the material, before drying, with sodium acetate; but, of course, the protective influence of this salt disappears if the material is washed.

CLASS VII.—The vat dyes. Until comparatively recently, indigo was the sole representative of this group of dyestuffs. The synthetic production of indigo was, however, followed by that of a number of derivatives of this body. Other series of vat dyes have also been introduced within the past few years, and by their use it is now possible to produce on cotton many bright colours of a degree of fastness hitherto unattainable.

The essential features of a vat dye are its easy reduction to a form soluble in dilute alkali, its attraction in this condition by the fibre, and its ready reoxidation on the fibre to the original insoluble condition. The reduced solution is termed the 'vat.'

The vat dyes include the following: indigo (indigotin); mono-, di-, tri-, and tetra-halogen derivatives of indigotin; methyl and tolyl indigotins; ciba dyes (brom indigotins); thioindigo red and scarlet; helindone dyes (sulphur derivatives); algole dyes; cibanone dyes, and the indanthrene dyes. The group includes dyes of all hues. The blues predominate in importance.

Indigo is the oldest and by far the most important of the vat dyes. It has been employed

in India for at least 3500 years, by methods not differing essentially from some of those which are still employed. It is used upon all fibres, but least commonly upon silk.

Various reducing agents are employed for the conversion of the insoluble indigo blue into indigo white, and they are always associated with an alkali to dissolve the latter substance. After saturating the fibre with the alkaline solution, the indigo white is reconverted into indigo blue upon the fibre by atmospheric oxidation.

The dyeing of wool with indigo vat blue.—The two chief indigo vats used for wool are the fermentation vat and the hydrosulphite vat, the former being chiefly used for dark shades on woollen cloth (Army and Navy cloth, &c.), and the latter for light colours on slubbing, yarn, &c. There are several forms of fermentation vat, of which the woad vat is the most important in this country. The precise composition and 'setting' of the vat is largely a matter of experience, the ingredients being somewhat as follows: finely ground indigo, 12 to 18 lbs.; woad, 300 lbs.; bran, 10 lbs.; madder, 12 to 18 lbs.; lime, 12 lbs.; water, 600 gallons. After warming the liquor, various fermentations set in, the essential bacterium being the *Desmobacterium hydrogeniferum*. The starchy matters present are first converted into glucose, which then splits up into lactic acid, the latter undergoing butyric fermentation with evolution of hydrogen.

Excessive fermentation is prevented by making suitable additions of lime, or it is accelerated, if necessary, by adding further quantities of bran.

In the so-called German or soda vat and the Indian or potash vat, the woad is replaced by bran with the addition of molasses, and the lime by sodium or potassium carbonate.

To avoid the derangements to which all fermentation vats are liable, Collin and Benoit (J. Soc. Chem. Ind. 1885, 493) proposed to employ a pure ferment and a completely fermentable food material; but this process has not come into practical use.

Natural indigo is still largely used in the fermentation vats, but in the hydrosulphite vat the synthetic product is generally employed. The hydrosulphite vat may be prepared as follows: synthetic indigo (20 p.c. paste), 10 lbs.; caustic soda solution 42°Tw., 3 pints; sodium hydrosulphite solution 20°Tw., 7½ gallons; water, 50 gallons. The liquid is heated to 50° until it becomes clear greenish-yellow. The solution of indigo white thus obtained is diluted to 250 gallons with water at 50°, to which a little hydrosulphite has been previously added.

The hydrosulphite solution may be replaced by 3 lbs. of solid sodium hydrosulphite, in which case the amount of caustic soda must be increased. 3½ lbs. of natural indigo (60 p.c. indigotin) are about equivalent to 10 lbs. of synthetic indigo (20 p.c. paste). After working in the vat, the goods are well squeezed, and then exposed to the atmosphere to oxidise the indigo white: they are then well washed.

Dark shades of indigo blue on wool are usually 'bottomed' with a red dye (diamine fast red or barwood) before vatting, and are frequently 'topped' after vatting with orehil

or other dyestuff in order to add 'bloom' to the colour.

In most respects indigo vat blue is an extremely fast colour, but has the defect of being liable to 'rub off.'

The dyeing of silk with vat indigo.—This dye is not much employed on silk. If used, the most suitable vat to employ is the hydrosulphite vat set with synthetic indigo.

The dyeing of cotton with vat indigo.—The hydrosulphite vat is largely employed in cotton dyeing as well as in the dyeing of wool, but it is used cold in the case of cotton. Other cotton vats are the 'copperas vat' and the 'zinc-powder' vat.

A strong copperas vat contains, indigo (60 p.c.), 10 lbs.; ferrous sulphate, 30 lbs.; and quicklime 35 lbs., in about 200 gallons of water. The lime decomposes the ferrous sulphate, with the production of ferrous hydroxide, and this in the presence of lime and indigo decomposes the water, yielding ferric hydroxide and hydrogen; the latter at once combines with the indigotin and produces indigo white, which dissolves by reason of the excess of lime present. The normal colour of the vat liquor thus obtained is brownish-amber.

The zinc-powder vat is made up with water, indigo, zinc-powder, and lime. In the presence of the lime and indigo, the zinc decomposes the water even at the ordinary temperature, and the liberated hydrogen effects the reduction of the indigo.

Vat dyes other than indigo.—These may be roughly divided into two groups: (a) the *indigoids*, which may be considered as derivatives of indigotin; and (b) the *anthracene* derivatives. They all possess the common property of forming vats when treated with hydrosulphite of soda, but whereas the indigoids may be applied to the animal as well as to the vegetable fibres, the anthracene derivatives are only suitable for cotton on account of the large amount of caustic alkali required for their solution. The reduced anthracene vat dyes also do not appear to possess much affinity for wool.

(a) *Indigoids.*—The dyes of this series now on the market are: thioindigo red and scarlet; helindone red and scarlet; ciba red and scarlet; vat red; helindone orange and yellow; ciba green; brom indigos; ciba blues and greys; ciba violets and heliotropes; helindone brown. Some of the algole reds also probably belong to this group.

(b) *Anthracene vat dyes.*—Indanthrene red; algole reds; indanthrene yellows and oranges; algole yellows and oranges; cibanone yellows and oranges; indanthrene greens; algole greens; indanthrene blues; algole blues; indanthrene grey; indanthrene browns; algole browns; cibanone browns.

The application of the indigoid vat dyes to wool and silk.—Vats suitable for the dyeing of wool and silk are obtained by reduction with sodium hydrosulphite in alkaline (caustic soda) solution. Bright reds of excellent fastness are obtained with these dyes, and they are used in conjunction with indigo for producing bright purplish blues. Separate vats are preferable for the indigo blue and the red dye, since the best conditions of dyeing do not coincide in the two cases.

The application of indigoid vat dyes to cotton.

—Vegetable fibres are readily dyed with these dyes from a hydrosulphite vat, or alternatively they may be dyed from a sodium sulphide bath, as used for the sulphide dyestuffs. They may be mixed with most sulphide dyes and dyed from the same vat.

The application of the anthracene vat dyes.—This group of dyes are also applied in the hydrosulphite vat, but usually require such a strongly caustic solution that their application to wool and silk is not practicable.

By use of the vat dyes, it is now possible to produce a great variety of colours on cotton which are extremely fast to light, washing, and other influences. The high cost of these dyes at present somewhat limits their application.

Indophenol is a vat dye of different type, being obtained by the action of nitroso-dimethyl aniline on α -naphthol. On reduction, it is converted into *indophenol white*, a body sufficiently stable to be sold commercially. On oxidation with chromic acid, indophenol white is reconverted into indophenol blue.

Indophenol has been employed in conjunction with, or as a substitute for indigo, but has the defect of being readily affected by acids.

Tyrian purple.—As the result of an extremely interesting investigation, P. Friedländer has shown (Ber. 1909, 765) that this ancient dyestuff is identical with one of the dibrom-indigotins. Tyrian purple, as described by Pliny, was obtained from various species of the mollusc *murex*, and from 12,000 of the species *M. brandaris* Friedländer obtained 1.4 grams of the colouring matter.

Under the law of the ancient Romans, the use of Tyrian purple was confined to royalty, and the method of its production was a lost art for many centuries. At the beginning of the 18th century, it was investigated by Rcaumur (Mém. de l'Acad. Royale des Sciences, 1711), but it never again assumed any importance as a dye-stuff.

CLASS VIII.—The ingrain dyes. The term *ingrain dye* may be applied to designate those colouring matters other than mordant dyes which are produced from their constituent bodies upon the fibre. Three sub-groups may be distinguished: (a) *aniline black*; (b) *the insoluble azo-dyes*; and (c) *the metallic dyes*.

(a) *Aniline black.*—This term is applied to the insoluble black pigment which is produced by the oxidation of aniline in acid solution. In 1834 Runge noticed that a blue-black compound was produced by oxidising aniline with chromic acid, but Wilm, in 1860, first described the formation of the product on the cotton fibre. The first successful aniline black was patented by Lightfoot, in 1863, who used potassium chlorate and cupric chloride as oxidising agents, and the black proved to be of such excellent fastness that innumerable modifications of the process have since been proposed, and the literature of the subject is very extensive.

Numerous oxidising agents have been employed in the production of aniline black, e.g. chlorates, chromates, salts of copper, vanadium, tungsten, cerium, &c. Aniline black may also be produced by electrolytic (Göppelsröder, Jahresber. 1876, 702) or by atmospheric (Green, J. Soc. Dyers, 1908, 231) oxidation.

Pure aniline on oxidation yields a blue-black,

the homologues and allied compounds giving somewhat different shades; e.g. orthotoluidine produces a brownish-black, paraphenylene diamine a deep black, and para-aminodiphenylamine (diphenyl base) a greenish black. The oxidation of α -naphthylamine on the fibre results in the formation of *naphthylamine violet*, but this colour is not of much importance.

The composition of aniline black has been the subject of much investigation (see Armand Müller, Chem. Zentr. 1871, 288; Göppelsröder, Jahresber. 1876, 702; Nietski, Ber. 1878, 1094; Caro, Verhandt. d. Ges. Deutscher Naturforcheren u. Arzte, 1896, 119; Willstätter and Moore, Ber. 1907, 2665; Marsden, J. Soc. Dyers, 1908, 9; Willstätter and Moore, Ber. 1909, 4118; Green and Woodhead, Chem. Soc. Trans. 1910, 223).

Three chief and successive products of the oxidation of aniline may be distinguished—*emeraldine*, *nigraniline*, and *ungreenable black*.

Emeraldine is produced by the limited oxidation of aniline, several residues linking up to form a chain of 4 molecules (Willstätter and Moore) or a chain or ring of 8 molecules (A. G. Green). The aniline residues are in all probability linked by nitrogen atoms in para-position, since para-compounds only have been obtained on oxidation or reduction.

Emeraldine is a greyish-green body which is always formed during the early stages of the production of aniline black. By the action of oxidising agents, it is converted into *nigraniline* and by the action of reducing agents it forms first proto-emeraldine by addition of two atoms, and then leuco-emeraldine by addition of four atoms of hydrogen (Green, Chem. Soc. Trans. 1910, 223). More powerful reducing agents split the molecule and produce amino- and para-diamino-compounds.

Nigraniline, the second oxidation product of aniline, appears to contain eight aniline residues, and is produced either by removal of two hydrogen atoms from the emeraldine molecule (Green) or by polymerisation with loss of hydrogen (Willstätter and Moore).

Nigraniline or aniline black is a violet-black body which is unaffected by alkalis, but which is turned green by mild reducing agents (sulphurous acid), owing to its reversion into emeraldine. Dilute mineral acid also brings about indirectly the production of emeraldine from *nigraniline*. Oxidation of a portion of the latter substance probably takes place at the expense of the reduction of other molecules, since both quinone and emeraldine are formed in the reaction.

Ungreenable black, the final product in the technical formation of aniline black, is produced by the further oxidation of *nigraniline* in presence of aniline. It is a very stable body, and is not readily attacked by acids, alkalis, oxidising or reducing agents. Powerful oxidising agents, however, convert it almost quantitatively into quinone, and powerful reducing agents into a brown leuco-compound which is reoxidised to the original black on exposure to air. The presence of free aniline is essential to the production of ungreenable black, which suggests that it is a condensation product of emeraldine and aniline.

Technical production of aniline black.—Of the large number of modifications of Lightfoot's

original process which have been suggested, very few have withstood the test of practical experience. The following technical methods may be distinguished: (1) *dyed blacks*; (2) *aged blacks*; (3) *steam blacks*.

(1) *Dyed blacks*, also known as *one-bath blacks*, are used for the dyeing of cotton yarn, which is often previously dyed in a sulphide black vat. The ingredients used are aniline (12 lbs.), hydrochloric acid (18 lbs.), sulphuric acid (24 lbs.), and sodium dichromate (24 lbs.), in 40 gallons of water. The use of hydrochloric acid alone produces a bluish-black, and sulphuric acid alone a reddish-black, the mixed acids yielding a jet black.

The yarn is worked in the solution while slowly heating to the boiling-point, and the bronzy black thus produced is steamed to convert it into a good black which is ungreenable. This process does not tender the cotton. Many modifications of the process are used.

(2) *Aged blacks* are obtained by padding (saturating) the cotton with a solution containing aniline salt, some oxidising agent (sodium chlorate) and an oxygen carrier (copper sulphate, or vanadium chloride), after which the fabric is dried and 'aged,' or the colour developed, by passing through an ageing chamber in which a moist atmosphere and a temperature of about 45° are maintained. The padded cotton has a green colour (emeraldine) which turns black (nigraniline) during ageing. The final change to ungreenable black is brought about by working the fabric in a solution of sodium dichromate.

Copper aged blacks are very largely produced on cotton piece goods by a process which differs only in detail from Lightfoot's original process.

Vanadium blacks are chiefly used in calico printing. Lightfoot (Bull. Soc. Ind. de Mulhouse, 1871, 285) first noticed the special efficiency of vanadium salts as oxygen carriers in the production of aniline black, and Witz (Bull. Soc. Ind. de Rouen, 1876, 310) showed that 1 part of vanadium chloride was sufficient to convert 40,000 parts aniline into aniline black.

Aged blacks are liable to tender the cotton unless their production is very carefully controlled.

Air oxidation black.—A. G. Green (J. Soc. Dyers, 1909, 191) has introduced an aniline black process in which atmospheric oxygen is the oxidising agent; some carrier such as cuprous chloride being present. The mineral acid usually employed is also replaced by formic acid, and by these modifications the liability to tendering of the fibre is greatly reduced.

The process is based on the fact that aniline oxidises much more readily in presence of a small quantity of a paradiamine or a para-amino-phenol.

After padding, the goods are dried, aged, and chromed as in the case of the ordinary aged black.

(3) *Steam blacks* are more costly but safer than aged blacks as regards tendering of the fibre. They are produced by padding with an aniline solution which contains sodium chlorate as oxidising agent, and sodium ferrocyanide as oxygen carrier. After padding, the goods are dried, steamed, and chromed. Lightfoot's original steam black only differed in that it contained potassium ferri-cyanide in place of the less expensive sodium chlorate and ferrocyanide.

Aniline black, when successfully dyed on cotton, is the fastest and most intense black which it is possible to produce. Its chief drawbacks are the tendency to turn green and the liability to tendering of the fibre, unless great experience and close supervision are exercised.

Application of aniline black to wool and silk.—The animal fibres are rarely dyed aniline black. The black may be produced on silk by the same methods as on cotton, but the process is chiefly confined to the silk-cotton union material used for umbrella cloth.

Aniline black does not readily develop on wool, but if the wool is previously chlorinated (Lightfoot) or boiled with a mineral acid (Bethmann, Eng. Pat. 1901, 21236), the aged black may be produced. It is rarely met with.

(b) *The insoluble azo-dyes*.—The sulphonated azo-dyes which are so largely used in the dyeing of wool and silk have little or no affinity for cotton. Azo-compounds are, however, produced on cotton by impregnating the fibre with one of the constituents, and then passing it into a solution of the necessary combining body. The non-sulphonated compounds are used in this process, and the insoluble dyes thus obtained are, in many cases, useful colours.

The constituent parts of an azo-dye are (a) a phenol or amine, and (b) a diazotised base; and the process (introduced by Holliday, in 1880) consists in saturating the cotton with an alkaline solution of a phenol, drying, and then developing in a solution of the diazotised base.

In calico printing (rarely in dyeing) the fibre may be impregnated with a paste containing the whole of the colour ingredients, and the colour developed by steaming.

Substances employed in the process: Phenols. The only phenol practically employed in the padding operation is β -naphthol. Amines are not used.

Aromatic bases.—The following list gives the principal bases employed and the colours they produce when combined with β -naphthol:—

Base	Colour produced with β -naphthol
Aniline	Orange yellow
Paranitraniline	Red (with copper, brown)
Paratoluidine	Yellow orange
Nitroparatoluidine	Orange
Xylidine	Red
Cumidine	Bluish-scarlet
Phenetidine	Scarlet
α -Naphthylamine	Blue shade of claret red
Aminoazobenzene	Crimson
Benzidine	Purplish-brown
Tolidine	Reddish-brown
Dianisidine	Blue (with copper)
Azo-black base	Black

Padding or grounding.—The intensity of the ultimate colour depends entirely upon the concentration of the padding solution, which, for a shade of medium strength may contain, per litre, 25 grams β -naphthol, 45 grams sodium hydroxide solution 36°Tw., and 75 grams Turkey-red oil. Cotton is evenly saturated in the cold with this solution, then dried at a low temperature and developed.

The developing process.—The most important dye produced by this process is *paranitraniline red*, which is dyed on a very large scale and used

as a substitute for Turkey red. The diazo-solution is prepared as follows: Stir to a paste 10 lbs. paranitraniline with 2 gallons water; then add 2 gallons hydrochloric acid (35°Tw.) and 6 gallons water. After mixing well, add 5½ lbs. sodium nitrite dissolved in 2 gallons water. Dilute to 200 gallons, and add sodium acetate to neutralise the excess of hydrochloric acid. The colour is produced instantaneously on passing the padded cotton into this solution, the cotton being subsequently washed, dried, and soaped.

Various stable forms of the diazotised base appear under the names azophor red, nitrazol, and nitrosamine red.

Azo-oranges, yellows, crimsons, claret-reds, &c., are obtained in a similar manner by the use of the various bases given in the above table.

Azo-browns are produced by adding an alkaline solution of copper to the β -naphthol prepare, and developing with paranitraniline or β -naphthylamine.

Azo-blues are obtained by padding with β -naphthol, developing with dianisidine, and subsequently treating with cupric chloride and chromic acid.

(c) *The metallic dyes: Iron buff and Nankin yellow.*—These two colours, which differ only in depth of shade, are produced by precipitating hydrated ferric oxide on the fibre. They are dyed chiefly on cotton, and produce yellow to light-brown colours which are fast to light, washing, or alkalis, but are readily attacked by acids. The cotton is padded in a solution of a ferrous or ferric salt, and then passed into an alkaline solution. If the cotton is previously mordanted with tannin, more regular shades are produced, the black tannate of iron being subsequently destroyed by a treatment with sodium peroxide (Knecht) or other oxidising agent. Iron buff is only produced on wool or silk as an intermediate product in dyeing Prussian blue.

Manganese bronze.—This colour is produced on cotton by precipitating manganous hydroxide on the fibre, and oxidising this to the brown manganic peroxide.

Chrome yellow is produced on cotton by impregnating with a solution of lead acetate, drying, and passing into a solution of potassium dichromate.

Chrome orange.—This compound is a mixture of normal lead chromate (chrome yellow) and basic chromate. It is obtained by treating cotton dyed chrome yellow with lime water.

Prussian blue is produced on cotton by first dyeing an iron buff, and then passing into an acid solution of potassium ferrocyanide. This colour is extremely fast to light, but is sensitive to alkalis. It is produced on silk in a similar manner as a constituent in dyeing the fibre black. Prussian blue is little used on wool, but is readily produced either by a process analogous to the above, or by making use of the fact that when heated in acid solution with wool, the prussiates undergo decomposition with formation of Prussian blue.

COLOURING MATTERS USED IN DYEING.

Natural dyestuffs: Indigo.—There are two distinct methods of applying indigo in dyeing, and the most important, the vat method, has already been described (*v. Vat dyes*, p. 293).

Indigo may also be used as an acid dyestuff by converting it into a sulphonic acid. The sulphonic acid is known as indigo carmine or indigo extract. It dyes a brighter blue shade than vat indigo, but it is much less fast to light and washing. It is largely used on wool and silk, but is inapplicable to cotton.

Logwood is a mordant dyestuff used for all fibres. On wool it is largely employed for producing blacks, and in conjunction with other dyestuffs for browns, olives, greys, &c.

Potassium or sodium dichromate, the usual mordant, but a single-bath logwood black may be produced by using a mixture of logwood, ferrous sulphate, and oxalic acid. Logwood is now chiefly employed in the form of unoxidised (for cotton) or oxidised (for wool) extract. On silk and cotton, logwood is only used for black dyeing.

Brazilwood, peachwood, and Limawood constitute the class of soluble red woods. They are now very little employed, the colours they produce being fugitive to light. They produce reddish-browns with chromium, and purples with iron mordants.

Camwood, barwood, and sanderswood are known as the insoluble red woods. If wool is boiled with the ground wood, it acquires a reddish-brown colour, which is still employed as a 'bottom' for indigo vat blue. They are, however, mordant dyestuffs, producing brownish reds with chrome mordant.

Madder.—This dyestuff, once of great importance, has now been almost entirely superseded by synthetic alizarin. It is still used to a limited extent in the dyeing of wool felt, since it penetrates through the material more readily than alizarin. With chromium mordant it gives a reddish-brown; with aluminium a red, and with iron a purple shade. The use of madder in the wood vat has already been referred to (*v. Vat dyes*). This dyestuff is now not used on cotton or silk.

Cochineal.—The use of this valuable dyestuff in dyeing is now confined to the production of scarlet shades on woollen cloth, for which purpose considerable quantities are still imported. Stannous chloride is the mordant employed, and the colour is produced by the one-bath method. The aluminium and tin lakes are used as pigments in painting and printing.

Lac-dye may be employed in the same way as cochineal, and gives similar shades. Since the commercial product contains a considerable amount of mineral matter, the ground dyestuff is treated with dilute hydrochloric acid before use.

Cudbear and orchil (or *archil*). These products are essentially the same dyestuff, the former in the solid and the latter in the condition of paste. It is one of the few natural colouring matters which dye wool without a mordant. Wool and silk may be dyed in a neutral, slightly acid, or slightly alkaline, solution. It produces full, rich crimsons, and is still used to a considerable extent. The colouring matter is not applicable to cotton.

Safflower was formerly much used in dyeing bright pinks upon cotton, but is now obsolete as a dyestuff.

Annatto produces orange shades on silk without a mordant: it is applied in a hot soap-

bath. Annatto is still used in colouring cheese and butter.

Weld.—This mordant dyestuff produces pure yellows in conjunction with aluminium mordant. When used as a 'topping' for indigo vat blue, a special shade of green, known as 'carriage green,' is obtained.

Fustic is the most important of the natural yellow dyewoods, and is still employed in conjunction with chrome mordant on wool as the yellow constituent in compound browns, olives, greys, &c. It is chiefly used in the form of fustic extract.

Quercitron bark and flavin are also natural yellow mordant dyes, producing somewhat brighter shades than fustic, but now obsolete.

Persian berries.—This mordant dyestuff is employed by the calico printer for producing bright orange shades with tin mordant.

Turmeric is the only representative of the natural colouring matters which acts as a direct dye towards cotton, silk, and wool. It produces yellow shades, which are brighter if dyed in a bath acidified with alum.

Catechu, cutch, and gambier.—These dyestuffs are still largely employed in cotton dyeing. The cotton is steeped in a strong solution of the dye, and attracts the colouring matter. The cotton is then passed into a boiling solution of potassium dichromate, which, by oxidation, produces insoluble brown japonic acid upon the fibre. A little copper sulphate is frequently added to the catechu bath, whereby fuller and faster shades are produced.

Silk is dyed in a similar manner in the production of weighted blacks, the chromium, fixed during the oxidising process, subsequently acting as a mordant for logwood.

Other natural dyestuffs.—Colouring matters are very widely distributed in the vegetable kingdom, and all countries where the textile arts have attained any great development (notably India, Persia, and Japan) had until recently each its own series of indigenous products which were used as dyestuffs. In Donegal, Sutherland, and other localities, the homespun tweeds, &c., are still largely dyed by means of the various lichens, roots, barks, nuts, &c., found in the neighbourhood.

Synthetic dyestuffs. The number of individual synthetic dyestuffs now at the dyer's disposal is very large, and includes dyes belonging to all groups and yielding all possible hues. There is infinite variety in the characteristics of the various artificial dyes, and in most cases it is not difficult to match a given shade or to comply with given conditions as regards properties. Being, therefore, more convenient to use, and in very many cases cheaper and faster than the natural dyestuffs, the latter are being gradually superseded.

The dyeing properties and the characteristics of the dyed colours depend chiefly upon the chemical groups to which the dyes belong, but, as indicated in the section dealing with the classification of dyes, the chemical groups do not coincide with groups based on the method of application (*v. Classification of colouring matters*).

(1) *Nitroso colouring matters*. This class includes fast-green or dark-green and naphthol-green. In conjunction with iron mordants,

both these dyestuffs give olive-green colours remarkable for their fastness to light.

Cotton is dyed with dark-green by mordanting with iron, and dyeing in a neutral bath. Wool is mordanted with ferrous sulphate and oxalic acid, and dyed in a neutral bath. Silk is dyed in a similar manner.

Naphthol green which contains iron is only applicable to the animal fibres. Wool is dyed with the addition of sulphuric acid.

(2) *Nitro-colouring matters*.—The important members of this class are: picric acid, Victoria orange, aurantia, palatine orange, naphthaline yellow, naphthol yellow. These colouring matters are only applicable to the animal fibres, which are dyed in a bath slightly acidified with sulphuric acid. The colours they yield are not fast to light. Picric acid yellow is remarkable for its extreme freedom from any trace of orange. On exposure to light it rapidly becomes orange.

(3) *The azo-group*.—These may be divided into monazo-, disazo-, trisazo-, and tetrakisazo- dyes, according to the number of azo-groups they contain. They may be further classified into aminoazo- (NH_2) and oxyazo- (OH) dyes, and into other subdivisions based upon the state of combination of the azo-group. A few of the azo-colours are basic dyes; a large number of the acid dyes belong to this group, and practically the whole of the direct dyes. The azo-dyes vary greatly in their degree of fastness to light, and in other properties.

(4) *The di- and tri-phenylmethane group*.—This group includes most of the basic dyes, such as auramine, magenta, methyl violet, malachite green, &c. These bodies, when sulphated, form acid dyes, and therefore such dyestuffs as acid magenta, guinea green, &c., and also patent blue, Victoria blue, fall under this group. As a class, these dyestuffs are fugitive to light.

(5) *The oxyketone group*.—This group includes most of the artificial mordant dyes; *e.g.* the alizarin reds, yellows, blues, browns, &c. Most of the dyestuffs of this group are extremely fast to light and other influences, which renders them of the greatest importance.

(6) *The pyronine group*.—This includes (1) the pyronines proper, a small class of basic dyes, of which pyronine red is an example; (2) the much more important group of the phthaleins. The latter includes both basic and acid rhodamines, the eosins and the mordant dyestuffs gallicin and cœrulein.

(7) *The acridine group*.—This includes a few basic dyestuffs of which the chief is acridine orange.

(8 and 9) *The oxazine and thiazine group*.—This group also includes both acid (thiocarmine), basic (methylene blue), and mordant dyes (gallocyanin).

(10) *The azine group* includes the valuable basic dyes the safranines, and the basic and acid indulines and nigrosines.

The dyeing of mixed fabrics of cotton and wool may be carried out by selecting those colouring matters for which both fibres have an attraction, *e.g.* the benzidine dyes, &c., or by first dyeing the wool in the usual manner with an acid colouring matter, then mordanting the cotton with tannic acid and tartar emetic or stannic chloride, and dyeing in the cold with

a basic colouring matter. The so-called "cross-dyeing" process is carried out by first dyeing the cotton warp, then weaving with a wool weft and dyeing the latter by means of acid dyes. Logwood blacks on union are dyed by first mordanting the cotton in the cold with tannic acid and nitrate of iron, then the wool with a boiling solution of potassium dichromate, and finally dyeing both fibres thus mordanted in a hot decoction of logwood. Mixtures of cotton and silk are dyed by methods similar to those employed for cotton and wool. Fabrics of wool and silk are dyed by methods similar to those usual for wool or silk alone.

When dyeing *compound shades*, the main principle to be observed is to apply simultaneously only such colouring matters as are applicable, when used singly, by methods as similar as possible to each other. Basic and acid colouring matters ought not to be applied together in the same dye-bath, since the one requires a neutral, the other an acid, bath in order to yield their full colouring power. Basic colouring matters, however, may be quite well applied to mordanted cloth along with phenolic colouring matters, since both these classes usually dye in a neutral bath.

It is very irrational to produce compound shades by the application of a mixture of fast and fugitive colours; the best results are obtained by employing colouring matters of about equal fastness to various influences. If this rule is not observed, the dyed colour is liable to change materially in shade under those influences to which it is subsequently submitted, *e.g.* light, washing, &c.

Identification of the Commercial Dyestuffs. Mulliken. W. M. G.

DYESTUFFS, IDENTIFICATION OF, ON FABRICS. The recognition of the particular dyestuff which has been employed in dyeing a fabric is frequently a matter of considerable difficulty. If one dyestuff only has been used, it may be possible to identify it with little trouble, but when, as is often the case, two or more dyes have been employed to produce a given colour, their separation and recognition may become a very complex problem.

In the identification of dyestuffs, the ordinary basis of qualitative analysis is as far as possible made use of, *i.e.* the *group* to which the colouring matter belongs is first determined, and then tests are applied to identify it as an individual substance. There are, however, such a large number of closely related compounds amongst the dyestuffs, many being isomeric, and differing only (*e.g.*) in the position of a sulpho-group, that with the small amount of substance frequently at disposal it is quite impossible to definitely identify a specific commercial product. This is, however, of minor importance.

The recognition of a dyestuff is greatly facilitated by a knowledge of the dyeing properties of the various groups of colouring matters. In a given case this may greatly limit the possibilities. For example, no one with a knowledge of dyeing processes would search for a cochineal scarlet on cotton or a parantraniline red on wool. The presence or absence of certain metallic bases in the ash of the incinerated material is also a useful indication of the nature of the dyestuff under investigation, and an examination of this point should be made.

What may be termed the 'dyeing groups' of colouring matters do not coincide with the 'chemical groups.' For example, the dyeing group of 'basic' dyes, the members of which are fixed on cotton by means of a tannin mordant, includes members of the triphenyl methane, azine, azo-, acridine, and other chemical groups.

To determine the dyeing group to which a colouring matter present on a fabric belongs, acid and alkaline solvents are used as 'stripping' agents. The following are the general reactions:

ACTION OF 'STRIPPING AGENTS.'

<i>Dyeing group</i>	<i>Stripping solution</i>
Mordant dyes	50 c.c. HCl (conc.) per litre
Basic dyes on wool	5 p.c. acetic acid
" " on cotton	3 p.c. sodium hydroxide
Acid dyes	} A small piece of mercerised cotton is placed in the solution.
Direct cotton dyes	

In each case the fabric is boiled for 5 minutes in the solution.

With direct cotton dyes the small piece of white cotton placed in the solution becomes dyed. With acid dyes this does not occur.

The action of the above stripping agents can only be considered as general in regard to a particular group, and many exceptions will be found

in dealing with particular members of the group, e.g. some acid dyes are only slightly stripped by boiling in dilute ammonia, and a few of them stain mercerised cotton. Too much reliance must not, therefore, be placed on these stripping reactions.

The most satisfactory group reagents for classifying dyestuffs into the chemical groups are acid or alkaline reducing agents; on the use of which several schemes of identification have been based. These reagents were first proposed by Witt, in 1886, whose scheme was extended by Weingaertner, in 1887; but the systematic development of the scheme of analysis is mainly due to A. G. Green.

The reactions of dyestuffs are considerably influenced by the nature of the fibre upon which they have been fixed, which also determines the particular dyeing process necessary. For example, the basic colours dye wool and

silk direct, whereas their fixation on cotton involves the use of a tannin mordant. It is convenient, therefore, to treat separately the identification of dyestuffs on animal and on vegetable fibres.

Identification of dyestuffs on wool.—Tables for the identification of dyestuffs on wool have been published in Hummel's *Dyeing of Textile Fabrics*; in Knecht, Rawson, and Loewenthal's *Manual of Dyeing*; in Lehne's *Färber Zeitung*, and by many other authors; but the most systematic and reliable scheme is that of Green (*J. Soc. Dyers*, 1905, 236; and 1907, 252). In this scheme, which is now to be described, the dyeing groups are first distinguished by the action of suitable solvents, and then further differentiation is carried out by the use of reducing agents with subsequent reoxidation. The various groups of dyestuffs as dyed on animal fibres, show the following reactions:—

Decolourised by hydrosulphite			Not altered by hydrosulphite	Not decolourised, but changed to brown. Original colour restored by air or persulphate
Colour restored on exposure to air	Colour not restored by air, but restored on oxidation with persulphate	Colour not restored either by air or persulphate		
Azines, oxazines, thiazines, indigo	Triphenyl-methane group	Nitro-, nitroso-, and azo-groups	Pyrone and acridine groups. Some members of the oxyketone group.	Most dyestuffs of the oxyketone group

In Green's scheme the following reagents are employed, and must be used of the strength indicated:—

Dilute ammonia (1:100).—1 c.c. conc. ammonia; 100 c.c. distilled water.

Aqueous alcoholic ammonia.—1 c.c. conc. ammonia; 50 c.c. strong alcohol or methylated spirit; 50 c.c. water.

Dilute acetic acid (5 p.c.).—5 c.c. glacial acetic acid; 95 c.c. water.

Dilute alcohol (1:1).—50 c.c. strong alcohol or methylated spirit; 50 c.c. water.

Dilute hydrochloric acid (1:10).—10 c.c. conc. hydrochloric acid; 90 c.c. water.

Caustic soda (10 p.c.).—10 grams solid caustic soda in 100 c.c. of water.

Hydrosulphite sol. A.—A 10 p.c. solution of hydrosulphite NF (M. L. & B.) or 'hyraldite' (Cassella), i.e. the formaldehyde compound of sodium hydrosulphite. This solution, which is slightly alkaline, is employed in most cases. In a few other cases, however, in which the reduction is more sluggish (e.g. azo- yellows), it is found necessary to employ a slightly acid solution. This is termed

Hydrosulphite sol. B.—Prepared by acidifying 200 c.c. of hydrosulphite A with 1 c.c. of glacial acetic acid.

Persulphate.—A cold saturated solution of potassium persulphate, or a 1 p.c. solution of ammonium persulphate.

Sodium acetate (5 p.c.).—5 grams crystallised sodium acetate; 100 c.c. distilled water.

Procedure.—The reactions are carried out in

test-tubes upon pieces of the material about $\frac{3}{4}$ –1 inch square, which are covered with about $1\frac{1}{2}$ inches of the reagent. The tests should be carried out exactly as described. In making 'stripping tests,' the degree of stripping is judged by comparing the remaining shade with that of the original pattern. The colour of the stripping solution cannot be relied upon as a guide. In boiling with dilute acetic acid and dilute ammonia, it is found advantageous to repeat the extraction, as a better stripping is thereby obtained, and with acid dyestuffs any staining of the cotton by the first strong extract is removed during the second boil. In testing with dilute ammonia or sodium acetate, the material is placed in a test-tube with a piece of white mercerised cotton cloth, somewhat smaller in size, and boiled for the time prescribed. If the shade is a pale one, the size of the sample should be increased and that of the cotton diminished. The dilute ammonia is replaced by aqueous alcoholic ammonia in the case of the violet and black dyestuffs (Tables III. and VII.), as in these cases the acid dyestuffs are less easily extracted, and the cotton is more liable to be stained by them. In making reduction tests, the sample is boiled for on one-quarter to one minute with the hydrosulphite, then rinsed well under the tap, and allowed to lie on white paper. With most dyestuffs which form air-oxidisable leuco-compounds, the colour returns immediately or in a few minutes, but with others a longer time is required. The reaction is accelerated by exposing the pattern to ammonia

vapour. If the colour does not return, the pattern is boiled with a little water in a test-tube, and potassium persulphate is added drop by drop, carefully avoiding an excess. If this also fails to cause any return of colour, the dyestuff is to be regarded as a nitro-, nitroso-, or azo-compound. The depth of the restored colour varies greatly in different cases; with some dyestuffs the colour reappears with nearly its original depth, but with others (probably on account of the greater solubility of their leuco-compounds) only a pale shade may return. Safranin and its azo-derivatives are peculiar in yielding a violet colour on reoxidation of the leuco-compound, this being due to the condensation of the leuco-safranin with the formaldehyde present in the hydrosulphite NF.

The tables (I. to VII., pp. 302-308) give the scheme of analysis.

These tables do not differentiate between closely related individual dyes, for which purpose further tests must be made. At this stage of the investigation it is very desirable to procure small pieces of material dyed with such known colouring matters as the group tests, combined with the colour of the sample, have indicated as probable. Parallel individual tests should then be applied with these and with the sample under examination.

The following series of reagents have been found by W. M. Gardner to be convenient for this purpose. They should be applied in the order given, and are best used as follows:—

Application of cold reagents.—Steep a piece of the material (say) 1 by $\frac{1}{2}$ inch in (say) 5 c.c. of reagent for 5 minutes in a small porcelain dish.

Application of reagents by boiling.—In a test-tube place (say) 10 c.c. of reagent and a piece of material 1 by $\frac{1}{2}$ inch. Boil gently for 3 minutes.

Application of nitric acid test.—On a white glazed porcelain plate, spot the material by dipping a glass rod into the acid and then pressing it on to the cloth. Note the changes in colour which occur during the formation of the spot, and re-examine after several hours, noting any further change.

Reagents for identifying individual dyestuffs:

- | | |
|--|--|
| 1. Boiling water. | } Use small pieces of white wool, silk, and cotton along with the dyed sample. |
| 2. 5 p.c. acetic acid, boiling. | |
| 3. 3 p.c. ammonia, boiling. | |
| 4. 3 p.c. soap, boiling. | |
| 5. Boiling alcohol. | |
| 6. Concentrated sulphuric acid, cold. | |
| 7. 3 p.c. ammonium persulphate, cold. | |
| 8. Bleaching powder solution, 5°Tw., cold. | |
| 9. 50 grams $\text{SnCl}_2 \cdot 2\text{H}_2\text{O} + 100$ c.c. HCl. 32°Tw. per litre, cold. | |
| 10. 5 c.c. NaNO_2 (5 grams per litre), and 5 c.c. H_2SO_4 (3.5 grams per litre) boiling. | |
| 11. Apply test 10 cold, then wash and steep the material in a solution of sodium β -naphtholate 5 grams per litre. | |
| 12. Concentrated nitric acid (spot test). | |

If the sample under examination shows the same reactions as any one of the control samples, with each of the above reagents, its identity may be considered as clearly established.

Kuecht (J. Soc. Dyers, 1904, 98) states that titanous chloride possesses advantages over

both stannous chloride and sodium hydrosulphite as a test for dyestuffs. The solution is prepared by boiling together 25 c.c. commercial titanous chloride solution (20 p.c.) and 25 c.c. HCl, 32°Tw., and diluting to 1000 c.c. with water.

IDENTIFICATION OF DYESTUFFS ON COTTON.

Green (J. Soc. Dyers, 1907, 252) has worked out an analytical scheme for the detection of dyestuffs on cotton on the same lines as that previously described for wool.

The reagents are as follows:—

1. *Dilute ammonia.*—1 c.c. strong ammonia to 100 c.c. distilled water.
2. *Dilute caustic soda.*—10 grams caustic soda in 100 c.c. water.
3. *Saline caustic soda.*—10 c.c. caustic soda solution (35-40 p.c. NaOH) to 100 c.c. saturated solution of salt.
4. *Formic acid 90 p.c.*—Concentrated commercial acid.
5. *Dilute formic acid.*—1 c.c. formic acid (90 p.c.) to 100 c.c. distilled water.
6. *Dilute hydrochloric acid.*—5 c.c. hydrochloric acid (30 p.c.) to 100 c.c. of water.
7. *Soap solution.*—10 grams soap in 300 c.c. of water.
8. *Tannin solution.*—10 grams tannin acid and 10 grams sodium acetate in 100 c.c. of water.

9. *Bleaching powder solution.*—Fresh solution at 5°Tw.

10. *Hydrosulphite A* (same as for wool).—10 p.c. solution of hydrosulphite NF or of hyraldite, or a 5 p.c. solution of hydrosulphite NF conc., or of rongalite (formaldehyde sodium sulphoxylate).

11. *Hydrosulphite B* (same as for wool).—The preceding solution slightly acidified by addition of 1 c.c. glacial acetic acid to 200 c.c. of solution.

12. *Hydrosulphite X.*—Dissolve 50 grams of rongalite or hydrosulphite NF conc. in 125 c.c. of hot water. Grind 1 gram of anthraquinone (precipitated, not sublimed) to a fine powder, and reduce to a smooth paste with a little of the rongalite solution. Add this paste to the remaining solution, and heat the whole for 1 or 2 minutes at about 90°. Then dilute with cold water to 500 c.c., and, after standing until cold, add 1½ c.c. of glacial acetic acid. Keep in a well-stoppered bottle with greased stopper. The reagent should be tested occasionally by trying its effect on cotton dyed with α -naphthylamine bordeaux, which should be fully discharged after boiling for 1 or 2 minutes. The anthraquinone may be replaced by β -oxyanthraquinone, which can be employed in the same way or previously dissolved in a little alcohol before it is added to the hydrosulphite. It has the advantage of giving a clearer solution, but is not so generally available.

13. *Persulphate solution.*—A cold saturated solution of potassium persulphate, or a 2 p.c. solution of ammonium persulphate.

14. *Acid stannous chloride.*—100 grams stannous chloride to 100 c.c. hydrochloric acid (30 p.c.) and 50 c.c. water. In testing for sulphide colours, this reagent may be replaced with advantage by a strong solution of titanous chloride.

Procedure: General.—All the reactions are performed in test-tubes, with pieces of material about $\frac{1}{2}$ – $\frac{3}{4}$ of an inch square, which are covered to the depth of from $1\frac{1}{2}$ to 2 inches with the reagent. The degree of stripping is judged by comparing the remaining shade with that of the original pattern; the colour of the stripping solution cannot be relied upon as a guide. In testing the colours of calico prints, the separate colours should be cut out and the reactions tried upon them separately. With cotton and wool, or cotton and silk unions, the weft is separated from the cotton warp, and both submitted to examination. Doubt may frequently exist as to how a particular shade should be classified, whether, for instance, a reddish-blue is to be regarded as a blue or a violet. In such cases the tables referring to both shades should be employed: but since the same general scheme is adopted throughout the tables, this can scarcely give rise to confusion. The same remark applies to possible mixtures; thus in examining a certain green shade, both the yellow and the blue tables may have to be used.

It is obvious that in many instances the analytical procedure may be greatly simplified by exclusion of dyestuffs the presence of which is rendered improbable or impossible by the special circumstances of the case, e.g. by the material, shade, or mode of application of the colour.

Stripping test.—A few of the direct dyestuffs are partially stripped by dilute ammonia, and may thus give rise to the impression that they are acid colours. To avoid this error, it is advisable to add a small piece of white cotton when carrying out the test. With an acid dyestuff the cotton is either not tinted or becomes white on boiling a second time with dilute ammonia.

Transference of basic dyes to wool.—The tannin mordant is first removed, as in testing for a basic colour, by boiling the pattern for half a minute with saline caustic soda. It is then well washed to remove all alkali, and is boiled with a piece of white wool (half the size of the cotton or less) in a little water for 1 or 2 minutes. In most cases the dye base will leave the cotton almost entirely, and dye the wool a full shade. If the colour does not develop on the wool, one or two drops of dilute formic acid (1:100) may be added. In the case of a few dyestuffs which are more difficult to strip (e.g. basic greys), it is necessary to extract the colour with dilute hydrochloric acid (1:20), carefully neutralising the extract with ammonia before adding the wool.

Tannin test for basic dyes.—Add a few drops of tannin solution to the formic acid extract. Shake well, and if the precipitate does not form at once, allow to stand a few minutes. Some colouring matters such as the rhodamines, gallocyanines, and chrome colours of the rosaniline series (which contain carboxyl- or hydroxyl-groups in addition to basic groups) only precipitate slowly, and the precipitate, being more finely divided, is sometimes difficult to see.

Bleeding test for direct dyestuffs.—In testing for direct dyestuffs by the bleeding test, the sample is placed in a test-tube together with a smaller piece of white mercerised cotton cloth, and boiled with soap solution for about a minute,

the soap solution may be replaced by a 5 p.c. solution of sodium carbonate.

Lead acetate test for sulphide dyes.—The sample is first boiled for two minutes with a 10 p.c. solution of sodium hydroxide to remove any adventitious sulphur compounds. It is then well washed and just covered with acid stannous chloride solution. The mouth of the test tube is closed by a cap of filter paper closely wrapped round it, into the centre of which is placed, by means of a glass rod, one drop of lead acetate solution. The contents of the test-tube are slowly heated to the boiling-point, when a blackish-brown stain of lead sulphide appears if a sulphide colour is present. The brown spot will again disappear on continued boiling on account of the decomposition of the lead sulphide by the hydrochloric acid evolved. It is important to pay special attention to the cleanliness of the test-tubes employed for this test, as tubes which have been previously used for hydrosulphite reductions acquire a thin invisible deposit of sulphur upon their walls, which, on boiling with stannous chloride, gives rise to hydrogen sulphide, and thus may lead to error.

Reduction and reoxidation tests.—The reduction with hydrosulphite X is carried out by boiling the sample with the reagent for from a minute to a minute and a half. The azines, thiazines, oxazines, &c., and most of the azo-dyestuffs are fully reduced in about half a minute, but the insoluble azo-colours and some direct dyestuffs require longer boiling to complete their reduction. In testing the reoxidisability by air, the reduced sample may be exposed to the fumes of ammonia, which in many cases accelerates oxidation.

The analytical tables worked out by Green for the identification of dyestuffs on cotton, are given on pp. 309–315, Tables VIII. to XIV.

S. T. Mulliken (Identification of the Commercial Dyestuffs, 1910) has published a systematic scheme of analysis, primarily intended for the examination of the dyestuffs in substance. The tables give the reactions of 1475 distinct dyestuffs, and are of great service in the identification of dyes on the fibre.

Spectroscopic examination of dyestuffs.—The absorption spectra of dyestuffs may be used as an aid to their identification. In the second edition of Vogel's 'Practische Spectralanalyse irischer Stoffe' (1889), charts were given of the absorption bands of various dyestuff solutions. This work was greatly extended in 'Formánek's Spectralanalytischer Nachweis Künstlicher organischen Farbstoffe' (1900), which contains a systematic scheme for the spectroscopic identification of upward of 350 distinct dyestuffs. In a later publication (1905) entitled 'Qualitative Spectralanalyse anorganischen und organischen Körper,' Formánek has extended his data to include the natural colouring matters, and, in conjunction with E. Grandmougin, has published *histables* as 'Untersuchung und Nachweis organischen Farbstoffe auf spectroscopischen Wege.'

The value of spectroscopic tests for the identification of dyestuffs on the fibre is limited to those dyestuffs which can be removed without change by suitable solvents.

Spectroscopic examination of dyed fibres has not yielded useful results. W. M. G.

RECOGNITION OF DYES ON WOOL OR SILK.

TABLE II.—RED COLOURS.

Boil twice for one minute with 5 p.c. acetic acid

The colour is stripped:—Basic dyestuff or Soluble red woods. Boil with dilute alcohol (1:1) twice for one minute

Boil twice for one minute with dilute ammonia (1:100) and a small piece of white cotton. Keep the ammoniacal extract

Little or no colour is stripped:—Acid, Direct, or Mordant dyestuffs.

Keep the ammoniacal extract

Much of the colour is stripped:—Basic dyestuff. Boil with dilute alcohol (1:1) twice for one minute

Much colour is stripped, but cotton remains white:—Acid dyestuff. Boil with hydrosulphite A

Some of the colour is stripped and the wool becomes much bluer. Boil with hydrosulphite A

Little or no colour is stripped. The cotton remains white. (Mordant dyestuffs), or is stained (Direct dyestuffs). Boil with 5 p.c. sodium acetate and white cotton for 2 or 3 minutes

The cotton remains white:—Mordant dyestuff. (Confirm by testing ash for metallic mordants.) Boil with hydrosulphite A

The cotton is stained:—Direct dyestuff. Test ash for chromium

Chromium is absent. Treat fibre with conc. sulphuric acid

Decolourised. Colour is not restored by persulphate. Cr in ash

Cr is present. Solution in conc. H_2SO_4 is red

Decolourised. Colour is quickly restored on exposure to air

Changes to dark maroon or violet black

Decolourised. Colour does not return on exposure to air, but is restored by persulphate:—Triphenylmethane group

Decolourised. Colour returns on exposure to air:—Azine group

Decolourised. Colour is not restored either by air or by persulphate

Decolourised. Colour does not return on exposure to air, but is restored by persulphate

Decolourised. Colour returns quickly on exposure to air

Colour not affected

17	A mordant azo- colour.
16	Insoluble red woods, e.g. camwood or barwood.
15	Alizarin reds.
14	Cochineal crimson.
13	Anthracene red.
	Hessian purple.
	Diamine fast red.
	Diamine scarlet.
	Erica, geranines.
12	Archil or cudbear.
	Dianthine or rosopenine.
11	Cochineal scarlet.
10	Chromotropes, azofuchsine, &c.
	Biebrich scarlet, &c.
	Crocein scarlet, fast red B, &c.
	Crystal scarlet, fast red A, &c.
	Xylidine or Palatine scarlet.
9	Acid magenta.
8	Azocarmine or rosinduline.
7	An acid eosin, or acid rhodamin, e.g. fast acid eosin, fast acid phloxin, acid rhodamin, acid rosamin, &c.
6	Eosin, phloxin, erythrosin, safrosin, rose bengal, &c.
5	Soluble red woods, e.g. brazilwood, limawood, peachwood, &c.
4	Basic azo- dyestuff, e.g. Janus red.
3	Basic dyestuff of triphenylmethane group, e.g. magenta, fuchsine, isorubine, cerise, new magenta, &c.
2	Basic dyestuff of azine group, e.g. safranine, induline scarlet, rhoduline red, rhoduline pink, &c.
1	Basic dyestuff of pyrone group, e.g. rhodamines, irisamine, rhodines, anisolines, pyronines.

RECOGNITION OF DYES ON WOOL OR SILK.
TABLE III.—PURPLE AND VIOLET COLOURS.

Boil twice for one minute with 5 p.c. acetic acid

Colour is nearly completely stripped :— Basic dyestuff. Boil with hydrosulphite A	Decolourised. The colour returns on oxidation with persulphate :— Triphenylmethane group	1	Neutral violet, rhoduline violet, rosolane, iris violet, methylene violet, tannin heliotrope, &c.		
		2	Methyl violet, crystal violet, Hofmann violet, benzyl violet, &c.		
Much colour is stripped, but cotton remains white :— Acid dyestuffs. Boil with hydrosulphite A	Decolourised. The colour does not return on exposure to air, but is restored upon oxidation with persulphate. Triphenylmethane group The ammoniacal extract is colourless, but becomes violet on acidifying. Spot fibre with conc. HCl Becomes green	3	Fast acid violets or violamines.		
		4	Acid violets, formyl violets, &c.		
		5	Alkali violets.		
		6	Red shade soluble blues.		
The colour is not stripped :— Acid, Direct, and Mordant dyestuffs. Boil twice for one minute with dilute ammonia and white cotton	Decolourised. The colour is not restored either by exposure to air or by oxidation with persulphate. Azo group	7	Red shade induline or fast blue R, &c.		
		8	Lanacyl violet, Victoria violet, &c.		
The cotton remains white :— Mordant colour. (Confirm by testing for metallic mordants in ash.) Boil with hydrosulphite A	The cotton remains white :— Mordant colour. (Confirm by testing for metallic mordants in ash.) Boil with hydrosulphite A	Colour not altered :— Pyrone group	9	Hessian violet, diamine violet, oxamine violet, benzo fast violet, Columbia violet, oxydiamine violet, chlorantine violet, &c.	
			10	Gallein.	
		Colour changed to brown :— Alizarin group. Boil with dilute HCl	Fibre and solution yellow	11	Alizarin on Fe ¹ or Cr.
				12	Alizarin bordeaux.
		Fibre and solution red or reddish-brown	Fibre and solution red or reddish-brown	13	Galloeyanine, prune, celestine blue, &c.
				14	Chrome violet.
		The cotton is stained :— Direct dyestuffs	Decolourised. Colour is not restored either by exposure to air or by oxidation with persulphate :— Azo group	15	A mordant azo-colour.
				16	Decolourised. Colour does not return on exposure to air, but is restored by persulphate :— Triphenylmethane group

RECOGNITION OF WOOL OR SILK.

TABLE IV.—BLUE COLOURS.

Boil twice for one minute with 5 p.c. acetic acid

Little or no colour is stripped. Boil twice for one minute with dilute ammonia (1 : 100) and keep the ammoniacal extract	The cotton remains white. Boil with a little aniline oil	Decolourised. Colour does not return on exposure to air, but is restored by persulphate :— Triphenylmethane group	20	A mordant azo-blue, e.g. cyprus blue, peri wool blue, anthracene chrome blue, chromotrope blue, &c.
				Decolourised. Colour returns on exposure to air :— Oxazine or Thiazine group. Treat fibre with conc. H ₂ SO ₄
Little or no colour is stripped. The cotton remains white (Mordant dyestuff) or is tinted (Direct dyestuff). Boil with 5 p.c. sodium acetate and white cotton for 2 or 3 minutes	The cotton remains white. Boil with a little aniline oil	Decolourised, but colour returns on exposure to air :— Oxazine or Thiazine group. Treat fibre with conc. H ₂ SO ₄	18	Gallocyanins, celestin blue, gallamin blue, prune, &c.
				Decolourised, but colour returns on exposure to air :— Oxazine or Thiazine group. Treat fibre with conc. H ₂ SO ₄
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	17	Brilliant alizarin blue.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	16	An alizarin blue (anthraquinone-quinoline).
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	15	An alizarin cyanine, or anthracene blue.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	14	Indigo.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	13	Diamine, benzo, dianil, or Chicago blues, sulphone cyanines, &c.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	12	Alizarin sapphirole, alizarin astrole, alizarin irisol, &c.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	11	An acid azo-blue, e.g. lanacyl blue, azo-acid blue, azo-merino blue, azo-navy blue, &c.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	10	A 'soluble' or 'alkali' blue (rosaniline blue).
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	9	A dyestuff of the 'patent blue' class, e.g. patent blue V, A, N, &c. Cyanol, cyanine, ketone blue, erioglaucine, &c.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	8	A 'wool' blue.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	7	Prussian blue.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	6	Thiocarmine, induline, fast blue.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	5	Indigo extract, indigo earmine.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	4	Logwood blue.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	3	A basic blue of the triphenylmethane group, e.g. Victoria blue, night blue, brilliant milling blue B, &c.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	2	A safranin-azo- colour, e.g. indoine or Janus blue.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group
Little or no colour is stripped. The cotton remains white. Boil with 5 p.c. acetic acid	The cotton is stained :— Direct dyestuff. On reduction with hydrosulphite A the colour is not restored either by air or persulphate :— Azo-group	Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group	1	A basic blue of the azine, oxazine, or thiazine group, e.g. methylene blue, Nile blue, Capri blue, Meldola's blue, cresyl blue, &c.
				Decolourised, but colour returns on exposure to air, but is restored by persulphate :— Triphenylmethane group

RECOGNITION OF DYES ON WOOL OR SILK.

TABLE V.—GREEN COLOURS.

Boil twice for one minute with 5 p.c. acetic acid

The colour is stripped :—Basic dyestuff. Boil with hydrosulphite A	Decolourised. A dark violet colour returns on exposure to air :—Azine, or Thiazine group	Decolourised. The colour does not return on exposure to air, but is restored by persulphate :—Triphenylmethane group	Decolourised. Colour does not return on exposure to air, but is restored by persulphate :—Triphenylmethane group	Decolourised. Colour is not restored either by air or persulphate :—Azo-group	The cotton remains white :—Direct dyestuff	The cotton is deeply stained :—Direct dyestuff	Colour changes to brown :—Alizarin group	Original colour does not return on exposure to air, but is restored by persulphate	Original colour returns on exposure to air :—Oxazine or Thiazine group	Colour returns on exposure to air :—Nitroso- or Azo-group. Boil with conc. hydrochloric acid	Colour does not return on exposure to air or upon oxidation with persulphate :—Nitroso- or Azo-group. Boil with conc. hydrochloric acid	Fibre and solution light- and solution brown :—Nitroso- group	Fibre blue and solution colourless :—Azo-group
The colour is stripped :—Acid, Direct, or Mordant dyestuff. Boil twice for one minute with dilute ammonia (1 : 100) and a small piece of white cotton	Much colour is stripped, but the cotton remains white :—Acid dyestuff. Boil with hydrosulphite A	The cotton remains white :—Mordant dyestuff. Confirm by testing for metallic mordant in ash. Boil with hydrosulphite A	Little or no colour is stripped. The cotton remains white (Mordant dyestuff) or is stained (Direct dyestuff). Boil for two or three minutes with 5 p.c. sodium acetate and a piece of white cotton	The cotton remains white :—Mordant dyestuff. Confirm by testing for metallic mordant in ash. Boil with hydrosulphite A	Decolourised (or changed to light buff)	Decolourised (or changed to light buff)	Decolourised (or changed to light buff)	Decolourised (or changed to light buff)	Decolourised (or changed to light buff)	Decolourised (or changed to light buff)	Decolourised (or changed to light buff)	Decolourised (or changed to light buff)	Decolourised (or changed to light buff)
1	A safranin-azo- colour	A basic green of the triphenylmethane group, <i>e.g.</i> malachite green, brilliant green, setoglauine, fast green, &c.	Azine green S.	Acid greens, light green, guinea green, wool green, Neptune green, naphthalene green, &c.	Chiefly mixtures of an azo-blue and yellow.	Diamine green, Columbia green, chloramine green, benzo-green, &c.	Cœrulein or alizarin green S.	Alizarin cyanine green or alizarin viridine.	Alizarin green G or B (oxazine group)	Nitroso-mordant colours, <i>e.g.</i> gambines, dioxine, dark green, naphthol green, &c.	Azo-mordant colour, <i>e.g.</i> diamond green, chrome patent green, &c.	12	11
21	A basic green of the azine, thiazine, or oxazine group, <i>e.g.</i> fast green M, azine green, Capri green, methylene green, &c.	A basic green of the triphenylmethane group, <i>e.g.</i> malachite green, brilliant green, setoglauine, fast green, &c.	Azine green S.	Acid greens, light green, guinea green, wool green, Neptune green, naphthalene green, &c.	Chiefly mixtures of an azo-blue and yellow.	Diamine green, Columbia green, chloramine green, benzo-green, &c.	Cœrulein or alizarin green S.	Alizarin cyanine green or alizarin viridine.	Alizarin green G or B (oxazine group)	Nitroso-mordant colours, <i>e.g.</i> gambines, dioxine, dark green, naphthol green, &c.	Azo-mordant colour, <i>e.g.</i> diamond green, chrome patent green, &c.	12	11

1 With azo-mordant colours the cotton may be slightly tinted, especially if the fixation by chrome is not complete.

RECOGNITION OF DYES ON WOOL OR SILK.
TABLE VII.—BLACK AND GREY COLOURS.

Boil twice for one minute with 5 p.c. acetic acid

The colour is not stripped :—Acid, Direct, or Mordant dyestuff. Boil twice for one minute with dilute ammonia and a small piece of white cotton		The colour is not stripped :—Direct or Mordant dyestuff. Boil with 5 p.c. sodium acetate and small piece of white cotton												
Much colour is stripped :— Basic dyestuff (N.B.—Logwood black on Fe mordant also becomes much paler though solution is not coloured)	Much colour is stripped, but the cotton remains white :— Acid dyestuff. Permanently discharged. By hydro-sulphite A. Test ash for chromium	The cotton remains white :— Mordant dyestuffs. (Confirm by testing ash for mordant.) Boil with dilute hydrochloric acid (1 : 10)												
		The cotton is stained :— Direct or A-mordant dyestuff. Permanently discharged. By hydro-sulphite A. Test ash for chromium	The cotton remains white :— Mordant dyestuffs. (Confirm by testing ash for mordant.) Boil with dilute hydrochloric acid (1 : 10)	Fibre and solution pale brown	Fibre and solution pale brown	Fibre and solution crimson	Fibre blue and solution crimson. Test for indigo by boiling with a little aniline : blue solution, which on evaporation to dryness gives residue subliming in violet vapour	Not affected. Boil with hydrosulphite A	Becomes brown. Original colour slowly returns on exposure to air	Decolourised. Colour is not restored by exposure to air or by persulphate	Unaffected. Treat fibre with conc. H ₂ SO ₄	Blue solution	Colourless solution	11

1 Diazine black, Janus black, methylene grey, &c.

2 Naphthol black, naphthylamine black, Palatine black, nerol, azo-acid black, azo-merino black, &c.

3 Union black, half wool black, Columbia black, diamine blacks, dianil blacks, carbide blacks, &c.

4 Anthracene chrome blacks, Palatine chrome black, chromotropes, acid chrome black, chromate black, &c.

5 A 'vatted black' (indigo and logwood).

6 Logwood on Cr.

7 Logwood on Fe, or Bonsor's black.

8 Naphthazarine, alizarin blacks, alizarin blue black SW.

9 Diamond blacks.

10 Alizarin cyanine black.

RECOGNITION OF DYES ON COTTON.

TABLE VIII.—YELLOW AND ORANGE COLOURS.

The colour is stripped. Boil with acidified water and small piece of white wool	The colour is not stripped. Boil with dilute ammonia (1 : 100)¹	The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff. Transfer to wool and boil with hydrosulphite B	Decolourised or becomes light-yellow. Original colour is not restored by air oxidation:— Azo- dyestuff (including the Stilbene group). Boil with soap solution and white mercerised cotton	The colour is unaffected or changed in shade, becoming lighter, browner or bluer. It altered in shade, exposure to air restores the original colour. Apply the lead acetate test:— No H₂S is evolved. Boil with soap solution and white mercerised cotton²	The colour is not stripped with weak formic acid (1 : 100)³	
Colour is transferred to the wool:— Acid dyestuff. Boil wool with hydro-sulphite B	Fibre is not blackened. Boil with hydrosulphite X	Wool is not decolourised. Boil cotton with hydro-chloric acid (1 : 20)	White cotton is stained:— Direct dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	The white cotton is stained:— Thiazol direct dyestuff	
Not decolourised:— Pyrone or Quinoline group	Fibre blackened. Cr present in ash	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	H₂S is evolved:— Sulphide dyestuff	The white cotton is not stained:— Thiazol direct dyestuff	
Permanent decolourised:— Azo- group	Not decolourised. Test for Al in ash	Not decolourised. The conc. H₂SO₄ and alcoholic solutions are fluorescent:— Acridine group	Fibre after reduction is colourless:— Azo-direct-dyestuff	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
Colour not transferred to the wool. Sn is present in ash	Al absent	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
1 Persian berries on tin mordant.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
2 Quinoline yellow, eosin orange.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
3 Indian yellow, orange IV., G, &c.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
4 Chrome yellow or chrome orange. (lead chromate).	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
5 Alizarin yellow A.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
6 Thioflavine T.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
7 Flavinduline.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
8 Auramine.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
9 Phosphine, benzoflavine, acridine yellow, acridine orange, &c.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
10 Chrysoidine, tannin orange, Janus yellow, &c.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
11 Primuline developed with phenol or with resorcinol, cotton yellow G and R, oriol yellow, dianil yellow, &c.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
12 Chrysofenine, ehrysamine, toluylene yellow and orange, stilbene yellows and oranges, benzo, Congo, diamine, and dianil yellows and oranges, pyramine orange, &c.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
13 Metantraniline orange or nitrotoluidine orange (formed on fibre).	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
14 Chrome orange, alizarin yellow R, GG, &c., diamond flavine, flavazol, &c.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
15 Yellows and oranges of the immiedial, katigene, pyrogene, thiogene, sulphur, &c., series.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
16 Chlorophenine, chloramine yellow, diamine fast yellow B, FF, and C, Clayton yellow, thiazol yellow, thioflavine S, &c., primuline developed with hypochlorite.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
17 Persian berries on Al or Cr mordants, alizarin orange on Al mordant.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	
18 Helindone orange R, helindone yellow 3G,⁵ anthraflavone G, algole yellow 3G and R, algole orange R, indanthrene yellow, indanthrene orange RT and golden orange,⁶ indanthrene copper, cibanone yellow R and orange R.	Al present	Decolourised	Fibre after reduction is light-yellow and can be diazotised and developed red with β-naphthol:— Primuline-azo-colour	Colour is not stripped. Cr present in the ash:— Azo-mordant dyestuff	The white cotton is not stained:— Mordant or Vat dyestuff. Boil with 80 per cent. formic acid. Also test ash for metallic mordant	

¹ Brilliant yellow is largely stripped by weak ammonia, but if white cotton is present it will be stained.

² Sulphide yellows of the thiazol- class such as katigene yellow 2B, pyrogene yellow, &c., stain white cotton slightly when boiled in soap.

³ Auramine G is almost completely stripped by saline caustic soda, and the formic extract therefore gives no precipitate with tannin solution.

⁴ Diamond flavine, if not fully fixed, may stain cotton from a soap solution.

⁵ Helindone yellow and helindone orange give yellow vapours on heating the dry fibre. Upon reduction with hydrosulphite X, helindone yellow becomes olive, helindone orange colourless.

⁶ Indanthrene yellow (flavanthrene) is reduced by hydrosulphite X to a blue, indanthrene golden orange remains unchanged.

RECOGNITION OF DYES ON COTTON.

TABLE IX.—RED COLOURS.

Boil with dilute ammonia (1 : 100)

The colour is not stripped. Boil for half a minute with saline caustic soda, rinse, and boil twice for one minute with weak formic acid (1 : 100)	The colour is not stripped or the acid extract is not precipitated by tannin solution. Reduce with hydrosulphite X	The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	Wool decolourised. Colour not restored by air or by persulphate:— Azo group	16	Algole red B, indanthrene red, indanthrene claret.
			Wool decolourised. Colour does not return on exposure to air, but is restored by persulphate:— Triphenylmethane group	15	Alizarin purpurin or alizarin maroon on Cr mordant.
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	The colour is not stripped or the acid extract is not precipitated by tannin solution. Reduce with hydrosulphite X	The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	Wool decolourised. Colour returns on exposure to air:— Azine group	14	Turkey red, alizarin red, alizarin pink, alizarin maroon.
			Wool not decolourised:— Pyrone group	13	Primuline developed with β -naphthol or with R-salt.
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	The colour is not stripped or the acid extract is not precipitated by tannin solution. Reduce with hydrosulphite X	The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	Wool decolourised. Colour not restored by air or by persulphate:— Azo group	12	Algole red 5G and scarlet G, algole pink R, ciba red G and scarlet G, ciba bordeaux B, helindone red B and 3B, helindone scarlet S, helindone fast scarlet R, thioindigo red B, thioindigo scarlet, vat red.
			Wool decolourised. Colour not restored by air or by persulphate:— Azo group	11	Thiogene rubine, &c.
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	The colour is not stripped or the acid extract is not precipitated by tannin solution. Reduce with hydrosulphite X	The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	Wool decolourised. Colour not restored by air or by persulphate:— Azo group	10	Chrome red, brilliant chrome red, chrome bordeaux, &c.
			Wool decolourised. Colour not restored by air or by persulphate:— Azo group	9	Paranitraniline red, α -naphthylamine bordeaux, chloranisidine pink, nitroanisidine pink.
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	The colour is not stripped or the acid extract is not precipitated by tannin solution. Reduce with hydrosulphite X	The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	Wool decolourised. Colour not restored by air or by persulphate:— Azo group	8	Diamine fast red F, &c.
			Wool decolourised. Colour not restored by air or by persulphate:— Azo group	7	Benzopurpurine, diamine scarlets, diamine reds, benzo-fast scarlets, diazo-brilliant scarlet, rosanthrenes, Zambesi red, erica, diamine rose, geranine, rosophenine, &c.
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	The colour is not stripped or the acid extract is not precipitated by tannin solution. Reduce with hydrosulphite X	The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	Wool decolourised. Colour not restored by air or by persulphate:— Azo group	6	Janus red.
			Wool decolourised. Colour not restored by air or by persulphate:— Azo group	5	Magenta, fuchsine, isorubine, corise, granadine, &c.
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	The colour is not stripped or the acid extract is not precipitated by tannin solution. Reduce with hydrosulphite X	The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	Wool decolourised. Colour not restored by air or by persulphate:— Azo group	4	Safranines, rhoduline reds and pink, azine scarlet, induline scarlet, neutral red, &c.
			Wool decolourised. Colour not restored by air or by persulphate:— Azo group	3	Rhodamines, rhodines, irisamine, acridine reds, &c.
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	The colour is not stripped or the acid extract is not precipitated by tannin solution. Reduce with hydrosulphite X	The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution:— Basic dyestuff (on tannin or other mordant). Transfer to wool and boil with hydrosulphite A	Wool decolourised. Colour not restored by air or by persulphate:— Azo group	2	Crocein scarlets, brilliant croceines, fast reds, &c.
			Wool decolourised. Colour not restored by air or by persulphate:— Azo group	1	Eosins, phloxin, crythrosin, rose bengal, &c.

RECOGNITION OF DYES ON COTTON.
TABLE X.—PURPLE AND VIOLET COLOURS.

Boil with dilute ammonia (1 : 100)	
The colour is not stripped. Boil for half a minute with saline caustic soda, rinse, and boil twice for one minute with weak formic acid (1 : 100)	
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution	Decolourised or yellowish. Colour restored on exposure to air.—Azine, Oxazine, Thiazine or Indigoid groups. Apply lead acetate test. Also heat fibre in Al or Cr is present. Mor. absent. Apply mordant dye stuff lead acetate test
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution	Decolourised or yellowish. Colour restored on exposure to air.—Azine, Oxazine, Thiazine or Indigoid groups. Apply lead acetate test. Also heat fibre in Al or Cr is present. Mor. absent. Apply mordant dye stuff lead acetate test
The wool is dyed.—Basic dyestuff. Boil wool with hydrosulphite A	No H ₂ S is evolved.—Anthracene vat dyestuff
The wool is dyed.—Basic dyestuff. Boil wool with hydrosulphite X	H ₂ S is evolved.—Sulphide dyestuff
Decolourised. Colour returns on exposure to air.—Azine (Oxazine or Thiazine) group	The colour on reduction is browner or darker
Decolourised. Colour returns on exposure to air.—Azine (Oxazine or Thiazine) group	The colour on reduction is unchanged
Decolourised. Colour does not return in air, but is restored by persulphate.—Triphenylmethane group	Cr is absent. Coloured vapours on heating.—Indigoid dyestuff
Decolourised. Colour does not return in air, but is restored by persulphate.—Triphenylmethane group	Cr is present. No coloured vapours on heating.—Mordant oxazine dyestuff (not falling in group 7)
Decolourised. Colour returns on exposure to air.—Azine (Oxazine or Thiazine) group	No H ₂ S is evolved. Test ash for mordant
Decolourised. Colour returns on exposure to air.—Azine (Oxazine or Thiazine) group	H ₂ S is evolved. No coloured vapours on heating.—Sulphide dyestuff
Not decolourised.—Pyrene group	The colour is not stripped. Cr present in ash :—Mordant azo-dyestuff
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution	The colour is not stripped.—Insoluble azo-colour
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution	Colour destroyed, giving yellow solution. Fe present in ash :—Alizarin red on Fe mordant
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution	Cr or Cu present :—Azo direct dyestuff after-treated
The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution	No Cr or Cu present :—Azo direct dyestuff
The wool is dyed.—Basic dyestuff. Boil wool with hydrosulphite A	Decolourised only slowly. Colour does not return in air, but is restored by persulphate.—Triphenylmethane group
The wool is dyed.—Basic dyestuff. Boil wool with hydrosulphite X	Decolourised. Colour returns on exposure to air.—Oxazine group
Decolourised. Colour returns on exposure to air.—Azine (Oxazine or Thiazine) group	Decolourised. Colour does not return in air, but is restored by persulphate.—Triphenylmethane group
Decolourised. Colour returns on exposure to air.—Azine (Oxazine or Thiazine) group	Decolourised. Colour returns on exposure to air.—Azine (Oxazine or Thiazine) group
Not decolourised.—Pyrene group	Not decolourised.—Pyrene group
The ammoniacal solution is violet	The ammoniacal solution is violet
The ammoniacal solution is colourless, but becomes blue on acidifying	The ammoniacal solution is colourless, but becomes blue on acidifying

1. Alizarin on chromium becomes rather browner on reduction with hydrosulphite X.
2. Janus claret red does not easily transfer to wool.

RECOGNITION OF DYES ON COTTON.

TABLE XI.—BLUE COLOURS.

Boil with dilute ammonia (1 : 100)		Boil for half a minute with saline caustic soda, rinse, and boil twice with weak formic acid (1 : 100)			
The colour is not stripped.	The colour is not stripped or the acid extract is not precipitated by tannin solution. Reduce with hydrosulphite X	The colour is not stripped or the acid extract is not precipitated by tannin solution. Reduce with hydrosulphite X	Colour unchanged or becomes darker, browner, &c., the original colour being restored on exposure to air.— Anthracene mordant or Anthracene vat dyestuff (also Ultramarine). Boil with 90 p.c. formic acid		
				The colour is not stripped. Al in ash. Apply lead acetate test	Cr absent :— Anthracene vat dyestuff
No H ₂ S evolved :— Alizarin dyestuff on Al	Cr present in ash :— Alizarin dyestuff on Cr	17	Alizarin blue, alizarin cyanines or anthracene blues on Cr mordant.		
		H ₂ S is evolved	No H ₂ S evolved :— Alizarin dyestuff on Al	16	Alizarin cyanines or anthracene blues on Al mordant.
Colour changed to greenish-yellow, which can be diazotised and developed red with β-naphthol :— Primuline azo- colour	The colour is not stripped. Al in ash. Apply lead acetate test			H ₂ S is evolved	The colour is not stripped. Al in ash. Apply lead acetate test
		No H ₂ S evolved :—Heat fibre carefully in dry test-tube	No coloured vapour. Cr in ash :— Mordant thiazine or oxazine (not falling in Group 6)		
H ₂ S is evolved :— Sulphide dyestuff	No Cr or Cu present :— Azo-direct dyestuff after-treated			Cr or Cu present :— Azo-direct dyestuff after-treated	The white cotton is stained. Test ash for Cr and Cu
		The white cotton is stained. Test ash for Cr and Cu	No Cr or Cu present :— Azo-direct dyestuff		
The white cotton is stained. Test ash for Cr and Cu	No Cr or Cu present :— Azo-direct dyestuff			Cr or Cu present :— Azo-direct dyestuff after-treated	The white cotton is stained. Test ash for Cr and Cu
		The white cotton is stained. Test ash for Cr and Cu	No Cr or Cu present :— Azo-direct dyestuff		
The white cotton is stained. Test ash for Cr and Cu	No Cr or Cu present :— Azo-direct dyestuff			Cr or Cu present :— Azo-direct dyestuff after-treated	The white cotton is stained. Test ash for Cr and Cu
		The white cotton is stained. Test ash for Cr and Cu	No Cr or Cu present :— Azo-direct dyestuff		
The wool is not dyed. Cr present in ash :— Basic mordant dyestuff . Boil cotton with hydrosulphite X	Decolourised slowly. Colour restored only by persulphate :— Triphenylmethane group			Decolourised. Colour returns on exposure to air :— Oxazine group	The wool is not dyed. Cr present in ash :— Basic mordant dyestuff . Boil cotton with hydrosulphite X
		Decolourised. Colour does not return on exposure to air, but is restored by persulphate :— Triphenylmethane group	Colour changes to red just before being decolourised. Colour returns violet or blue :— Safranin azo-dyestuff		
Decolourised. Colour does not return on exposure to air, but is restored by persulphate :— Triphenylmethane group	Colour changes to red just before being decolourised. Colour returns violet or blue :— Safranin azo-dyestuff			Decolourised. Colour returns on exposure to air :— Azine, Oxazine, or Thiazine group	The wool is not dyed. Cr present in ash :— Basic mordant dyestuff . Boil cotton with hydrosulphite X
		Decolourised. Colour does not return on exposure to air, but is restored by persulphate :— Triphenylmethane group	Colour changes to red just before being decolourised. Colour returns violet or blue :— Safranin azo-dyestuff		
Decolourised. Colour does not return on exposure to air, but is restored by persulphate :— Triphenylmethane group	Colour changes to red just before being decolourised. Colour returns violet or blue :— Safranin azo-dyestuff			Decolourised. Colour returns on exposure to air :— Azine, Oxazine, or Thiazine group	The wool is not dyed. Cr present in ash :— Basic mordant dyestuff . Boil cotton with hydrosulphite X
		Decolourised. Colour does not return on exposure to air, but is restored by persulphate :— Triphenylmethane group	Colour changes to red just before being decolourised. Colour returns violet or blue :— Safranin azo-dyestuff		
Decolourised. Colour does not return on exposure to air, but is restored by persulphate :— Triphenylmethane group	Colour changes to red just before being decolourised. Colour returns violet or blue :— Safranin azo-dyestuff			Decolourised. Colour returns on exposure to air :— Azine, Oxazine, or Thiazine group	The wool is not dyed. Cr present in ash :— Basic mordant dyestuff . Boil cotton with hydrosulphite X

¹ Alkali blue dyed on a tannin and the mordant is only partly stripped by weak ammonia, the solution being colourless.

RECOGNITION OF DYES ON COTTON.

TABLE XII.—GREEN COLOURS.

Boil with dilute ammonia (1 : 100)

The colour is not stripped. The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution.— Basic dyestuff (on tannin or other mordant) or Basic mordant dyestuff . Boil with saline caustic soda, rinse well, and boil with white wool and water.	The wool is dyed.— Basic dyestuff . Boil wool with hydrosulphite A	The white cotton is not stained :— Direct dye-stuff . Test ash for Cr and Cu	Cr or Cu present :— Azo-direct dyestuff after-treated	6 Diamine green, benzo green, Columbia green, chloramine green, &c.	6 Group 6 coppered or chromed.	8 Russian green, fast green, O, steam green, Alsace green, gambines, dioxine, &c. ¹	9 Diamond green, &c.	10 Primuline developed with aminodiphenylamine.	11 Greens of the immedial, katigene, thiogene, pyrogene, sulphur, and thionol series.	12 Gallanilic green, indalzarin, &c.	13 Alizarin viridine, brilliant alizarin viridine.	14 Alizarin green S on Cr mordant.	15 Alizarin green S on Ni or Mg mordant.	16 Ceruleine, anthracene green.	17 Indanthrene olive or olivanthrene.	18 Indanthrene green or viridanthrene, leucole dark green B.	19 Algole green, indanthrene blue in admixture with indanthrene yellow or with anthraflavone.	20 Ciba green.	Reduced to yellow, which is restored by air oxidation :— Indigoid dyestuff
																			The colour is stripped :— Acid dyestuff . The colour transferred to wool is decolourised by hydrosulphite A and restored by persulphate :— Triphenylmethane group

¹ Greens of the nitroso-group (gambines, &c.) may become black on reduction if the hydrosulphite X is insufficiently acid (formation of FeS).

RECOGNITION OF DYES ON COTTON.
TABLE XIII.—BROWN COLOURS.

Boil with dilute ammonia (1 : 100)

The colour is not stripped.	Boil for half a minute with saline caustic soda, rinse, and boil twice with weak formic acid (1 : 100)	The colour is not precipitated by tannin solution. Reduce with hydrosulphite X	No H ₂ S is evolved. Test ash for Cr and Cu	Cr and Cu (or both) present:—Mordant dyestuff. Boil with HCl (1 : 20)	Cr and Cu absent:—Anthracene vat dyestuff, &c.	Indanthrene maroon, algole brown, leucole browns, cibanone brown, paramine brown (<i>p</i> -phenylene diamine oxidised on fibre).
Decolourised and colour not restored on exposure to air or by persulphate	—Azo- group or mineral colours. Boil with soap solution and white mercerised cotton	The white cotton is not stained. Boil with pyridine	The colour is not stripped:—Mineral colour. Treat with sodium bisulphite in the cold	Not stripped or only slightly. Boil with dilute caustic soda 10 p.c.	Fibre and solution dull violet	14 Cutch.
The white cotton is stained:—Direct dyestuff. Test ash for Cr and Cu	The colour is stripped:—In-soluble azo-colour. Test ash for Cu	The colour is not decolourised	Not decolourised	Completely stripped	13 Alizarin orange on Cr mordant, alizarin or purpurine on Cr.	15
The colour is not stripped	The white cotton is not stained. Boil with pyridine	The colour is not stripped:—Mineral colour. Treat with sodium bisulphite in the cold	Not decolourised	H ₂ S is evolved:—Sulphide dyestuff	12 Anthragalol, anthracene brown, alizarin brown.	11
Decolourised and original colour restored by air:—Indigoid group	The shade is changed to greenish-yellow, which can be diazotised and developed red with β -naphthol:—Primuline azo- colour	Iron buff, khaki (oxides of Cr and Fe). ¹	Helindone brown G.	11	11 Immedial cutch, cross dye brown, katigene browns, pyrogene browns, thiogene browns, &c.	10
The colour is not stripped	Boil with dilute ammonia (1 : 100)	Manganese bronze.	Primuline developed with metaphenylene diamine. Terra-cotta, &c.	10	10	9
The colour is not stripped	The white cotton is not stained. Boil with pyridine	Para-brown (chrysoindine and paranitraniline), benzidine or toluidine brown.	Iron buff, khaki (oxides of Cr and Fe). ¹	8	8	8
The colour is not stripped	The white cotton is not stained. Boil with pyridine	Group 3 coppered or chromed.	Paranitraniline cutch (para-red coppered).	7	7	7
The colour is not stripped	The white cotton is not stained. Boil with pyridine	Browns of the diamine, benzo, Congo, dianil, Columbia, Hessian, oxamine, and toluylene series.	Para-brown (chrysoindine and paranitraniline), benzidine or toluidine brown.	6	6	6
The colour is not stripped	The white cotton is not stained. Boil with pyridine	Group 3 coppered or chromed.	Para-brown (chrysoindine and paranitraniline), benzidine or toluidine brown.	5	5	5
The colour is not stripped	The white cotton is not stained. Boil with pyridine	Group 3 coppered or chromed.	Para-brown (chrysoindine and paranitraniline), benzidine or toluidine brown.	4	4	4
The colour is not stripped	The white cotton is not stained. Boil with pyridine	Group 3 coppered or chromed.	Para-brown (chrysoindine and paranitraniline), benzidine or toluidine brown.	3	3	3
The colour is not stripped	The white cotton is not stained. Boil with pyridine	Group 3 coppered or chromed.	Para-brown (chrysoindine and paranitraniline), benzidine or toluidine brown.	2	2	2

¹ Iron buff and khaki may become black on reduction if the hydrosulphite X is insufficiently acid (formation of FeS).

RECOGNITION OF DYES ON COTTON.
TABLE XIV.—BLACK AND GREY COLOURS.

Boil with dilute ammonia (1:100)		Boil with dilute hydrochloric acid (1:5)		Boil with dilute hydrochloric acid (1:20)	
The colour is stripped	Solution red. Cr in ash	4	Logwood black on chrome mordant, noir reudit.	The colour is not stripped (or only slightly). Boil for one minute with saline caustic soda, rinse, and boil with dilute hydrochloric acid (1:20). Reduce with hydrosulphite X. The colour is unaffected or changed in shade (becoming brown, maroon, &c.).	Colour not changed by reduction (or very slightly):—Anthracene group. Test ash for Cr
	Solution orange. Fe in ash	5	Logwood black on iron mordant.		
	Fibre and solution colourless	6	Tannate of iron.		
The colour is largely stripped and the acid extract is precipitated by tannin solution:—Basic dyestuff. Transfer to wool and boil with hydrosulphite A	Colour becomes red just before being decolourised. Violet or violet blue colour returns in air:—Safranine azo-group	6	Janus black, Janus grey, diazine grey.	The reduced colour is brown. Only slowly and imperfectly restored to black by air but at once by persulphate. Cr present in ash:—Naphthalene mordant dyestuff	Cr absent:—Anthracene vat dyestuff
	Decolourised. Colour returns on exposure to air:—Azine, Oxazine, or Thiazine group	5	Methylene grey, new methylene grey, new fast grey, nigrisine, &c.		
The colour is not stripped nor acid extract precipitated by tannin solution. Reduce with hydrosulphite X	Decolourised and colour not restored by air or persulphate:—Azo-group. Boil with soap solution and white mercerised cotton	The white cotton is stained. Test ash for Cr and Cu	Cr or Cu present:—Azo-direct dyestuff after-treated	8	Group 7 coppered or chromed.
			Cr and Cu absent:—Azo-direct dyestuff	7	Blacks of the diamine, oxydiamine, benzo, Columbia, dianil, Pluto, &c., series. Also diaminogen, diazo blacks, &c. (developed or coupled).
The reduced colour is brown, but is rapidly restored to black on exposure to air:—Azine, Oxazine, or Thiazine group. Apply lead acetate test	No H ₂ S evolved. Fibre becomes reddish-brown on boiling with bleaching powder solution 5°Tw.:—An oxidation black	H ₂ S is evolved. Fibre becomes colourless or pale buff on boiling with bleaching powder solution 5°Tw.:—Sulphide dyestuff	The white cotton is not stained. Colour is stripped by boiling pyridine:—Insoluble azo-colour	9	Azophor black, &c.
				10	Ciba grey G and B.
The colour is not stripped (or only slightly). Boil for one minute with saline caustic soda, rinse, and boil with dilute hydrochloric acid (1:20). Reduce with hydrosulphite X	Decolourised and colour restored by air. Gives violet vapours on heating in dry tube:—Indigoid dyestuff	No H ₂ S evolved. Fibre becomes reddish-brown on boiling with bleaching powder solution 5°Tw.:—An oxidation black	The white cotton is not stained. Colour is stripped by boiling pyridine:—Insoluble azo-colour	11	Blacks of the immedial, katigene, cross dye, pyrogene, thiogene, thionol, pyrol, sulphur, &c., series.
				12	Aged aniline black, prussiate black, one bath aniline black, steam aniline black, diphenyl black.
The colour is not stripped (or only slightly). Boil for one minute with saline caustic soda, rinse, and boil with dilute hydrochloric acid (1:20). Reduce with hydrosulphite X	Decolourised and colour restored by air. Gives violet vapours on heating in dry tube:—Indigoid dyestuff	No H ₂ S evolved. Fibre becomes reddish-brown on boiling with bleaching powder solution 5°Tw.:—An oxidation black	The white cotton is not stained. Colour is stripped by boiling pyridine:—Insoluble azo-colour	13	Naphthazarine S, alizarin black S, alizarin blue black SW, naphthomelane.
				14	Alizarin cyanine black, alizarin blue black B.
The colour is not stripped (or only slightly). Boil for one minute with saline caustic soda, rinse, and boil with dilute hydrochloric acid (1:20). Reduce with hydrosulphite X	Decolourised and colour restored by air. Gives violet vapours on heating in dry tube:—Indigoid dyestuff	No H ₂ S evolved. Fibre becomes reddish-brown on boiling with bleaching powder solution 5°Tw.:—An oxidation black	The white cotton is not stained. Colour is stripped by boiling pyridine:—Insoluble azo-colour	15	Indanthrene grey or melanthrene.
				16	Alizarin cyanine black, alizarin blue black B.

The colour is stripped:—Acid dyestuff. The dyestuff transferred to wool and boiled with hydrosulphite A is permanently decolourised:—Azo-group

1 Naphthol blacks, naphthylamino blacks, Palatine black, &c.

DYER'S BROOM. *Genista tinctoria* (Linn.) (*Dyer's broom*, *Dyer's greenweed*; *Genet*, *Genestrole*, Trentanel, Fr.; *Genster*, (Ger.) is found in the pastures, thickets, and waste places throughout Central and Southern Europe, across Russian Asia to the Baikal, and northward to Southern Sweden. It is frequent in the greater part of England, but rare in Ireland and Scotland. The fact that it contains a yellow colouring matter is recorded by numerous writers, and the following embody the principal references to the dyeing and general properties of the plant: Bancroft (*Philosophy of Permanent Colours*, 1813, 2, 108); Gmelin (*Handbook of Chemistry*, 16, 517); Berthollet (*On Dyeing*, 1824, 2, 242); Gonfreville (*Art de la Teinture de Laines*, 501); Leuchs (*Farben u. Farbkunde*, 1846, 2, 309), and Schützenberger (*Traite de Matières Colorantes*, 1867, 4, 422).

To isolate the colouring matters, a hot aqueous extract of the plant is treated with lead acetate solution, and the pale-yellow viscous precipitate is collected and decomposed by means of boiling dilute sulphuric acid. The clear liquid decanted from the lead sulphate deposits on cooling a dull-yellow powder; this is filtered off, dissolved in a little alcohol, and the solution poured into a large volume of ether, causing the separation of a dark-coloured resinous impurity. The clear liquid is evaporated, yielding a yellow crystalline residue, which consists of two substances. To separate these advantage is taken of the fact that, with sulphuric acid in the presence of acetic acid, one only of these compounds gives an insoluble sulphate. This is collected and decomposed with water and the product crystallised from dilute alcohol. It is obtained as yellow needles, and was found to be identical with the *luteolin* of weld. (*Reseda luteola*) (Perkin and Newbury, *Chem. Soc. Trans.* 1899, 75, 830).

Genistein $C_{14}H_{10}O_6$, the second colouring matter of dyer's broom, is present in the mother liquors obtained during the purification of the luteolin, and also in considerable quantity in the filtrate from the lead precipitate, from which it is most readily isolated. To the boiling liquid ammonia is added, causing the separation of a lemon-yellow precipitate, which is collected and decomposed with boiling dilute sulphuric acid. The clear liquid is extracted with ether, and the extract evaporated, leaving a brownish crystalline mass. It is purified by crystallisation from acetic acid, and by conversion into the acetyl derivative.

Genistein crystallises in long colourless needles; m.p. 291°–293° (Perkin and Horsfall, *Chem. Soc. Trans.* 1900, 77, 1312); soluble in alkalis with a pale-yellow colouration. Alcoholic ferric chloride gives a dull-red violet colouration, and alcoholic basic lead acetate a lemon-yellow precipitate.

Triacetylgenistein $C_{14}H_7O_9(C_2H_3O)_3$, colourless needles, m.p. 197°–201°; and *tetrabromogenistein* $C_{14}H_6Br_4O_6$, colourless needles, m.p. above 290°, have been described.

On digestion with boiling 50 p.c. potassium hydroxide, *genistein* gives *phloroglucinol* and *p-hydroxyphenylacetic acid*.

By methylation with methyl iodide in the usual manner, *genistein dimethyl ether*

and *methylgenistein dimethyl ether* are produced.

Genistein dimethyl ether $C_{14}H_{10}O_3(OCH_3)_2$, forms colourless leaflets, melts at 137°–139°, and gives the *monoacetyl* compound,

in minute colourless needles, m.p. 202°–204°. When decomposed with alcoholic potash, it forms *methoxyphenylacetic acid* and *phloroglucinol-monomethyl ether* (identified by means of its disazobenzene derivative).

Methylgenistein dimethyl ether

melts at 202°; and the *acetyl* derivative

forms colourless needles, m.p. 212–214°. With alcoholic potash, *methoxyphenylacetic acid* and probably *methylphloroglucinol-monomethyl ether* are obtained.

Genistein diethyl ether $C_{14}H_8O_3(OC_2H_5)_2$, forms colourless needles, m.p. 132°–134°; whereas *acetylgenistein diethyl ether*

melts at 168°–170°. Alcoholic potash gives *p-ethoxyphenylacetic acid*.

According to Perkin and Horsfall, *genistein* is most probably a *trihydroxyphenylketocumarone*

Genistein is a feeble colouring matter, and upon woollen cloth gives, with chromium mordant, a pale greenish-yellow; with aluminium mordant, a very pale-yellow; and with iron mordant, a chocolate-brown shade.

Dyeing properties of dyer's broom.—In this respect there is a close resemblance between dyer's broom and weld. The dyeing power of the former is distinctly the weaker of the two; otherwise the only point of difference worthy of mention is that shown by the iron mordant, which, in the case of dyer's broom, gives a duller and more drab-coloured shade. A. G. P.

DYNAMAGNITE, DYNAMITE v. EXPLOSIVES.

DYNSCRASITE. Silver antimonide (v. ANTIMONY).

DYSODILE. A soft laminated carbonaceous substance of a yellowish-grey or green colour, burning with a luminous flame, and a smell resembling that of burning caoutchouc. Found in Sicily and in Bavaria (Ericklinger, *Jahrb. Min.* 1875, 760; also Church, *Chem. News*, 34, 155; Potonié, *Chem. Zentr.* 1907, ii. 555).

DYSPROSIUM. *Sym. Dy.* At. wt. 162.5. (Urbain and Dementroux, *Compt. rend.* 1906, 143, 598; Hinrichs, *ibid.* 1143.) From erbium—one of the fractions obtained from ytterbite—(Cleve separated an earth which he called 'holmia'; and from this material Lecoq de Boisbaudran isolated a simpler constituent, *dysprosia*, characterised by a well-marked absorption spectrum showing bands in the ultra-violet as well as in the visible region of the spectrum (*Compt. rend.* 1886, 102, 100). This oxide, one of the most basic constituents of holmia, was concentrated by precipitations with potassium sulphate and ammonia. Further fractionation of the nitrates and double nitrates gave a product rich in terbium and dysprosium (Urbain, *Compt.*

rend. 1904, 139, 736; 1905, 141, 521). The latter is separated from terbium by fractional crystallisation of the ethyl sulphates, terbium and yttrium being concentrated in the least soluble fraction, whilst dysprosium accumulates in the middle fraction (Urban, Ann. Chim. Phys. 1900, [7] 19, 184; Compt. rend. 1906, 142, 785).

Dysprosium is separated from yttrium by crystallisation of the nitrate with the addition of bismuth nitrate.

Dysprosium forms a white oxide Dy_2O_3 , but no peroxide. Its salts have a faint greenish-yellow tint: *chloride* $DyCl_3 \cdot 6H_2O$; *nitrate* $Dy(NO_3)_3 \cdot 5H_2O$, melting at 88° in its water of

crystallisation, very similar to bismuth nitrate (Urban and Jantsch, Compt. rend. 1908, 146, 127); *sulphate* $Dy_2(SO_4)_3 \cdot 8H_2O$, brilliant yellowish crystals, stable at 110° , and completely dehydrated at 360° . For other salts, v. Jantsch and Ohl Ber. 1911, 44, 1274.

Dysprosium stands first in the list of paramagnetic elements, its oxide Dy_2O_3 being 12.8 times more magnetic than ferric oxide. The high values for the magnetic susceptibility of the rare earths (yttria, erbia, &c.) fractionated by Cleve and Nilson are probably due to the presence of dysprosium (Urban, Compt. rend. 1908, 146, 922).

G. T. M.

E

EARTHNUIT OIL v. ARACHIS OIL.

EAU DE COLOGNE v. PERFUMES.

EAU DE JAVELLE. Solution of sodium hypochlorite (v. *Bleach liquor*, art. CHLORINE).

EAU DE LUCE. *Aqua lucia*. A milky liquid containing oil of amber, alcohol, and ammonia (v. AMBER, OIL OF).

EBONITE. *Sulphurised caoutchouc* (v. RUBBER).

EBULLIOSCOPE. An instrument for determining the strength of spirits of wine by means of its boiling-point.

ECBOLINE v. ERGOT OF RYE.

ECGONINE v. VEGETO-ALKALOIDS.

ECHITAMINE, ECHITENINE v. DITA BARK.

E. C. POWDER v. EXPLOSIVES.

EDESTIN. A crystalline proteid substance found in the seeds of hemp, sunflower, and castor-bean, capable of uniting with acids to form salts (Osborne, J. Amer. Chem. Soc. 24, 39).

EDIBLE OILS AND FATS. Under this term are comprised those oils and fats which serve as food. Most of the edible oils and fats, such as olive oil, cod liver oil, suet, lard, butter-fat, cacao butter, goose fat, &c., are immediately fit for consumption, if 'rendered' with sufficient care. Hence they rarely need undergo a process of technical purification, except simple filtration, before they are placed on the market. This applies, however, only to the freshly ('first') rendered products, as contact with putrescible organic matter rapidly causes hydrolysis of the oils and fats, so that, e.g., lard or olive oil which has been allowed to remain in contact for some little time with the organic tissues from which they have been derived, readily become rancid, and therefore unfit for food in their original state. This applies with especial force to cod liver oil.

The large demand made on the market by the rapidly growing consumption of oils and fats has, however, led to the employment of second and even third 'renderings,' in the case of animal fats, and second or third 'expressions' in the case of vegetable oils and fats. Such products contain, as a rule, notable amounts of free fatty acids, and small quantities of extractive substances, all of which must be

removed before the oils and fats become suitable for food purposes. The processes applied to the purification and decolourisation are treated as deep secrets. It may, however, be stated that most of the processes are based on physical methods of refining (see OILS AND FATS).

Chemicals involving the use of mineral acids must be altogether excluded from the purview of the refiner, since the mineral acids, however carefully they may be removed by subsequent washing, impart an objectionable flavour to the products, thus rendering them useless for edible purposes. Alkalis or alkaline earths are not so objectionable, and are, therefore, used commercially for the removal of free fatty acids. (A notable example of this kind is furnished by the usual method of refining cotton-seed oil.) The alkalis and alkaline salts chiefly employed in practice are caustic soda, sodium carbonate, lime, and magnesia. Baryta has also been proposed (and patented), but its poisonous properties would prohibit its use.

Whereas all animal oils and fats, when freshly prepared, are suitable for food, this holds good only in a somewhat restricted sense of vegetable oils and fats. If the vegetable oils and fats are free from objectionable substances they may hold in solution or may have dissolved from the vegetable matter from which they have been obtained by expression or boiling out, then they are suitable for edible purposes, and are so used to a very considerable extent.

We know, however, a number of oils which contain non-fatty toxic or injurious substances, such as tung oil, calophyllum oil, curcas oil, croton oil. In the case of castor oil, the fatty acids themselves are injurious to health; hence castor oil is unusable as a foodstuff. Experience has also shown that the fats belonging to the *Chaulmoogra* group are injurious to health. All these oils must, therefore, be excluded from the list of edible oils.

With regard to the palatableness of the edible oils and fats, much depends on the demand made in that respect by the population of the various countries of the world. Thus, whereas rape oil and linseed oil find a ready market for edible purposes in India, these oils are at present

used in exceptional cases only as table oils in Western Europe. They are replaced in richer countries by cotton-seed oil, sesamé oil, arachis oil, poppy-seed oil, and olive oil. The increased consumption of the available edible oils and fats has created, during the last decade, a new and growing industry.

Amongst the most important developments in this industry is the preparation of cocoa-nut oil and palm-kernel oils for edible purposes (see COCOA-NUT OIL and PALM-KERNEL OIL). Mixtures of several edible oils are now largely prepared as 'table oils' to replace olive oil. Amongst these substitutes the most important are: arachis oil, sesamé oil, cotton-seed oil, and to some extent also soya-bean oil. Mixtures of edible vegetable and animal oils and fats are chiefly represented by the 'suet substitutes,' which are prepared by mixing tallow with cotton-seed oil, and by 'lard substitutes,' which represent a mixture of animal fats with cotton-seed oil, maize oil, &c. Up to recently, 'compound lard' contained frequently no lard whatever, but, according to recent legislation in the United States, 'lard compounds' or 'lard substitutes' must contain at least 50 p.c. of lard (see LARD SUBSTITUTES).

The manufacture and sale of edible oils and fats has assumed such considerable importance that legislation has stepped in to protect the public against fraudulent practices both as regards the commercial description of a 'blended' fat and the absence of injurious substances (see MARGARINE).

J. L.

EDULCORATION. The act of washing insoluble matter so as to remove any soluble impurity.

EFFLORESCENCE. This term is applied to two or three different phenomena, characterised by the formation of a loose pulverulent deposit on the surface of a solid body.

1. Crystallised salts are said to effloresce when they lose their water of crystallisation and fall to powder, e.g. normal sodium carbonate.

2. The formation of a pulverulent crystalline deposit on the surface of a porous body, in consequence of the crystallisation of a salt existing in solution within its pores, or formed from materials existing therein, is also called efflorescence; e.g. the crystallisation of potassium nitrate on the surface of the earth or in caves, as in India, or on saltpetre plantations; of sodium sulphate and carbonate on walls; of alum on alum-slate; of ferrous sulphate on iron pyrites, &c. In all these cases the solution of the salt is drawn by capillary action to the surface of the solid body, and there crystallises in consequence of the evaporation of the water.

3. The term 'efflorescence' is likewise applied to the effect which sometimes takes place when a saline solution is left to evaporate slowly in an open vessel. The solid salt separates in dendritic crystals just where the surface of the liquid touches the side of the vessel, and the solution, rising by capillarity between these crystals, forms a fresh crystallisation just above the first layer; and this process is continually repeated till the crystallisation thus formed extends over the edge of the vessel, and sometimes down to the table on which it stands. Sal-ammoniac and other ammonia salts often effloresce in this manner. The effect may be prevented to a certain extent

by greasing the edge of the vessel, or better, by quickly boiling the solution, or evaporating it by heat from above.

EGG. The egg of the common fowl, *Gallus Bankiva*, consists of four principal parts: the shell; the white; the yolk or vitellum; the white yolk or germinal cell; and the membranes separating these parts. The usual weight of an egg is 40-60 grams; of this the shell and shell membrane form 5-8 grams; the yolk, 12-18 grams; and the white, 23-34 grams.

The shell has the composition:

Calcium carbonate	89.6 p.c.
Phosphates of lime and magnesia	5.7 "
Organic matter and sulphur	4.7 "

The colouring matter of egg-shells is a bile pigment (Liebermann, Ber. 11, 606).

The shell membrane or *membrana putaminis* separating the white from the shell is double, the two parts being in contact over the greater part of the inner surface of the shell, but separated by an air-space at the broad end of the egg. These membranes are composed of a proteid substance allied to keratin (Liebermann).

Abderhalden and Strauss have examined the products of hydrolysis of *ovokeratin*, and find them to be, from 100 grams of substance: 3.9 grams glycine; 3.5 grams alanine; 1.1 gram amino-valeric acid; 7.4 grams leucine; 4.0 grams proline; 8.1 grams glutamic acid; and 1.1 gram aspartic acid (Zeitsch. physiol. Chem. 1906, 48, 530).

The white is a faintly yellow albuminous fluid enclosed in large cells of thin membrane. The fluid has sp.gr. 1.045, and is really mobile, though it appears viscous because of its confinement by the cell walls. It has an alkaline reaction. The constituents are:

Water	85-88 p.c.
Proteid bodies	10-13 "
Salts	0.7 "
Fermentable sugars	0.5 "

with traces of fats, soaps, lecithin, and cholesterol. Salkowski states that the fermentable sugar is glucose (Chem. Soc. Abstr. 1894, i. 214).

The protein substances of egg white are all gluco-proteids, and in their solution and precipitation properties are similar to globulins, albumins, or proteoses (v. art. PROTEINS).

Ovoglobulin separates from egg white partly on dilution with water, and completely if the solution be saturated with magnesium sulphate or ammonium sulphate. By repeated solution in water and reprecipitation, part becomes insoluble (Langstein, Hofmeister's Beitrage, 1), and it is probably a mixture of several globulins (Corin and Berard, Bull. Acad. Belg. [3], 15, 643). The globulins form about 6.7 p.c. of the total proteids of egg white (Dillner, Hammarstein's Text-book Physiol. Chem. 430).

Ovalbumin is the chief proteid constituent of egg-white. It is obtained crystalline by precipitating the globulins with ammonium sulphate, as above, and allowing the filtrate to evaporate. (For details of methods, see Hofmeister, Zeitsch. physiol. Chem. 16, 187; Osborne and Campbell, J. Amer. Chem. Soc. 1900, 22, 422; Rosenkrantz, J. Russ. Phys. Chem. Soc. 1906, 38, 2; and Mayer, Compt. rend. 1906, 143, 515.)

Pure ovalbumin crystallises in large, well-formed needles. A 2.5 p.c. solution in water

becomes turbid at 60°, and at 64° yields a flocculent coagulum. The addition of sodium chloride to the solution raises the temperature of coagulation (Osborne and Campbell, *l.c.*; Stärke, Pflüger's Archiv. 12, 18).

The composition of ovalbumin is :

C	H	N	S	P	O
52.75	7.10	15.51	1.62	0.12	22.90 p.c.

(Osborne and Campbell, *l.c.* 441; in agreement with Hopkins, *J. Physiol.* 25, 306; and Hammarsten, *Zeitsch. physiol. Chem.* 9, 304).

Many attempts have been made to assign a formula to ovalbumin. Latham (*Biochem. J.* 1908, 3, 207 *et seq*) gives it a molecular weight of 5473, and the formula $C_{246}H_{397}N_{65}O_{75}S_3$, but this must be regarded as an approximation only.

It has been characterised by determining the various amino-acids yielded on hydrolysis with hydrochloric acid of sp.gr. 1.19 (*v. art.* PROTEINS). 100 grams ovalbumin yield: alanine, 2.1 grams; leucine, 20.0 grams; phenylalanine, 4.4 grams; tyrosine, 1.1 gram; cystine, 0.3 gram; proline, 2.3 grams; aspartic acid, 1.5 grams; and glutamic acid, 8.0 grams (Aberdalden and Pregl, *Zeitsch. physiol. Chem.* 1905, 46, 24; Osborne, Jones, and Leavenworth, *Amer. J. Physiol.* 1909, 24, 252; Levene and Beatty, *Biochem. Zeitsch.* 1907, 4, 305).

The specific rotation of pure albumin is given as -31° (Willcock, *J. Physiol.* 1908, 37, 27), -30.70° (Hopkins, *ibid.* 25, 306), and -29.31° (Osborne and Campbell, *l.c.*).

The precipitation of albumin by acids and salts is a completely reversible reaction (Galeotti, *Zeitsch. physiol. Chem.* 1905, 44, 461), and follows the law of mass action (Ostwald, *Chem. Soc. Abstr.* 1908, i, 375; Gerrini, *Zeitsch. physiol. Chem.* 1906, 47, 287).

Conalbumin. Only about one-half of the proteid of egg white can be obtained as crystallised ovalbumin; the other fractions have a higher rotation and sulphur content. By heating these fractions at 65°, *conalbumin* is obtained as a coagulum, which, when dried at 110°, has the following composition:—

C	H	N	S	O
52.25	6.99	16.11	1.70	22.95 p.c.

Its specific rotation is about -36° (Osborne and Campbell, *l.c.*; Panormoff, *Chem. Zentr.* 1898, 11, 487).

Ovomucoid is found in the residue after all proteids coagulated by heat have been removed from egg white (Neumeister, *Zeitsch. Biol.* 1890, 27, 369; Mörner, *Zeitsch. physiol. Chem.* 1893, 18, 525). It forms about 10 p.c. of the proteids of egg white. It is not precipitated from solution by mineral acids or organic acids (except phosphotungstic and tannic acids) or by metallic salts.

The *inorganic constituents* of egg-white in 1000 parts are: Potash, 276–285 parts; soda, 235–329 parts; lime, 18–29 parts; magnesia, 16–32 parts; iron oxide, 4.4–5.5 parts; chlorine, 238–205 parts; phosphoric acid, 32–48 parts; sulphuric acid, 13–26 parts; silica, 3–20 parts; carbon dioxide, 97–116 parts (Poleck and Weber, *Hammarsten's Physiol. Chem.* 1904, 432). Traces of fluorine have also been found (Nicklés, *Compt. rend.* 43, 885).

The yolk or yellow is contained within a membrane composed of a proteid allied to keratin (Liebermann, Pflüger's Archiv. 43). It is a viscous, opaque, yellow, alkaline emulsion having a mild taste, and consists chiefly of water, fats, and colouring matter, together with vitellin, lecithin, cholesterol, &c. Müller and Masuyama (*Zeitsch. f. Biol.* 1900, 39, 542) have found a diastatic enzyme in the yolk; and the presence of purine bases has been detected by Mesernitzki (*Biochem. Zentr.* 1, 739).

1000 parts of the yolk contain approximately: water, 480 parts; fats, 228.4 parts; proteid (vitellin), 156.3 parts; lecithin, 107.2 parts; cholesterol, 17.5 parts; insoluble salts, 6.12 parts; soluble salts, 3.53 parts.

According to Poleck, the ash of yolk of eggs contains, in 1000 parts: soda, 51.2–65.7 parts; potash, 80.5–89.3 parts; lime, 122.1–132.1 parts; magnesia, 20.7–21.1 parts; iron oxide, 11.9–14.5 parts; phosphoric acid, 638.1–667.4 parts; silicic acid, 5.5–14.0 parts.

The fat forms about 30 p.c. of the yolk, and may be extracted with ether. It is a mixture of solid and liquid fat, and contains 0.6 p.c. phosphorus, equivalent to 15.04 p.c. lecithin; 61.5 p.c. of neutral fat; and 23.2 p.c. free acids. The neutral fat contains glycerol and acid in such proportions as prove it to consist of *triglycerides* only (Thorpe, *Arch. Nédr. Sci. Exact. Nat.* 1901, 6, 155). On saponification it yields 40 p.c. oleic acid; 38.04 p.c. palmitic acid; and 15.21 p.c. stearic acid (Paladino, *Biochem. Zeitsch.* 1909, 17, 356).

Barbieri, by extracting yolks with carbon disulphide, obtained tristearin and triolein (*Compt. rend.* 1907, 145, 133), besides cholesterol; while MacLean has isolated pure tripalmitin from egg-fat (*Biochem. J.* 1909, 4, 168).

Berthelot and André have determined the heat of combustion of egg yolk to be 8124 calories per gram, as compared with about 5000 calories per gram for most other constituents of foodstuffs (*Compt. rend.* 110, 925).

Lutein, the colouring matter, is a mixture of two substances: *vitellolutein*, which is yellow, and soluble in petroleum; and *vitellorubrin*, a red body, soluble in carbon disulphide (Maly, *Chem. Zentr.* 1881, 485). The mixture is an orange-red amorphous substance, which is not affected by alkalis, and can, therefore, be isolated by hydrolysing the fats. It has been suggested that the characteristic spectroscopic behaviour of the lutein should be used to judge the purity of commercial dried egg yolk (Lewin, Miethe, and Stenger, Pflüger's Archiv. 1908, 124, 585).

Lecithin is present both free and in combination with proteid (Manasse, *Biochem. Zeitsch.* 1906, 1, 246), and may be obtained by extracting yolks repeatedly with alcohol, distilling off the alcohol from the united extracts under reduced pressure, adding ether to the syrupy product, and finally precipitating with acetone (Roaf and Edie, *Chem. Soc. Abstr.* 1905, ii, 364).

Phosphorus is present in the yolk, chiefly as lecithin and lecithin phosphoric acid, and it has been suggested that egg yolk could be estimated by igniting with a little sodium carbonate and nitre, and estimating the phosphoric acid in the residue. 1.129 gram of phosphoric acid represents 100 grams of yolks (Bein, *Ber.* 23, 423). The addition of alkali is necessary to prevent

loss of phosphoric acid during ignition (Juck-nack, *Zeitsch. Nahr. Genussm.* 1899, 905).

Cholesterol occurs in the yolk to the extent of about 1 p.c. (Juck-nack, *l.c.*; Benecke, *Bied. Zentr.* 1881, 568).

Vitellin, the proteid constituent of the yolk, is separated by mixing the yolks with brine, in which the proteid is soluble, and extracting the fat, &c., with ether. It has the properties of a globulin, and, on dialysis or dilution of the solution, is precipitated as a white granular substance. A solution coagulates at 70°–75°.

Vitellin thus obtained is a mixture of compounds of protein matter with lecithin, containing from 15–30 p.c. of the latter, called *lecithin-nucleovitellins*. The lecithin thus combined is not removed by ether, but is completely removed by alcohol, leaving an insoluble proteid, *nucleovitellin*, of constant composition, which, on digesting with pepsin, yields paraneucin.

It is probable that all these proteids are compounds of vitellin with phosphoric acid H_3PO_4 , or some very simple organo-phosphoric acid. The composition of vitellin, free from phosphoric acid, is:

C	H	N	S	O
52.71	7.46	16.64	1.05	22.14

(Osborne and Campbell, *J. Amer. Chem. Soc.* 1900, 22, 413).

Plimmer states that another distinct proteid '*livetin*,' can be obtained from the yolk (*Chem. Soc. Trans.* 1908, 1500).

The **germinal vesicle**, or **white yolk**, forms a layer between the yolk and the yolk membrane, with a process extending to the centre of the yolk. It is enclosed in a membrane, and contains proteids, lecithin, and a nuclein rich in phosphorus (Meischer, *Chem. Soc. Trans.* 1871, 24, 746).

The space between the shell membranes at the broad end of the egg contains a mixture of oxygen, nitrogen, and carbon dioxide, richer in oxygen than the surrounding air (Hufner, *Du Bois Reymond's Archiv. de Physiol.* 1892, *Phys. Abth.* 54).

Eggs contain, on the average, about 4.6 mgms. of ferric oxide. This amount is increased by feeding the hens with foods rich in iron, and '*iron-eggs*' thus obtained have been recommended for therapeutic use, but are very costly (Hartung, *Zeitsch. f. Biol.* 1902, 43, 195; Hofmann, *Zeitsch. anal. Chem.* 1901, 40, 450).

Bertrand states that arsenic is normally present in the egg to the extent of $\frac{1}{250}$ mgm. (*Compt. rend.* 1903, 136, 1083).

Development.—During incubation, the egg respire, giving off carbon dioxide and water, and absorbing oxygen. If this process be stopped by placing the egg in an inert gas, or by rendering the shell impervious to gases, the development of the chick ceases. The respiration is slight for the first four days of incubation, and then increases until, at the ninth day, the respiration of the egg is equal to that of a fowl, weight for weight. This respiration involves combustion of the fat of the egg, and a steady loss in weight (Pott, *Landw. Versuchs. Stat.* 23, 203; *Chem. Soc. Abstr.* 1879, 474).

Levene states that the quantity of xanthine bases and nuclein compounds increases with the growth of the embryo (*Amer. J. Physiol.* 1900, 3, xii).

All the phosphorus in the chick is derived from the yolk and white, and, until the last few days of incubation, no lime is taken from the shell (Voit, *Zeitsch. Biol.* 13, 518; Pott, *l.c.*). At the end of incubation, the shell may supply some of the lime required (Carpiaux, *Bull. Acad. Roy. Belg.* 1908, 283; see also Plimmer and Scott, *J. Physiol.* 1909, 38, 247).

The freezing-point of fresh eggs is 0.427°–0.480°, and rises slightly as incubation proceeds, corresponding to a rise of osmotic pressure from 5.5 atmospheres to 7.3 atmospheres (Atkins, *Biochem. J.* 1909, 480).

The chief *uses of eggs* are as an article of food and in the tanning industry. As the supply of new-laid eggs varies with the season, recourse is had to some means of preserving a proportion of those that come into the market at the time of greatest production.

The following is a list of some processes for preserving whole eggs, which have been patented.

Saturating with carbon dioxide (Lake, *Eng. Pat.* 1653, 1888); wrapping air-tight in rubber-coated paper (Jessen, *Eng. Pat.* 15580, 1891); coating with gelatin (Mills, *Eng. Pat.* 17717, 1891; Farquhar and North, *Eng. Pat.* 15128, 1892; Coakley, *Eng. Pat.* 18816, 1899); with gelatinous starch solution (Schultz, *Eng. Pat.* 1328, 1902); with drying oils, wax, or varnish, with or without previous treatment with antiseptics (Stukes, *U.S. Pat.* 649899; Barlow, *Eng. Pat.* 11054, 1902; Lorne, *Eng. Pat.* 18439, 1901, and 8988, 1901); with boric acid (Markham, *Eng. Pat.* 3513, 1895); with lime (McArdle, *Eng. Pat.* 3592, 1892; Wilson and Wilson, *Eng. Pat.* 15461, 1899); with sulphuric acid (Reinhardt, *Eng. Pat.* 18130, 1898; Marks, *Eng. Pat.* 12867, 1903); and with water-glass (Stead, *Eng. Pat.* 4910, 1882; Rylander, *Eng. Pat.* 23523, 1901).

Comparative tests have been made (*J. Soc. Arts.* 1898, 46, 370; *J. Soc. Chem. Ind.* 1898, 261), which show that the only methods which keep over 90 p.c. of the eggs in good condition for 8 months are: (1) varnishing with vaseline; (2) keeping in milk of lime; and (3) keeping in water-glass solution. Of these the last method is the one least open to objection, and is that chiefly used. Eggs preserved in water-glass have a tendency to burst when boiled, but this can be prevented by piercing the shell with a needle.

The contents of eggs may be preserved by heating at 185°F. with a strong solution of a sugar (glucose, maltose, dextrose, &c.), until the product contains 40–60 p.c. of sugar. It is readily miscible with water, milk, &c., and will keep for some months without deterioration (Fordred, *Eng. Pat.* 15762, 1894; Goodlett, *U.S. Pat.* 692268).

An important method of preserving the whites and yolks of eggs consists in drying the mixture in a current of air at 37°–40° during 18 hours, powdering the product, and again exposing to dry air. The powder is packed in tins, or can be pressed into tablets, and is quite soluble in water (Foschi, *Fr. Pat.* 369967, 1906). A similar product is obtained by drying on a hot roller at a temperature above 212°F. (Hatmaker, *Eng. Pat.* 28, 1905; see also *Eng. Pat.* 8743, 1903, for apparatus).

Substitutes for eggs in baking are made from albumin and casein obtained from skimmed

milk, sometimes mixed with a proportion of dried egg; or from maize meal containing sodium bicarbonate and artificial colouring matter (Beythien and Waters, Zeitsch. Nahr. Genussm. 1906, 11, 272; Bernstein, Eng. Pat. 14336 and 29189 of 1897).

The eggs used for the treatment of leather, especially the finer sorts of glove leather, are preserved in the liquid state by the addition of salt and borax (Jean, Mon. Sci. 1892, 6, 561). Analyses of this material, 'eggio,' show that it contains 2-5 p.c. more water and $3\frac{1}{2}$ -6 p.c. less fatty acid than fresh egg yolk (Boyer, J. Soc. Chem. Ind. 1892, 447). Bein has pointed out that the addition of salt to yolks materially reduces the amount of fat (Bied. Zentr. 21, 138). Rotten eggs could well be used for this purpose, as Cech has found that the available oil is not much diminished in amount, and can be extracted by pressure (J. pr. Chem. [2] 22, 338).

Oil of egg, obtained by extracting yolks with ether, forms about 10 p.c. of the egg, and is used in pharmacy in the preparation of ointments and emulsions. It has no medicinal value (Paladino and Toso, Analyst, 1896, 21, 161). It has the following properties: m.p. 22° - 22.5° ; sp.gr. at 15° , 0.9144; acid number, 1.2; saponification number, 190.2; ether number, 189.0; iodine number, 72.1; Hehner's number, 95.16; Reichert-Meissl number, 0.4 (Kitt, Chem. Zeit. 1897, 21, 303).

Detection, estimation, and analysis.—The presence or absence of egg yolk in pastry can be determined by examination of the fat, there being a great difference in composition and properties between the fat of wheat and of the egg (Spaeth, Zeitsch. Nahr. Genussm. 1896, 10, 171). The amount of egg present in pastry, &c., may be determined by the amount of cholesterol present (Cappenberg, Chem. Zeit. 1909, 33, 985. (For methods for the determination of the constituents of egg yolk for commercial purposes, see J. Soc. Chem. Ind. 1906, 829.)

EGG ALBUMIN v. PROTEINS.

EGG FRUIT. The fruit of *Solanum melongena* (Linn.). A plant of tropical and sub-tropical countries. König gives, as the mean of three analyses—

Nitrogenous		Soluble carbo-		Fibre	Ash
Water matter	Fat	hydrates			
93.2	1.1	0.1	3.9	1.2	0.5

An American analysis (Bull. 28, U.S. Dept. of Agric.) shows a somewhat larger amount of carbohydrates (5.1 p.c.), but is similar in other respects.

This plant is sometimes called *Aubergine*. The fruit is used in much the same way as the tomato.

H. I.

EGOLS. A class of antiseptics consisting of the potassium mercury salts of *o*-nitrophenol-sulphonic acid, the individual members being termed 'phenegol,' 'eresegol,' &c., depending on the phenol from which they are derived. They are reddish-brown powders, readily soluble in water, and are strongly bactericidal (Gautrelet, Compt. rend. 129, [2] 113; J. Soc. Chem. Ind. 1899, 854) (v. SYNTHETIC DRUGS).

EGYPTIAN BLUE. This is a blue colouring matter which was used by the Romans in the first few centuries of the Christian era, but ceased to be manufactured about the time of the invasion of the barbarians. It figures in several beautiful

frescoes in the Vatican, and has also been found at Pompeii. Fouqué discovered the composition to be that of a double silicate of calcium and copper $\text{CaO}, \text{CuO}, 4\text{SiO}_2$, devoid even of traces of alkali. The substance is crystalline, and is hardly attacked by any chemical reagents, which explains the perfect state of its preservation in the paintings for which it was employed 1900 years ago. It may be prepared at a bright-red heat, but this temperature must not be exceeded, as it is then decomposed into cuprous oxide, wollastonite, and a clear light-green glass. The higher the temperature, the more of the latter is formed, and, finally, wollastonite disappears entirely. By the old method of preparation, described by Vitruvius, fine sand and soda are intimately mixed with copper filings, then moistened with water, formed into cakes, and the latter dried. The cakes are then fused in an earthen pot until the blue colour is produced. Fouqué found this method practicable, but used potassium sulphate in preference to soda as a flux. It was not possible to replace chalk or lime by magnesia. The ancient Romans employed a large excess of silica, whilst Fouqué employed more basic mixtures, finally purifying the product with hydrochloric acid. The exquisite colour of this mineral body, the fact that it is absolutely unaffected by moisture, light, and most chemical reagents, as well as the facility and the low price of production, render it desirable that its manufacture should be again resumed (F. Fouqué, Compt. rend. 108, 325-327; and J. Soc. Chem. Ind. 8, 291).

EIKONOGEN. Sodium salt of 1-amino- β -naphthol-6-sulphonic acid. Used as a photographic developer.

EKSANTALAL $\text{C}_{12}\text{H}_{18}\text{O}$. Obtained on oxidation by ozone of the sesquiterpene primary alcohol α -santalol $\text{C}_{15}\text{H}_{24}\text{O}$, which, together with the isomeric β -santalol, constitutes 'santalol,' the oil resulting from the hydrolysis of the hydrogen phthalate made from the oil obtained by distilling sandalwood with steam (Semmler, Ber. 43, 1893).

It is dextro-rotatory ($\alpha_D +13.5^{\circ}$); b.p. 109° - 110° , under 10 mm.; sp.gr. 0.9846 at $20^{\circ}/20^{\circ}$; n_D^{20} 1.48519.

It gives an oxime, which yields the corresponding nitrile and amine, and gives eksantalol on reduction (Semmler, Ber. 41, 1488).

Heated with acetic anhydride and sodium acetate, it forms *enol*-eksantalol acetate

which, on oxidation with potassium permanganate, yields noreksantalol acid $\text{C}_{11}\text{H}_{16}\text{O}_2$ (Semmler, Ber. 43, 1722-1725), the methyl ester of which, on reduction by sodium and alcohol, yields noreksantalol $\text{C}_{11}\text{H}_{18}\text{O}$; and this on oxidation in benzene solution with potassium dichromate and dilute sulphuric acid, gives *noreksantalal* $\text{C}_{11}\text{H}_{16}\text{O}$, b.p. 92° - $94^{\circ}/11$ mm.; sp. gr. $20^{\circ}/20^{\circ}$ 0.9964, n_D 1.48301, α_D -30.8° .

The *enol*-noreksantalol acetate gives, on oxidation by potassium permanganate, *teresantalol* acid

(Semmler and Zaar, Ber. 43, 1890).

In all three series, containing 10, 11, and 12 carbon atoms respectively, the same tricyclic system is present as exists in α -santalol; and

Semmler (Ber. 43, 1893-1898) assigns to these bodies constitutions based upon the camphene or camphor type, and α -santalol and eksantalal are structurally represented as below:

EKTOGAN. Trade name for a mixture of zinc dioxide with zinc oxide and carbonate, used as a surgical dressing.

ELÆOMARGARIC ACID $\text{C}_{18}\text{H}_{32}\text{O}_2$. An acid, melting at 48° , obtained by the saponification of elæococoa oil (Japanese wood oil) with alcoholic potash, and decomposing the *trielæomargarin* thus formed. The glyceride when first formed is liquid, but on exposure to light gradually solidifies. Isomeric with elæostearic acid, elæoleic acid, and linoleic acid. On exposing an alcoholic solution to light, plates of elæostearic acid, m.p. 71° , are precipitated (Cloëz, Bull. Soc. chim. 1876, 26, 286; 1877, 28, 24); traces of iodine or sulphur also bring about this change (Maquenne, Compt. rend. 135, 696). Oxidation with potassium permanganate gives rise to azelaic acid, sativic acid, and dihydroxystearic acid (Kametaka, J. Soc. Chem. Ind. 1903, 1138; 1908, 1120; Kit, Chem. Soc. Abstr. 1905, i. 10; Maquenne, *l.c.*). Linoleic acid also on oxidation yields sativic acid, and on bromination, linolic acid and elæomargaric acid yield the same tetrabromide. Elæostearic acid and linoleic acid yield the same diozonide (Majima, Ber. 1909, 674). Elæomargaric acid and elæostearic acid are converted into elæoleic acid when heated at 180° in sealed tubes (Cloëz, J. 1878, 38).

ELÆOPTENE. The volatile portion of an essential oil, used in contradistinction to the *stearoptene* or solid portion.

ELÆIDIC ACID $\text{C}_{18}\text{H}_{34}\text{O}_2$. A solid stereoisomeric modification of oleic acid, obtained by the action of nitrous acid upon olive oil, saponifying the glyceride (elaïdin) so formed, and decomposing the salt by hydrochloric or sulphuric acid. May also be obtained by the action of nitrous acid or of nitric acid (sp. gr. 1.2) (Edmed, Chem. Soc. Proc. 1899, 190) upon oleic acid, or by decomposing barium oleate with fuming nitric acid; m.p. 52° (Saytzeff, Chem. Soc. Abstr. 1893, 551); b.p. $287.5^\circ\text{--}288^\circ$ at 100 mm. (Krafft and Mördlinger, Ber. 1889, 819). Soluble in alcohol and ether. Solutions have an acid reaction. The melted acid gradually absorbs oxygen from the air, and becomes permanently liquid. It may be distilled unchanged under diminished pressure. Heated with potassium hydroxide, it is converted into acetate and palmitate of potassium with evolution of hydrogen.

Elaïdic acid dissolved in benzene, toluene, ligrcin, or chloroform, and mixed with caustic soda and shaken, gives a brilliant phosphorescence (Radziszewski, Annalen, 203, 305). Hydriodic acid forms an addition compound (iodostearic acid) with elaïdic acid (Farb. vorm. Fried. Bayer & Co. D. R. P. 180087; Chem. Soc. Abstr. 1907, i. 380), which, on treatment with alcoholic potash, yields oleic and *iso*-oleic acids (Lebedeff, *ibid.* 1893, 550). On reduction with nickel or copper and hydrogen at $280^\circ\text{--}300^\circ$, elaïdic acid is converted into stearic acid (Sabatier and Mailhe, Ann. Chim. Phys. [8] 4, 319). Treated with dilute solution of potassium permanganate in presence of potash, it is converted into a dihydroxy acid, which differs from the corresponding compound obtained from oleic acid by its lower melting-point (99.5°), and its greater solubility in alcohol and ether, and also into pelargonic, azelaic, and oxalic acids (Saytzeff, Ber. 1886, 21; Edmed, Chem. Soc. Trans. 1898, 627); oxidation with sulphuric acid, however, gives rise to the same dihydroxystearic acid as is obtained from oleic acid under the same conditions (Tscherbakoff and Saytzeff, J. pr. Chem. 1898, 27).

Elaïdin, a solid isomeric of olein, is obtained by the action of nitrous acid upon olein, and is probably a triglyceride $\text{C}_{57}\text{H}_{104}\text{O}_6$. It melts at 36° ; is nearly insoluble in alcohol, readily soluble in ether. The *Unguentum oxygenatum* and *U. citrinum* of the pharmacopœias, prepared by the action of nitric acid upon hog's lard, contain impure elaïdin.

ELÆIDIN *v.* ELÆIDIC ACID.

ELALDEHYDE *v.* ALDEHYDE.

ELATERIN *v.* ELATERIUM.

ELATERITE. *Elastic bitumen, Mineral caoutchouc.* A fossil resin, somewhat resembling asphalt, found at Castleton in Derbyshire, in France, Switzerland, &c. It is a soft, flexible, elastic, and readily inflammable substance, with a resinous lustre and a dark-brown colour.

ELATERIUM. The sediment from the juice of the fruit of the *Ecballium elaterium* (Richard), or squinting cucumber. Elaterium is a drastic purgative.

Pereira (Mat. Med. 3rd ed. 2, 1742) gives a *résumé* of the work of Braconnot, Clutterbuck, Paris, Marquart, and others on elaterium, and of the discovery of *elaterin* by Hennel (J. Roy. Inst. 1, 532), and independently by Morris (ed. Med. Surg. J. 35, 339; Annalen, 2, 366). Good specimens of elaterium when extracted with chloroform yield 25 p.c. of elaterin, which by recrystallisation is obtained in minute shining six-sided plates. The dose of elaterin is $\frac{1}{10}$ to $\frac{1}{15}$ of a grain, and to it is ascribed the whole of the physiological activity of elaterium. Elaterin is a neutral bitter compound, insoluble in water, but soluble in chloroform and hot alcohol. It melts at 200° (Zwenger, Annalen, 43, 360). If sulphuric acid be added to a solution of elaterin in melted phenol, a crimson colour is produced which changes to scarlet (Lindo, Chem. News, 37, 35; Johannson, Zeitsch. anal. Chem. 24, 154).

On hydrolysis with alcoholic potash, elaterin furnishes acetic acid and an amorphous compound, *elateridin*. Further action of alkali gives *elateric acid*, also amorphous, and melting at $73^\circ\text{--}75^\circ$ (Berg, Bull. Soc. chim. [iii.] 35, 435).

Elaterin of English origin, examined by Power and Moore (Pharm. J. [iv.] 29, 501), was found to contain 5.3 p.c. of moisture and 6.7 p.c. of ash. By a suitable method of extraction, a colourless crystalline product, m.p. 217°-220°, was obtained, corresponding with the elaterin of the pharmacopœias. This was found to be non-homogeneous, consisting of at least two substances, one, *α-elaterin*, melting at 230° with decomposition, and *lævo-rotatory*, whilst the other, *β-elaterin*, has a lower melting-point, and is *dextro-rotatory*. Both have the same empirical composition, but the former is physiologically inert, whilst the latter shows marked physiological activity. Examination of commercial elaterin showed that it consists mainly of varying proportions of these two substances, which probably accounts for the marked difference in medicinal value of different samples. *α-Elaterin* has also been found in *colocynth*, the dried fruit of *Citrullus colocynthis* (Schraeder) (Power and Moore, Chem. Soc. Trans. 97, 99), and has been further investigated by Moore (*ibid.* 97, 1797).

According to Berg (Bull. Soc. chim. [iii.] 17, 85; [iv.] 7, 385), elaterin does not exist ready-formed in the fruit, but is produced after the rupture of the tissues by the action of an enzyme *elaterase* on a glucoside present. The latter consists of a brittle, amorphous powder, and gives the same reactions as elaterin with sulphuric acid and phenol. Power and Moore (Chem. Soc. Trans. 95, 1985), however, on examination of the fresh fruit, failed to obtain any evidence of the presence of a glucoside of elaterin, but a small amount of an enzyme was found to be present. These investigators also obtained from the fresh fruit a small amount of a hydrocarbon, m.p. 68°, probably hentriacontane; a phytosterol $C_{27}H_{48}O$, m.p. 148°; a substance melting at 258°-260°, which appears to be related to ipuranol; a mixture of fatty acids and a product corresponding to the elaterin previously examined.

A. S.
ELDERBERRY. The fruit of *Sambucus nigra* (Linn.). The only analysis quoted by König gives, as the composition of the fruit—

Water	Crude fibre	Pentosans
81.9	6.6	1.2

The berries are used for the preparation of a wine and of 'elderberry syrup,' an old-fashioned cordial. From the wine, a brandy is sometimes distilled, which according to analyses by Arnthor and Zink, quoted by König, contains 39.2 p.c. of alcohol (by weight) and has a sp.gr. of 0.836. According to de Sanctis (Gazz. chim. ital. 1895, 25, 49), elder leaves and stems contain conine. Malméjac (J. Pharm. Chim. 1901, 14, 17) attributes the diuretic and purgative action of the bark of the elder to an alkaloid, *sambucine*, a deliquescent bitter substance, yielding the usual alkaloid reactions. He also found elder bark to contain tannin, a resin resembling scammony and a yellowish-red oil possessing a strong odour of elder. Elder pith contains both xylan and araban (Browne and Tollens, Ber. 1902, 35, 1457). The oil extractable from the juice of red elderberries (*S. racemosa*) by ether, is light yellow in colour, has a sp.gr. of 0.9072, solidifies at -8°, and melts at 0°; contains 6.65 p.c. of free acid (as oleic acid), 0.66 p.c. of unsaponifiable matter, has a saponification number 209.3, iodine number 81.4, and

Reichert-Meißl value of 1.54 (Byers and Hopkins, J. Amer. Chem. Soc. 1902, 24, 771).

The leaves of the elder contain a cyanogenetic glucoside, which, under the influence of emulsin, yields dextrose, benzaldehyde, and hydrogen cyanide; the yield of the last mentioned amounts to 0.126 gram per kilogram of fresh leaves (Guignard, Compt. rend. 1905, 141, 16; Bourquelot and Danjon, *ibid.* 59). This glucoside, which has been named *sambunigrin* $C_{14}H_{17}O_6N$, crystallises from ethyl acetate in long, colourless needles, melting at 151°-152°, is readily soluble in water or alcohol, but nearly insoluble in ether (Bourquelot and Danjon, Compt. rend. 1905, 141, 598).

According to Ravenna and Tonegutti (Chem. Zentr. 1910, i. 544) the enzyme which decomposes the glucoside in the plant is not soluble in water. The hydrocyanic acid is present in larger quantities than has hitherto been believed, and is most abundant in the stalks. H. I.

ELECTRO-DEPOSITION AND ELECTRO-PLATING. Electrolytic processes are now used to a considerable extent in the precipitation of metals in a reguline form, so as to be available for many commercial purposes. Thus the common and easily corroded metals are coated with thin films of electro-deposited metal of a more permanent and less oxidisable character, in the process of electroplating; for the reproduction of engraved surfaces, type, &c., in electro-deposited copper, electrolysis is applied in electrotyping; and in the deposition of a pure metal from an impure form or a mixture of metals, the principles of electrolysis are applied in the processes of electrolytic refining and in chemical analysis.

An electric current passed through solutions of metallic salts brings about decomposition of a particular type, and is accompanied by the deposition or evolution of the products, or others which may have been formed as the result of secondary changes. When copper sulphate solution is electrolysed with a platinum anode, copper is deposited at the cathode, and oxygen and sulphuric acid are formed at the anode, thus:

Other metallic compounds follow a similar course. The primary products of decomposition consist of charged atoms or groups of atoms. These are termed *ions*, and migrate to the electrodes, those to the anode being called the *anions*, and those to the cathode *cations*. Anions consist of the acidic group of the salt, while the cations comprise hydrogen, the metals, and basic radicles. At the electrodes, the electrical charges are neutralised, and the substance appears in the nascent form, subsequently being deposited or evolved. Elementary anions, such as chlorine, bromine, and iodine may enter into subsequent secondary changes, while others, such as NO_2 , SO_4 , $\text{C}_2\text{H}_3\text{O}_2$, &c., react with water, giving generally the corresponding acid, and liberating oxygen. With soluble anodes—those attacked by the anion—solution of the metal takes place, and thus, in a copper solution, a copper anode supplies metal under

the best conditions as rapidly as metal is deposited. The strength of the solution is thus maintained, a condition necessary for continuous deposition as required for plating and refining purposes.

The deposition of metals follows the usual law of chemical equivalents as enunciated by Faraday in 1835. The ampere-hour is thus associated with a definite amount of metal, which cannot be exceeded, but may not be attained owing to failure in realising the best conditions. The weights of metals deposited by the coulomb, ampere-hour, and 746 ampere-hours, are shown in the following table :

Metal	Chemical equivalent	Mgs. per coulomb	Grams per ampere-hour	Ozs. (av.) per 746 ampere-hours
Copper (cupric)	31.8	0.329	1.182	31.0
.. (cuprous)	63.6	0.658	2.364	62.0
Gold (auric)	65.7	0.680	2.440	58.6 (Troy)
.. (aurous)	197.0	2.040	7.320	176.0 "
Iron	28.0	0.290	1.040	27.3 "
Lead	103.5	1.070	3.870	101.0
Nickel	29.3	0.302	1.085	28.5
Silver	108.0	1.118	4.025	96.5 (Troy)
Tin (stannous)	59.0	0.610	2.190	57.5
.. (stannic)	29.5	0.305	1.095	28.7
Zinc	32.5	0.336	1.210	31.8

These amounts, however, can only be deposited when the cathode is surrounded by a considerable amount of strong electrolyte, and only under this condition can the facts of electrolysis be applied, as in the voltmeter, to the determination of the number of coulombs passing through a circuit. While for most industrial purposes it is not necessary for the theoretical amount of metal to be deposited per ampere-hour, yet the most satisfactory deposits are, in many cases, obtained when this condition is most nearly attained. Failing the full amount of metal per ampere-hour, hydrogen is deposited, and this often leads to a dark powdery deposit unsuitable for industrial purposes. Such deposits, caused usually by excessive current, are said to be 'burnt.' In some solutions—for example, those of copper, iron, or nickel sulphate—this inferior deposit seems to result from the simultaneously deposited hydrogen due to a weak electrolyte. In other examples, that of the alkaline or cyanide copper bath, it would seem (from the fact that much hydrogen may be deposited without 'burning') more probably due to the deposition of traces of basic compounds with the metal (Banerft, Trans. Amer. Electrochem. Soc. vi. [ii.] 27). This view is supported by the fact that the presence of substances in the solution, which are good solvents for such basic compounds, prevents 'burning' to a considerable extent. Thus, in the alkaline copper-bath, 'burning' is reduced, and the quality of the deposit improved by the addition of such salts as sodium bisulphite and potassium cyanide. In other examples, notably those of tin and lead, the deposit is much improved by the addition of a trace of a colloid, such as glue or gelatine.

Migration of ions. It is well known that ions migrate to their respective plates with definite speeds under unit potential gradient. If deposition proceeds more rapidly than this rate of migration, the cathode liquid becomes impoverished of its metal, and this involves a falling off in the ampere-hour yield. The deficiency of metal around the cathode is counteracted to a limited extent by the ordinary process of diffusion, but there is a limit at which metal may be satisfactorily deposited, unless special steps are taken to make up for this slow migration. Methods of circulation and stirring are based on this fact, and also on the further fact that the heavier solution formed around the anode falls to the bottom of the solution, and, owing to its superior conductance, gives rise to the conduction of an undue proportion of the current and consequently thicker deposits on the portion of the cathode in this heavier layer; hence a limit to the rate at which deposition may be safely allowed to proceed is set, and the time required to deposit a given amount of metal varies correspondingly.

E.M.F. for deposition. With an insoluble anode, a definite minimum E.M.F. is required to maintain electrolysis. Thus, when copper sulphate is decomposed with a platinum anode, the total change is as follows:—

This, as a chemical change, is endothermic, and electrolytically it demands a minimum E.M.F. of about 1.25 volts for its continuance. When a copper anode is used, no change in the composition of the solution occurs. Energy changes at both electrodes are equal and of opposite character, and hence a much smaller E.M.F., viz. that required to overcome the mere resistance of the solution, is required. With efficient anode solution and a good conducting electrolyte, such as is obtained in an acidified copper sulphate solution, a P.D. of about 0.3-0.5 volt will maintain a fair rate of deposition. In the case of nickel, where there is usually inefficient anode solution and a poorly conducting electrolyte, a much higher P.D. is required, partly on account of the greater stability of nickel compounds. Figures given, therefore, for P.D.'s at both terminals are of a very elastic character, depending upon the efficiency of anode solution, strength of solution, temperature of the solution, distance between electrodes, presence or otherwise of conducting substances in the solution, and current density required; while the conditions controlling the allowable current density at the cathode are chiefly the strength of the electrolyte and its motion.

The deposition of copper may be accomplished by simple immersion methods, resulting in a chemical exchange with the more positive metal plated; thus:

The process is but little used, and then only for very cheap work. Deposits on a surface which is undergoing simultaneous corrosion, cannot be sufficiently adherent to withstand the frictional processes of polishing and burnishing.

The single-cell process, practised at one time, involves the generation of current and the deposition of metal in the same apparatus.

more positive and more corrodible metals, and as a preliminary deposit before coating with the more expensive metals. Deposits of copper on iron may then be burnished or polished and the surface improved by metal-colouring, when, by chemical processes, the surface is covered with a uniform film of oxide or sulphide by immersion in solutions producing these compounds, such as the salts of copper and soluble sulphides. Uniform and pleasing effects are readily obtained, and may be rendered more permanent by subsequent lacquering. The metal is also deposited on a considerable scale in the electrotyping process, thin, but rigid reproductions of type, engraved plates and blocks being made in electro-deposited copper, and subsequently strengthened by backing with a lead-antimony alloy, which is then planed down to the required thickness.

Analytically, copper deposition is applied in the separation of this metal from more positive metals in an acid solution with a platinum anode. From a solution of brass in nitric acid, the copper may be most completely deposited without interfering with the zinc. The copper deposit made on a platinum dish or suitable electrode is then weighed, and the zinc obtained by either a chemical or a further electrolytic method (*v. ANALYSIS*). On a commercial scale, the deposition of copper has been applied by Cowper-Coles to the production of parabolic mirrors for lighthouse work, and to the production of sheet, wire, and tubes. The manufacture of deposited tubes of large diameter has been successfully carried on by Elmore Bros., who arrange an agate burnisher to travel backwards and forwards along the tube during deposition, thereby producing a compact deposit of good mechanical properties. Tubes up to 16 feet long by 8 feet diameter, and weighing more than 3 tons, have been produced by this method. More usually, however, tubes are of smaller dimensions, and are subsequently drawn down or opened longitudinally for the production of sheets. Copper is deposited on a most extensive scale in the refining process, more than half a million tons of the metal annually being refined in this manner, using a solution of the sulphate with thick anodes of the crude metal. The crude metal contains up to 1.0 p.c. of impurities. The deposited metal is almost entirely free from impurity. Positive impurities pass into the solution, and are retained there by the application of the principle used in electrolytic analysis. Electro-negative impurities, as silver and gold, pass as chloride and metal respectively into the mud at the bottom of the tank, from which they may be recovered. Tin, antimony, arsenic, and bismuth are prevented from being deposited by a careful control of the conditions, and the sum-total of impurities in the refined metal is usually less than 0.05 p.c.

Deposition of silver. Silver, being an electro-negative metal, is readily deposited by simple immersion. The process is applied commercially under the name of 'whitening.' Solutions for this purpose contain a small proportion of a silver compound, such as chloride or cyanide, dissolved in cream of tartar, sodium chloride, or similar solvent. The deposition on properly prepared work is a case of simple replacement, and only very thin

deposits are obtainable by this means. The same materials may also be used in the form of pastes, and rubbed on the prepared work with a wet rag, this method finding application in silvering clock and instrument dials.

Electro-deposition is most frequently practised. For this purpose the nitrate solution is unsuitable on account of its instability, being serviceable only as a voltameter electrolyte where the very electro-negative metal platinum is used. For silvering on more positive metals, those which usually require silver plating, a solution of the double cyanide of silver and potassium is used. This may be prepared from the metal as follows:—

(a) The metal is converted into nitrate, and precipitated with potassium cyanide. When precipitation is just complete, the clear liquid is decanted and the precipitate washed and subsequently dissolved in more cyanide solution, a further supply of cyanide being added for 'free cyanide.'

(b) Precipitation may be effected by common salt, and the washed chloride dissolved in excess of potassium cyanide.

(c) A silver plate may be made the anode in a 5 p.c. solution of potassium cyanide, using a small copper or carbon cathode contained in some of the solution in a porous cell. The silver dissolves electrolytically, and the process can be continued until sufficient silver has passed into the solution and a good deposit is obtainable from it.

The solution is used cold, and yields a dull deposit of the metal, which may subsequently be scratch-brushed, burnished, and polished. The addition of a small proportion of carbon disulphide (1 oz. in 250 gallons) completely alters the character of the deposit from dull to bright. 'Bright plating' is, therefore, much practised. The silver compound in the solution being somewhat unstable, special precautions are necessary before placing work in the solution for deposition. Copper, brass, and German silver may be plated directly, though previous to deposition it is common practice to pass such work through a solution of mercury cyanide. This solution can be prepared by treating a soluble mercuric compound with excess of potassium cyanide, or by dissolving the oxide in cyanide. A usual strength is 1 oz. of metal per gallon. From such a 'quicking' solution a bright deposit of mercury is obtained on brass, copper, and German silver by simple immersion, with the advantages that the more negative metal mercury is less oxidisable than copper, &c., and prevents simple immersion deposition of silver when the work is put into the bath, and possibly promotes the adhesion of the subsequently electrolytically deposited silver, by amalgamation. More positive metals, like iron and zinc, are first coppered in the alkaline bath, and subsequently treated as copper. With the lead alloys it is usual to pass them straight from the cleansing processes through a separate silver solution, from which a rapid deposit is first made. This, similarly with nickel, is termed 'striking,' after which the work is transferred to the main solution to complete the deposition.

The current density permissible is controlled largely by the metal content of the solution,

Excessive current produces a light-grey, dark-grey, or black deposit, which, being powdery, is unable to withstand the processes of burnishing and polishing.

Silver anodes should be of fine metal, preferably annealed, and, therefore, more susceptible to solution. Their behaviour is an indication of the condition of the solution. If a dull deposit collects upon them, with a falling off in the current, more free cyanide is required to dissolve the insoluble single cyanide which forms upon them. On the other hand, excessive free cyanide unduly promotes the solution of the anode, limits the permissible current density at the cathode, lowers the cathode efficiency, and promotes simple immersion deposition on work which is not 'quicked.' The amount of free cyanide present can easily be determined in this and other cyanide solutions with standard silver nitrate.

The deposition of gold is practised considerably on account of the pleasing colour and permanence of the deposit. Deposition is easy owing to the strong electro-negative character of the metal, and for electro-gilding, as with electro-silvering, cyanide solutions are used. Gold may be applied to metallic surfaces by three methods, viz.: (1) mercurial gilding; (2) simple immersion; and (3) the electrolytic method. Mercurial gilding is used for heavy deposits of gold. An amalgam of gold is first prepared by pouring mercury on to hot gold. Excess of mercury is squeezed through chamois leather, and the pasty amalgam preserved in balls under water. It is applied to the prepared metallic surface with a wire brush, which has first been wetted with a weak solution of mercuric nitrate. This is rubbed on the amalgam and then on to the work, depositing a layer of amalgam. When a uniform coating is obtained, the mercury is expelled in a muffle, and the process repeated for thicker deposits. The dull surface is improved by scratch-brushing. This process is largely employed.

Simple immersion methods are followed, for mere films of metal, in solutions of very varied composition. A moderately strong solution of sodium pyrophosphate is prepared (5-10 p.c.), and gold chloride added a little at a time. The warm solution at once gives up its metal, but the deposits can, in any case, only be very thin, though they may be thickened somewhat by 'quicking' in a mercury solution and reimmersing in the gold solution.

Gilding with the separate current is largely practised, using a solution prepared by the following or similar methods:—

(1) Making a gold sheet the anode in a cyanide solution (4 ozs. per gallon), using a cathode contained in a porous cell. The process is continued until sufficient metal is lost from the anode or until the solution yields a good deposit.

(2) Precipitating gold chloride with ammonia, avoiding excess, and dissolving the washed precipitate in potassium cyanide solution.

The metal content may vary from a few pennyweights to a few ounces per gallon. The solution is used warm with a gold anode, which is electrolytically corroded, or by a less desirable method of using an insoluble platinum anode

and making frequent small additions of gold chloride. The colour of the deposit varies considerably with the conditions, chiefly that of current. Other conditions, such as temperature, size of anode, distance between electrodes, metal content, also apparently affect the colour; but these varying conditions primarily influence the current. Cold and weak solutions give a pale colour, which may be improved by warming. Excessive current produces darker and foxy deposits, which are, however, improved by scratch-brushing. More satisfactory deposition proceeds when the work is kept in motion. The colour of the deposit is heightened somewhat by a preliminary coating of copper, while a deposit of silver has the reverse effect, though occasionally required. The colour is modified also by the addition of copper and silver cyanides to the solution. Thick deposits are most satisfactorily obtained by occasional scratch-brushing and 'quicking.'

The deposition of nickel is now very largely applied on account of the hardness of the deposit and its permanence, together with the exceptional lustre which can be imparted to it by polishing. The solution most commonly employed is:

Nickel ammonium sulphate	12 ozs.
Water	1 gallon.

To this solution, additions are frequently made to increase the conductance, sal-ammoniac or common salt being used. Owing to the fact that no free mineral acid is permissible, and the tendency also to the formation of nickel hydroxide at the cathode, small additions of acids, such as citric, boric, or acetic, are made with varying success. The only modification in the above solution which adds any appreciable advantage, is that of nickel sulphate, which is so much more soluble than the double salt, and from which, therefore, much stronger and therefore better, conducting solutions can be prepared. For thick deposits, Langbein recommends the use of 3 lbs. of nickel sulphate per gallon, with the addition of ethyl sulphate or magnesium ethyl sulphate. On account of the greater stability of nickel compounds and the poor solution of the anodes, and also the absence of free mineral acid, a distinctly higher E.M.F. is required than for copper deposition, viz. 5-6 volts for 'striking,' that is, rapidly coating the work with nickel, and then 2-3 volts for depositing the bulk of the metal. The absence of free acid necessitates especial care in the preliminary cleansing processes, most work being finally passed through a weak solution of cyanide (5 p.c.), and quickly and thoroughly rinsed before being put into the vat. The nickel-plating solution is usually worked cold, and is conveniently contained in lead-lined vats. Anodes may be of cast or rolled metal, the cast being much superior, as its porosity assists its corrosion under the influence of the current. Rolled metal is but little attacked by the anion SO₄, and, failing the solution of the anode, sulphuric acid is produced and oxygen evolved; thus:

This acidity is to be avoided, and with it there is a diminution in the metal content of the solution which is similarly undesirable.

Cast anodes are therefore much more largely used, more uniform conditions being maintained with them. On account of the high E.M.F. used, some hydrogen is evolved at the cathode, though the current efficiency should not ordinarily fall below 90 p.c. Occasional motion of the work is desirable in order to disengage any bubbles which may collect. Once deposition has commenced, the work should not be exposed more than momentarily, otherwise an imperceptibly thin film of oxide will form and almost entirely prevent the adhesion of further deposited metal. In fact, it is considered impossible to successfully deposit nickel on such a surface or on a previous deposit. On this account, previously nickelled work should be entirely freed from its nickel, and, while this may be done by acid solutions, common practice follows the method of polishing, at the same time preparing the surface for the new deposit. Copper and brass work is nickelled directly after the usual cleaning operations, whilst positive metals like zinc and Britannia metal require a previous deposit of copper from the cyanide bath. Iron and steel may be nickelled without coppering, the polished surface being first rendered somewhat dull by scouring with finest pumice. The deposit should be kept bright, and this is attained by a current density not exceeding 5 amperes per square foot. Higher current densities produce dull deposits, tending to become powdery on the edges. The nickel deposit is very hard, and the final lustre is obtained by 'finishing' with Sheffield lime, which produces a highly lustrous surface. In addition to the extensive cycle and motor industry, nickel-plating is applied considerably for small machine parts and instrument work and for 'facing' stereotypes, the deposit being much more durable than the stereotype metal.

The **deposition of iron** is carried out on lines similar to those for nickel, solutions of ferrous sulphate or ferrous ammonium sulphate being used. These must be entirely free from mineral acid, more so than in the case of nickel, and water should be well boiled before being used, to expel air and prevent the oxidation of ferrous to ferric compounds. Ferric compounds under electrolysis yield little metal, being reduced to ferrous at the cathode. The process is not much used beyond the application in 'steel-facing' engraved plates. The iron deposit obtained is free from carbon, but is very hard. Anodes of the softest wrought iron containing a minimum of carbon are desirable, and require occasional scouring to remove the layer of insoluble carbon. The deposition of iron has also been used for thicker deposits, which have subsequently been removed and examined to investigate the properties of pure iron, and to more successfully determine the effect of impurities. For 'steel facing,' the engraved plates are cleaned, any scouring being done with only a light brush. The plate is then hung in the bath and covered quickly by 'striking.' Deposition is then continued more slowly for 10-15 minutes. The deposit is very hard and withstands the printing process much better than copper. When the deposit shows signs of wear by the exposure of copper, the metal is simply and readily removed by immersion for a short time in a 5-10 p.c. sulphuric acid. By voltaic

action the iron is soon dissolved from the plate, and, after a light scouring with a fibre brush and subsequent rinsing, the plate is again immersed in the solution to receive a further coating of iron, thus considerably lengthening its life.

Deposition of alloys. (1) *Brass.* From mixed solutions of zinc and copper sulphates with the addition of acid, copper can be completely deposited free from zinc, this principle being applied in electrolytic analysis and also in refining. With salts more alike in stability, the two metals are deposited simultaneously in proportions varying with conditions. The cyanides are invariably used for this purpose, the zinc and copper compounds being used in about the same quantity. The mixed solution may be prepared in many ways, of which the following are in common use:—

(a) Treating solutions of the mixed sulphates with excess of ammonia and adding about 30 p.c. more cyanide (KCN) than is required to decolourise the blue solution.

(b) Preparing a solution of potassium cyanide (1-1½ lbs. per gallon) and saturating about three quarters of it with the mixed carbonates of zinc and copper, subsequently adding the remaining solution for 'free cyanide.'

The solution may be used warm or cold. If cold, a higher concentration is desirable, and also a smaller proportion of zinc compound. If warm, the zinc compound should be increased and the solution may be safely diluted. Brass anodes are used, and, in a warm solution with a fair proportion of free cyanide, dissolve under the influence of the current. Lack of free cyanide gives rise to the formation of a deposit of the two single compounds on the anode, adding resistance and reducing the current, and thus altering the colour of the deposit. The colour and composition of the deposit vary with several conditions. In general, the conditions which demand a higher E.M.F. give rise to a lighter deposit containing more zinc, whilst those which reduce the resistance of the solution tend to the production of redder deposits containing more copper. Thus yellower deposits are produced in cold dilute solutions with little free cyanide, whilst the copper in the deposit is increased when the solution is strengthened or warmed, or more free KCN added. The composition of the deposit is controlled also by the proportion of the two metals in the solution, and the fact that from cyanide solutions copper and zinc are ordinarily deposited in the proportion of 63.6 of copper: 32.5 of zinc accounts approximately for the 2:1 proportion in deposited yellow brass. The colour of the deposit is lightened by the addition of ammonia or ammonium carbonate, these substances assisting the solution of the zinc compound, which is less soluble than the copper compound, and preventing the formation of basic compounds.

The methods of deposition of brass follow on the same lines as those of copper from the cyanide solution.

(2) Other alloys are deposited to only a very limited extent. The choice of solutions depends upon the ease of mixture of solutions from which the constituents can be separately deposited. Thus for bronze, the sulphate, chloride and cyanide solutions, are unsuitable.

A satisfactory mixture can be made from the double oxalates of the two metals with ammonium oxalate, the solution being worked warm with a bronze anode. Similarly, a solution from which German silver may be deposited may be prepared by mixing the separate double cyanides of copper, zinc, and nickel with potassium cyanide, or by dissolving the alloy in nitric acid, precipitating the mixed carbonates and dissolving the mixture in cyanide. The deposition of these alloys is subject to the same conditions as for brass, attention being paid to those conditions which facilitate the deposition of the more positive constituents, viz. tin, zinc, and nickel.

Deposition of tin may be successfully carried out from a number of solutions. The chloride yields a beautiful crystalline deposit, but reguline deposits may be obtained from solutions of the stannite, stannate, or double oxalate with ammonium, with ease. They are prepared as follows:—

(1) The hydrate is precipitated from stannous chloride with alkali, and the precipitate dissolved in excess of alkali.

(2) By converting the metal to hydrated oxide with nitric acid, and dissolving the washed oxide in alkali.

(3) By adding a solution of ammonium oxalate to tin chloride. A white precipitate first forms, and this is soluble in excess.

Solutions containing from 1 to 2 ozs. of metal per gallon are of convenient strength. From these solutions tin may be obtained as a reguline deposit within certain limits of current density. Excessive current produces a grey spongy deposit, which may, however, be considerably improved by the addition of a small amount of glue or gelatine, thereby extending the limit of allowable current. Solutions of moderate strength yield metal quantitatively, and the anode suffers normal corrosion, maintaining the strength of the electrolyte. The dull white deposit is improved by gentle scratch-brushing with a soft brush. Tin may also be deposited without the current by using an oxalic acid solution to which tin chloride is added. The metal is deposited by simple immersion, and the process may be improved by the addition of grain tin with the work, which facilitates deposition by local voltaic action, while tin passes into the solution. The process is hastened by immersing the small work in zinc trays, the zinc passing into the solution as an anode. In this case the solution must be replenished with tin chloride, and rejected when any large amount of zinc has accumulated in it.

The **deposition of lead** may be similarly effected from alkaline solutions, which yield reguline deposits, whilst the acetate produces the well-known crystalline deposit. The process has but little application, but more recently the deposition of the metal has been successfully applied by Betts to the refining of the metal. The electrolyte is a solution of lead fluosilicate, which may be made by dissolving the oxide or carbonate in the acid. With unrefined anodes the lead passes into solution, whilst silver is retained in the anode mud. Good reguline deposits are obtained by the addition of glue or gelatine in small amount.

A feature of lead deposition is the production

of lead peroxide at the anode. This has long been known, and the production of coloured rings and films was first observed by Nobili, in 1826. Thus in a solution of lead acetate, or of litharge in alkali, and a polished anode of nickel or iron, coloured rings are obtained if a wire cathode is held close to the anode. The colours are due to the gradually varying thickness of the film, which brings about interference in the light falling upon them. With anodes of other shapes the colours follow the shape of the anode, though they pass off into a more or less rounded form. These colours are called 'metallochromes.' With excessive current a dull-brown deposit of lead peroxide is at once formed.

The **deposition of platinum** is carried out from a solution of the chloride in sodium phosphate. A platinum anode is insoluble and the solution needs the addition of the platinum compound. A brown colour sometimes occurs owing to some of the metal passing into the colloidal form.

Palladium may be successfully deposited from a solution of its double chloride, and the process has been applied by Cowper-Coles for producing a non-corrodible covering for electrolytically deposited parabolic mirrors in copper.

Cobalt deposition follows on lines similar to those for nickel, whilst **mercury**, which may be deposited from the nitrate solution, has been applied to the construction of electrolytic meters, in which a small and definite fraction of the total current is shunted through a cell in which mercury is deposited, the weight of the mercury deposit automatically recording the current passing through the meter, and at constant potential difference the energy absorbed in the circuit. S. F.

ELEMI v. OLEO-RESINS.

ELEMI, ESSENTIAL OILS OF, v. OLEO-RESINS.

ELIQUATION or **LIQUATION.** A metallurgical term to denote the operation of separating substances by taking advantage of their different fusibilities.

ELLAGIC ACID. Ellagic acid $C_{14}H_6O_8$ is obtained from numerous tannin matters which contain an ellagitannin (see art. on TANNIN) by boiling the aqueous extract with dilute sulphuric acid. In many cases it is to be found in the free state, due probably to the hydrolysis, by fermentation, of the ellagitannin or ellagic acid glucoside originally present, and such a fermentation frequently occurs when aqueous extracts of the tannin matters are allowed to stand for some time.

Divi-divi (*Casalpinia coriaria* [Willd.] (Löwe, Fresenius Zeitsch. anal. Chem. 1876, 14, 40), myrabolan (*Terminalia chebula* [Ratz.] (Löwe, *ibid.*), algarbilla (*Casalpinia brevifolia*) (Zölffel, Beilstein, 2, 1085), and valonia (*Quercus Acgilops* [Linn.]) yield considerable quantities of ellagic acid, and are the best natural sources of this material. It has also been isolated from oak galls (Chevreul, Ann. Chim. Phys. 1828, [2] 9, 329); oak bark (Etti, Montash. 1880, 1, 226); the bark of *Picea excelsa* (Link.) (Strohm, *ibid.* 1881, 2, 539); pomegranate rind (Rembold, Annalen, 1867, 143, 288); *Quebracho colorado* (Perkin and Gunnel, Chem. Soc. Trans. 1896, 69, 1307); *Arctostaphylos Uva-ursi* (Spreng.) and *Cortaria myrtifolia* (Linn.) (Perkin, *ibid.* 1900, 77, 424); *Hamamelis campechianum* (Linn.)

(Perkin, *ibid.* 1897, 71, 1137): the fruit of *Cæsalpinia digyna* (Rottl.) (Nierenstein, Chem. Zeit. 1909, 87); and the bark of *Terminalia Catappa* (Linn.) (*ibid.*). In fact, ellagic acid probably always occurs, if only in minute quantity, in all plant products which contain gallotannin. Most interesting are the Oriental bezoar stones, concretions which are found in the stomachs of goats and other animals, and consist largely of ellagic acid. These originate, without doubt, from the fact that the animal has fed upon plants in which some quantity of an ellagitannin is present.

Ellagic acid was first discovered by Chevreul (Ann. Chim. Phys. *l.c.*) in oak galls, and more closely examined by Braconnot (*ibid.* 9, 187). According to Pelouze, it possesses the composition $C_8H_6O_4$ (*ibid.* 54, 356); whereas Merklein and Wöhler (Ann. Chem. Pharm. 55, 129), who isolated it from bezoar stones and termed it 'bezoaric acid,' showed that its formula is $C_{14}H_6O_8$.

The precipitate of crude ellagic acid, which is produced by boiling the tannin extract with dilute acid, is purified by washing with alcohol and subsequent recrystallisation. A similar procedure is also satisfactory with the deposits so frequently produced by fermentation and alluded to above. Ellagic acid is most readily crystallised from pyridine (Perkin and Nierenstein, Chem. Soc. Trans. 87, 1416), and the product, which contains pyridine of crystallisation, is washed with alcohol.

Löwe (Zeitsch. Chem., 1868, 4, 653) was the first to prepare ellagic acid synthetically by oxidising gallic acid with arsenic acid, and this was subsequently accomplished by Ernst and Zwenger (Annalen, 1871, 159, 32) by heating the acid ethyl gallate with sodium carbonate solution in the presence of air, and by Griessmayer (Annalen, 1871, 160, 55) by heating gallic acid with water and iodine. It is readily produced by oxidising gallic acid dissolved in acetic acid by means of potassium persulphate and sulphuric acid (Perkin and Nierenstein, *l.c.*), and together with flavellagic acid by the addition of potassium persulphate to a solution of gallic acid in sulphuric acid (Perkin, *ibid.* 1906, 89, 251). Under similar conditions, gallotannin produces ellagic acid (Nierenstein, Ber. 1908, 41, 3015; and 1909, 42, 353), and it can also be prepared by boiling the tannin with hydrogen peroxide solution (*ibid.* 1907, 40, 917). Herzig and Bronneck obtained good results by passing air through an ammoniacal solution of gallic acid, and also of gallotannin (Monatsh. 1908, 29); whereas Sisley (Bull. Soc. chim. 1909, [4] 5, 727) prepared ellagic acid from tannin by means of alcoholic potassium hydroxide solution. According to Rupe, a 60 p.c. yield is produced when gallic acid in sulphuric acid solution is oxidised with sodium nitrite (Chemie d. natürl. Farbstoffe, 1909, 2, 162).

Ellagic acid crystallised from pyridine forms prismatic needles, which are converted by alcohol into a pale-yellow crystalline powder; but when purified by means of its acetyl-derivative, the product is almost colourless (P. and N.). It is very sparingly soluble in all the usual solvents, dissolves in alkaline solutions with a pale-yellow colour, and from these liquids, when diluted with hot alcohol, is deposited on acidifying in a crystalline condition. When

heated, it does not melt below 360° ; and sublimes at higher temperatures with considerable carbonisation. With nitric acid containing nitrous acid and subsequent dilution, it gives a blood-red colouration (Griessmayer's reaction), and this reaction, considered to be characteristic, is known to be also possessed by flavellagic acid (P.).

According to Merklein and Wöhler (*l.c.*), the alkaline solution of ellagic acid becomes reddish-yellow on exposure to air, and deposits black crystals of potassium glaucomelanate $K_2C_{12}H_{14}O_7$. When boiled with phenylhydrazine in alcoholic solution, or when carefully heated with phenylhydrazine, ellagic acid forms the product $C_2H_5NH \cdot NH_2 \cdot C_{14}H_6O_8$, which crystallises in yellow needles, and is readily reconverted into ellagic acid. Ellagic acid gives similar compounds with aniline and quinoline (Goldschmidt, Monatsh. 1905, 26, 1139).

Tetraacetyl ellagic acid $C_{14}H_2O_8(C_2H_3O)_4$ (Barth and Goldschmidt, Ber. 1878, 11, 846; Schiff, *ibid.* 1879, 12, 1534; Zülfel, Arch. Pharm. 229, 123), colourless needles, m.p. 343° - 346° (Perkin and Nierenstein); *tetra-benzoyl ellagic acid* $C_{14}H_2O_8(C_2H_5O)_4$, colourless needles (Goldschmidt and Jahoda, Monatsh. 1892, 13, 151), m.p. 332° - 333° (Perkin); *ellagic acid monomethyl ether* $C_{14}H_5O_7(OCH_3)$, yellow crystalline powder (Goldschmidt, Monatsh. 1905, 26, 1139); *diacetyl ellagic acid monomethyl ether*

$(C_{14}H_3O_7(OCH_3)(C_2H_3O)_2)$, crystalline powder (G.); *ellagic acid dimethyl ether* $C_{14}H_4O_6(OCH_3)_2$, crystalline powder (G.); and *ellagic acid tetramethyl ether* $C_{14}H_2O_4(OCH_3)_4$, colourless microscopic needles (G.; Herzig and Polak, Monatsh. 1908, 29, 263), have been described.

Ellagic acid gives the following salts: $KC_{14}H_5O_8$, minute yellow needles (Perkin and Wilson, Chem. Soc. Trans. 1903, 83, 134); $K_2C_{14}H_4O_8$, prisms (Merklein and Wöhler; P. and W.); $K_2C_{14}H_4O_8 \cdot KOH$, microscopic prisms (M. and W.); $Na_2C_{14}H_4O_8$, crystalline powder; $NaC_{14}H_5O_8 \cdot H_2O$, yellow needles (Ernst and Zwenger, Annalen, 1871, 159, 32).

The tinctorial properties of ellagic acid are somewhat feeble, but in 1887 it was placed on the market by Messrs. Meister, Lucius, and Brüning, under the name of 'Alizarin Yellow in paste,' and was recommended as yielding, with chromium mordants, greenish-yellow shades of considerable permanence.

Rembold (Annalen, 1867, 143, 288) states that when ellagic acid is treated with sodium amalgam, it gives γ -hexahydroxydiphenyl

$C_{12}H_4(OH)_6$, three distinct *rufohydroellagic acids*, $C_{14}H_{10}O_8$, $C_{14}H_{10}O_7$, $C_{14}H_{10}O_6$, and *glaucydroellagic acid*; but, according to Nierenstein (Ber. 1908, 41, 1649), this latter compound is in reality the pentahydroxydiphenylmethyloid referred to later. By the action of boiling potassium hydroxide solution (Barth and Goldschmidt, Ber. 1879, 12, 1242), ellagic acid gives *hexahydroxydiphenylacetone* (?) $C_{13}H_8O_7$, by fusion with potassium hydroxide β -*hexahydroxydiphenyl*, and by fusion with sodium hydroxide γ -*hexahydroxydiphenyl*, together with some of the β -compound.

When ellagic acid is distilled with zinc-dust fluorene is produced (Rembold, Ber. 8, 1494; Barth and Goldschmidt, *ibid.* 11, 846; cf. also Graebe, *ibid.* 1903, 36, 212).

As a result of their investigation, Barth and Goldschmidt (*ibid.* 1879, 12, 153) suggested that ellagic acid could be represented by one of the two following formulæ:—

and of these the first was preferable.

Whereas such a constitution requires the presence of five hydroxyl-groups, Schiff (Ber. 1879, 12, 1534) considered that acetyl-ellagic acid was $C_{14}H_2(C_2H_3O)_4O_8$, and this was subsequently corroborated by Zöllfel (Arch. Pharm. 229, 123). Schiff, at the same time, proposed two formulæ for ellagic acid:

the latter of which is identical with that preferred by Graebe (*l.c.*). In a later investigation, Goldschmidt and Jahoda (Monatsh. 13, 49), as the result of their preparation of a tetra-benzoyl ellagic acid, were satisfied of the existence in ellagic acid of but four hydroxyls, and consequently adopted their second formula.

Graebe (Ber. 1903, 36, 314), among other criticisms, pointed out that a substance having this constitution, and which may be more clearly written as follows (I.):—

would yield, on distillation with zinc-dust, not fluorene, but an isomeric hydrocarbon (II.), if this, indeed, were capable of existence. In the same paper this author announced the interesting fact that diphenylmethylolid

on distillation with zinc-dust, gives not only diphenyl and methyl-diphenyl, but also fluorene; and in a theoretical discussion of the subject, suggested that Schiff's second formula (given above) most probably represents the true constitution of this substance.

The subject was reinvestigated somewhat later by Perkin and Nierenstein (*l.c.*), who, on digesting ellagic acid with boiling potassium hydroxide solution, obtained Barth and Goldschmidt's so-called hexahydroxydiphenylene-ketone $C_{13}H_2O_7$. From this substance a *pentacetyl* derivative $C_{13}H_2O_7(C_2H_3O)_5$, prismatic needles, m.p. $224^\circ-226^\circ$, and a *pentabenzoyl* derivative, $C_{13}H_2O_7(C_7H_5O)_5$, plates, m.p. $257^\circ-259^\circ$, were prepared. As, moreover, zinc-dust

distillation gave fluorene, there could be little doubt that this compound was in reality *pentahydroxydiphenylmethylolid*, as, indeed, was surmised by Graebe:

From their results, together with a study of other similar compounds, Perkin and Nierenstein considered that Schiff's formula, also advocated by Graebe, and which can be more clearly written thus:

is a correct representation of the constitution of ellagic acid.

These authors have also prepared from *m*-hydroxybenzoic acid, *p*-hydroxybenzoic acid, protocatechuic acid; and from ellagic acid itself, other members of this group:

Metallagic acid $C_{13}H_5O_4(OH)$, (P. and N.)

Catellagic acid $C_{14}H_4O_4(OH)_2$, (P. and N.) (*see also Schiff, Ber. 1882, 15, 2570*).

Flavellagic acid $C_{14}HO_4(OH)_5$, (P.) (Chem. Soc. Trans. 1906, 89, 251).

Cæruleoellagic acid $C_{14}O_4(OH)_6$, (P.) (Chem. Soc. Proc. 1906, 22, 114).

The two latter compounds are possessed of well-marked dyeing properties.

Herzig and Tscherne also include resoflavine $C_{14}H_5O_4(OH)_2$ from sym. dihydroxybenzoic acid in this group (Annalen. 351, 24).

Finally, Herzig and Polak (Monatsh. 1908, 29, 263), by a study of the methylation products of ellagic acid, have given a further corroboration of its constitution.

When Goldschmidt's tetramethylellagic acid is digested with alcoholic potash and methyl iodide *diphenyl-1:2:3:6:7:8-hexamethoxy-5:10-dicarboxylic methyl ester* (m.p. $109^\circ-111^\circ$):

is obtained, together with a small quantity of *diphenylmethylolid-2:3:6:7:8-pentamethoxy-5-carboxylic acid methyl ester* (II.), m.p. $187^\circ-189^\circ$:

By means of alcoholic potash, these compounds I. and II. yield respectively *diphenyl-1:2:3:6:7:8-hexamethoxy-5:10-dicarboxylic acid* (III.), m.p. $238^\circ-240^\circ$ and *diphenyl-2:3:6:7:8-pentamethoxy-1-hydroxy-5:10-dicarboxylic acid* (IV.), m.p. $200^\circ-203^\circ$:

Ellagic acid is probably not a tanning matter in the true sense of the word, but is of considerable importance nevertheless in the tanning process. Thus the ellagitannic acid absorbed by the hide is at least in part converted into ellagic acid, and the deposit thus formed adds weight and bloom to the finished article.

A. G. P.

ELLAGITANNIC ACID. A tanning principle present in divi-divi (Löwe, *Frdl.* 14, 35); in algarobilla (Zöllfel, *Arch. Pharm.* 229, 123); in myrobalans (Löwe, *l.c.* 44; Zöllfel, *l.c.*); and probably to some extent in all plant products which contain a gallotannin (*v.* ELLAGIC ACID).

According to Löwe, the molecule of ellagitannic acid contains 5 hydroxyl groups replaced by acetyl. It gives precipitates with gelatin, albumen, alkaloids, tartar emetic, and a nearly black precipitate with ferric acetate. Its alcoholic solution gives, with lead acetate, a precipitate of the formula $2\text{C}_{14}\text{H}_{10}\text{O}_{10} \cdot 5\text{PbO}$.

Very little is known of its constitution. Zöllfel (*l.c.*) considers it a sugar-free tannic acid of the formula $\text{C}_6\text{H}_2(\text{OH})_3\text{COO} \cdot \text{C}_6\text{H}_2(\text{OH})_2\text{COOH}$. Perkin and Nierenstein (*l.c.*) consider it a glucoside of gallotannin or a condensation of two molecules of the latter, and suggest a constitutional formula.

Nierenstein (*Ber.* 1910, 43, 1267) has obtained it in a pure state by repeated treatment of the crude substance from myrobalans with alkali and ethyl chloroformate, and then decomposing with pyridine according to Fischer's method; and gives its formula as

It crystallises from a mixture of pyridine and acetic acid in pale-yellow plates, which, after sintering at $300^\circ\text{--}306^\circ$, melt at $329^\circ\text{--}336^\circ$ [α]_D¹⁷ +18°·02. So obtained, it readily yields ellagic acid with diluted sulphuric acid, but is not decomposed by 10 p.c. sodium carbonate solution. As it is hydrolysed by emulsin to luteoic acid, Nierenstein considers it to be a glucoside of luteoic acid (*v.* TANNINS).

ELUTRIATION. The separation of the lighter from the heavier particles of a powder by washing and decantation.

EMANIUM *v.* ACTINIUM.

EMBOHITE. Native silver chlorobromide containing chlorine and bromine in indefinite proportions. It is the commonest of the horn-silvers or cerargyrites (*q.v.*), occurring as compact horn-like masses or as small, indistinct cubic crystals of a greenish-grey colour. Frequently a small amount of iodine is also present, and the formula is $\text{Ag}(\text{Cl}, \text{Br}, \text{I})$; the colour is then usually greenish-yellow to orange-yellow. Large quantities have been mined with other ores of silver in Chile, Mexico, and Broken Hill in New South Wales (*v.* Prior and Spencer, *Min. Mag.* 1902, 13, 171).

L. J. S.

EMERALD *v.* BERYL, and GLUCINUM.

EMERALD GREEN. *Hydrated chromium sesquioxide* (*v.* CHROMIUM); also applied to *Schweinfürth green* (*v.* art. ARSENIC; also PIGMENTS).

EMERALD, ORIENTAL, *v.* CORUNDUM.

EMERY. (*Smirgel*, Ger.) An impure variety of corundum. Microscopic examination shows that it is a mechanical aggregate of crystalline or granular corundum and oxide of iron, chiefly in the form of magnetite, together with smaller amounts of several other minerals, such as tourmaline, hercynite (FeAl_2O_4), garnet, muscovite, diaspore, kyanite, rutile, &c. It was formerly obtained almost exclusively from Naxos, an island in the Greek archipelago, where it is found in large detached blocks in the soil, and also embedded in crystalline limestone. In consequence of deficient harbour accommodation, it is generally taken to the neighbouring island of Syra, and thence re-shipped. The lessee is bound by the Greek Government to extract a minimum of 1650 tons annually. The amount exported from Syra in 1907 was 10,982 tons, valued at 45,505*l.* In France, the Naxos emery is still used to the exclusion of most other kinds, but in many markets the Greek emery has been largely displaced by the Turkish.

J. Lawrence Smith first called attention to the occurrence of emery in Asia Minor, especially at Gumach Dagh, a mountain about 12 miles east of Ephesus. It is also found near Kulah, 20 miles from Philadelphia. The Thyra mines are situated in the hills between Cosbunar and Thyra; and at the foot of this range is the Coursack mine, where a large bed of emery is now worked. At some of these localities the emery is found as loose blocks in a reddish soil, but at most of the workings it is now systematically mined by shafts and galleries. The principal workmen are Italians. The large blocks of emery are broken by sledge-hammers, but as the mineral is extremely tough, it is often exposed to the action of fire and then cooled, to facilitate fracture. The broken emery is carefully picked over by hand, and sometimes not more than half is worth sending away. It is removed on camels and donkeys to the Ottoman Railway, and thence conveyed to Smyrna. From this port 28,559 tons were shipped in 1907. The only other emery-producing country is the United States, where it is mined at Chester in Massachusetts, and at Peekskill in Westchester Co., New York. The production in 1907 amounted to 970 metric tons, valued at 2524*l.*

Emery is extensively employed in a variety of ways as an abrading agent. The mineral is crushed, sifted through wire sieves, and sorted into different degrees of fineness, known as coarse, fine, and flour; and should then be washed and elutriated. Lawrence Smith found that the effective hardness, or abrading power, is not in direct proportion to the amount of alumina in the emery, but seems rather to depend on the state of aggregation of the mineral. The following analyses are by Lawrence Smith (*Amer. J. Sci.* 1851, 11, 366). The first column gives the effective hardness, taking that of sapphire as 100 (*v.* CORUNDUM):—

—	Hardness	Sp. gr.	Al ₂ O ₃	Fe ₃ O ₄	SiO ₂	CaO	H ₂ O
Gumach . . .	47	3.82	77.82	8.62	8.13	1.80	3.11
Naxos . . .	46	3.75	68.53	24.10	3.10	0.86	4.72
Samos . . .	56	3.98	70.10	22.21	4.00	0.62	2.10

Analyses of the emery of Naxos, Tyre, and Smyrna have been published by R. Jagnaux (Bull. Soc. Min. Fr. 1884, 7, 160). G. Tschermak (Min. Petr. Mitt. 1894, 14, 311) gives analyses and describes the microscopic structure of Naxos emery.

Emery is conveniently employed in the form of 'emery cloth,' 'emery paper,' 'emery sticks,' &c., which are prepared by causing powdered emery to adhere to the glued surface of cloth and other media. 'Emery wheels' are formed by mixing the powdered mineral with some plastic or liquid vehicle, moulding the mass into a convenient shape, and then causing it to set in a solid form. The vehicle may be shellac, or artificial stone, which forms a hard cementing medium, or it may be a paste of loam and water, which is afterwards baked so as to form a coarse terra-cotta.

L. J. S.

EMETINE *v.* VEGETO-ALKALOIDS.

EMIN RED *v.* PRIMULINE.

EMODIN *v.* CASCARA SAGRADA; GLUCOSIDES; RHUBARB; SYNTHETIC DRUGS.

EMPYROFORM *v.* SYNTHETIC DRUGS.

EMULSIN. The term 'emulsin' was applied originally to the enzyme or mixture of enzymes, present in bitter and sweet almonds, which hydrolyses amygdalin to glucose, benzaldehyde, and hydrogen cyanide. The same enzyme was shown subsequently to hydrolyse many natural glucosides as well as the synthetically prepared β -glucosides, though it was entirely without action on the stereoisomeric α -alkylglucosides (Fischer, Zeitsch. Physiol. Chem. 1898, 26, 60). The name is now used to comprise all enzymes which hydrolyse β -glucosides. Such enzymes are widely distributed in plants: besides the kernels of fruits, they also occur in the leaves and young twigs of the higher plants, in most mould fungi, especially in *Polyporus* species parasitic on trees, and in bacteria. Henry and Auld (Proc. Roy. Soc. 1905, B, 76, 568) have identified emulsin as present in yeast.

β -Glucosides are also hydrolysed by certain animal extracts, *e.g.* intestinal mucous membrane, a fact which is taken to indicate the presence of emulsin.

There are, however, well-marked differences in the number of substances which these various emulsin preparations are able to hydrolyse, and the investigations of Armstrong and others (Chem. Soc. Proc. 1910, 334) indicate, that whilst the leaf enzyme (emulsin) is, as a rule, a specific for the glucoside normally occurring in the particular plant, the seed enzyme, especially that of the almond, is able to attack a number of glucosides. For this reason almond emulsin is considered to be a mixture of several closely related enzymes. According to H. E. and E. F. Armstrong and Horton (Proc. Roy. Soc. 1908, 80, 321), it contains a β -glucase proper, which attacks β -glucosides; a cyanase, which eliminates hydrogen cyanide from amygd-

alin; an amygdalase, splitting off glucose from amygdalin; and a lactase, acting on milk sugar (compare Rosenthaler, Arch. Pharm. 1910, 240, 105).

Almond emulsin hydrolyses β -glucosides and also the disaccharides, lactose, gentiobiose, cellose, and melibiose. It further hydrolyses the synthetical β -methylgalactoside. The emulsin of *Aspergillus niger*, on the contrary, has no action on lactose or on β -galactosides. In referring to emulsin, it is therefore advisable to specify the source of the enzyme.

Preparation.—Ground sweet almonds from which the fat has been expressed are macerated with water and a little toluene or chloroform at the ordinary temperature for 12–24 hours. The liquid is expressed through a cloth, protein precipitated with a few drops of acetic acid, and the clear filtrate precipitated with alcohol added 50 c.c. at a time till no further precipitate is formed. The liquid is decanted and the precipitate rapidly washed with absolute alcohol and ether to dehydrate it, and dried in a vacuum. Alternatively the original precipitate may be collected on a filter paper, dried roughly on bibulous paper, and dissolved in water in a closed bottle, to which a little toluene is added. The clear solution so obtained is very active, and retains almost constant activity for many months. It is essential to carry out this preparation as rapidly as possible.

The dried enzyme is a soft, white powder, giving most of the reactions of proteins, but losing these on purification. Its chemical nature has not been the subject of any detailed investigation.

Emulsin exhibits maximum activity in neutral solution. Alkali stops the action; small quantities of acids usually increase the activity, owing to their effect in neutralising alkaline impurity.

Experiments with emulsin are usually carried out at about 37°; the optimum temperature is 45°.

Emulsin is detected qualitatively by its action on amygdalin, liberating hydrogen cyanide. The activity is tested quantitatively either against amygdalin or salicin, by measuring the amount of sugar formed in a given time.

Emulsin is also able to bring about synthetic change (Armstrong, Proc. Roy. Soc. 1905, B, 76, 592; van't Hoff, Sitzungsber. K. Akad. Wiss. Berlin, 1910, 48, 963).

(For a list of the glucosides attacked by emulsin, *v.* GLUCOSIDES.) E. F. A.

ENAMEL BLUE. Cobalt blue (*v.* PIGMENTS).

ENAMELS are vitreous compositions capable of adhering by fusion to the surface of metal or of pottery. The base of the enamel is generally a colourless glass, in which are suspended particles of an opaque metallic oxide or salt, generally stannic oxide. Up to about 900°, tin dioxide exists finely suspended in the enamel, but at a

higher temperature combination or solution may occur and opacity is diminished. Titanic oxide has been used in place of stannic oxide, and antimony compounds have been employed. Opacity may also be obtained by the use of arsenious oxide, calcium phosphate, cryolite, or fluorspar. A preparation known as 'artificial cryolite' sometimes replaces the mineral. When bone ash is used, a little nitre may be added to remove the grey colour; the nitre also prevents reduction of the lead. The vitreous base of most enamels is a glass containing much lead, but when the presence of lead is objectionable, as in enamelled vessels for culinary purposes, soda- and potash-glasses should be used. If great fusibility be required, it may be secured by the association of borates with the silicates. Borate enamels are very hard, but are deficient in elasticity, and may be affected by moisture. Colour is imparted to the enamels by the introduction of various compounds, generally metallic oxides, the use of which, in many cases, has been known from remote ages. Percy's analyses of the enamelled bricks of Babylonia (*circa* 700 B.C.) showed that a dense white was obtained by the use of stannic oxide; a rich yellow by means of antimony, apparently in the form of lead antimoniato ('Naples yellow'); and a deep blue by copper, probably introduced as oxide, but existing in the enamel as a copper sodium silicate. The ancient Egyptian blue enamel, or glaze, contains a definite copper calcium silicate, forming crystals remarkable for their intense pleochroism, to which Fouqué gave the name of *vestorien* (Bull. Soc. Fr. Min. [12] 1889, 36) (*v.* EGYPTIAN BLUE). The ancient Egyptians seem to have been ignorant of the art of enamelling on metal.

The enamelling of pottery is a simple operation, since it consists in the mere fusion of an opaque glaze on to the surface of the ware. But the application of a vitreous body to a metallic surface is less easy, and it is to this process that the term 'enamelling' is sometimes restricted, while the works of art produced by enamelling on metal are themselves known as 'enamels.'

The most ancient enamels found in North-Western Europe are referable to the prehistoric Iron Age, sometimes distinguished as Late Celtic. In these ancient enamels, brilliantly coloured opaque glass is embedded in cells or shallow cavities in bronze: it is probable that the vitreous material was applied as a powder, mixed with a vehicle so as to form a paste, and then heated sufficiently to cause its fusion, and thus secure firm attachment to the metal.

A similar method, known as *champ levé* enamelling, was extensively employed at a much later date in Germany and at Limoges in France—a town which for centuries was the chief centre of artistic enamelling. In this process the design is traced on a plate of copper or bronze, and all the parts to be enamelled are excavated by the graver; these hollows are then filled with enamel, which is afterwards fused, and the entire surface is finally ground smooth. The design thus appears in permanent colour, each tint being defined by ridges, or separated by areas, of metal which are the elevated parts of the original ground. The exposed metal is sometimes gilt.

Another and probably older method of inlaid enamelling is that known as *cloisonné* work. Here the design is outlined by strips of metal fixed to the metallic base, and the spaces between these bands are filled with enamel, which is then fused and the surface ground down. Each coloured area is, therefore, sharply separated from its neighbour by the edge of the metal fillet. Of this character were the early Byzantine enamels, which were generally executed on plates of gold. The Chinese have for many centuries (at least since the 13th) been extremely skilful in this work, and the Japanese have applied a similar method to the ornamentation of porcelain. The Japanese attach the cloisons to the base with a gummy cement, and even when the ground is a metal, they generally use no solder. In some *cloisonné* work the surface is not ground down, so that the fillets stand in relief above the general surface of the enamel.

The use of transparent enamels for the ornamentation of metalwork was introduced by the Italian goldsmiths of the 13th century, and afterwards became popular in France. The design was generally worked in low relief, or chased on gold or silver, and brilliant translucent enamels were applied in such a way that the varying thicknesses produced differences of tint. This style is known as *basse-taille*. In certain rare enamels, probably of the 15th century, the pattern is outlined by strips of metal without any foundation, and the spaces in this grating are filled in with coloured transparent enamels; such *cloisonné* work is termed *plique-à-jour*.

Artistic enamelling has been largely used, not only for inlaid and encrusted work, but for the production of paintings on metal. The painted enamels of Limoges, introduced in the 15th century, were usually executed on slightly convex plates of copper, the subjects being generally in white and grey on a deep-violet ground; but the process was extended to the decoration of dishes, ewers, and other objects, and various colours were employed, sometimes heightened with gold. In this country, enamel painting was largely practised, by the family of Bone, during the latter part of the 18th and the early years of the following century. While their smaller works, or miniatures, were executed on gold, the larger examples were on plates of copper. The copper plate, having been annealed and cleaned with dilute sulphuric acid, was coated on both sides with white enamel powder; it was then fired, and the enamelled face ground smooth. This white enamel, which was rendered so opaque by means of stannic oxide as to conceal the metal ground, was imported from Venice in the form of round cakes. The surface to be painted was further prepared by the application of a second coat of enamel, more fusible and transparent than the first; this material, known to the enameller as 'flux,' was used in the form of rods and beads of white Venetian glass. Upon the fluxed surface, carefully ground smooth, the painting was executed in enamel colours, or powdered glasses mixed with an appropriate vehicle; and as it was necessary to vitrify each colour separately, a complicated subject would require several successive firings in a muffle, each liable to injure or spoil the work.

Recent years have witnessed a great revival in artistic enamelling, with the introduction of various improvements in technical details.

In addition to art enamels, there is a growing demand for coarse work in enamelled sheet-iron for street plates, railway notices, and other advertisements, which are generally executed in blue and white. In applying enamel to metal it is necessary to use a material which will adhere firmly to the base; at the same time, it must fuse at a temperature lower than that which softens the metal, or melts the solder if any be present; and the enamel should have a coefficient of expansion by heat as nearly as possible that of the metal ground. It is obviously important that, when enamel is used as a lining for saucepans, stew-pans, and other vessels for culinary purposes, it should be free from all ingredients which are poisonous, or may become so by contact with food. An important industry has been developed in recent years, especially in Germany, Austria-Hungary, and France, in the manufacture of vessels for domestic use, in cast or sheet metal; soft sheet steel is commonly used for hollow ware.

The object to be enamelled, having been carefully cleaned by pickling in an acid bath, is coated with a thin layer of ground enamel. This primary coating need not be opaque, and generally contains a little cobalt or nickel oxide. A suitable material is obtained, according to P. Randau, by fusing a mixture of flint or quartz 30 parts, borax 25, and felspar 30. This product is then ground with kaolin 10.75 parts, felspar 6, and magnesia 1.25; the clay tends to lessen the fusibility. The finely powdered ground enamel is mixed with water to a creamy consistency and applied to the ware, slightly heated; after the coating has dried, the object is fired in a muffle furnace at a temperature rather under 1000°. After this stage of enamelling, the ware is scrubbed to remove scale, and a second coating is applied, this time opaque white. This enamel may be made, according to the same authority, from a mixture of flint 37.5 parts, borax 27.5, tin dioxide 30, soda 15, nitre 10, ammonium carbonate 7.5, and magnesia 7; this mixture is fritted and then ground with flint 6.12 parts, tin dioxide 3.66, soda 0.7, and magnesia 0.7. The cover enamel is suspended in water and spread over the ground enamel, and the ware is then carefully fired in a muffle at a lower temperature than that of the first firing. In some cases a third coat of enamel is applied, while in other cases the ground layer is dispensed with, and only a single white coating used. Finally the surface may be decorated by painting or transfer printing in enamel colours, or by photographs. In some enamels, like 'granite ware,' the colour is applied by spraying.

Day, Enamelling, London, 1907; Alexander Fisher, The Art of Enamelling upon Metal, London, 1906; Philipp Eyer, Die Eisenemalierung, Leipzig, 1907; Paul Randau, Die Fabrikation des Emails und das Emailieren, Vienna, 4th ed. 1909; Enamels and Enamelling, English translation of P. Randau by Charles Salter, London, 1900; Julius Grünwald, translated by Herbert H.

Hodgson, The Theory and Practice of Enamelling on Iron and Steel, London, 1909). F. W. R.

ENARGITE. Copper sulpharsenate Cu_3AsS_4 or $3Cu_2S \cdot As_2S_5$, occurring as orthorhombic crystals with perfect prismatic cleavages and usually a prismatic habit. The colour is iron-black with a metallic lustre; sp.gr. 4.44. It is not a common mineral, but in a few copper-mining districts, particularly at Butte in Montana, it is an important ore of copper. L. J. S.

ENDIVE. *Cichorium endivia* (Linn.), the blanched leaves are used as a salad or garnish.

According to König, their average composition is—

Water	Protein	Fat	Sugar	Other carbo-	Fibre	Ash
94.1	1.8	0.1	0.8	hydrates 1.8	0.6	0.8

There are two chief varieties—with crinkled leaves and with smooth leaves. The former is apparently richer in nitrogen and ash, but poorer in carbohydrates (Dahlen, Landw. Jahrb. 1874, 3, 312, and 4, 614).

An analysis of the ash of endives by Richardson (Annalen, 67, 377) gave the following figures:—

K ₂ O	Na ₂ O	CaO	MgO	SO ₃	P ₂ O ₅	SiO ₂	Fe ₂ O ₃
37.9	12.1	12.0	1.8	5.2	3.0	24.6	3.4

ENSILAGE is a process of preserving green fodder for cattle. The term *silo* is applied to the pit or other depository in which the fodder (*silage*) is contained, and appears to be of Basque derivation, and originally meant a pit for storing grain. This method of preserving grass and other succulent forage crops has been in use for many years in Germany, whence the practice was carried to France, and afterwards to America. Although the German system had been fully described by Johnston, in 1843, in the Transactions of the Highland Agricultural Society (new series, 9), no general notice of it was taken in these islands until 1882, when a report of the British Legation at Washington on ensilage, as practised on Mr. Havemeyer's estate in New Jersey, was published as a blue-book, since which time many silos, of varying forms and construction, have been made in this country. The object of all these is to exclude the air from the mass of fodder, allowing only a greater or less fermentation according to the practice of different authorities; and to this end silos have been formed (1) wholly or partly underground; (2) in the form of enclosed buildings. Silage has also been largely made by building up the green fodder in the form of an ordinary stack, of which only the top is covered. Whether it be silo or stack, the principal factor is the superposition of a sufficient pressure, either by dead weight or by some mechanical system of screws, levers, or similar appliances. The changes which forage undergoes in the silo

are due to fermentation, and, as may be supposed, this action varies considerably with the materials stored and with the condition of storage; as, for example, green maize undergoes principally lactic fermentation; whilst in English fodder fermentation produces alcohol, which is almost immediately converted into aldehyde. If the air has not been properly expelled from the silo, or if the fodder has been pitted in a very damp condition, the aldehyde becomes quickly converted into acetic acid.

Silage is of two kinds—viz. 'sweet' and 'sour.' Sweet silage is the result of allowing the grass to remain without pressure, and so permitting air to mingle with it until such time as a temperature of 125° to 150°F. is reached by the fermentation process; sour silage, on the other hand, results when pressure is at once applied, whereupon an acetic or lactic fermentation takes place. It appears that a temperature of about 125° is sufficient to kill the bacteria which produce acid fermentation; 'if the bacteria are killed and the silo is covered and weighted, the enclosed mass of green fodder will remain sweet, and be practically preserved under the same conditions as fruits, vegetables, or meats are preserved when canned. If this be the case, it will be at once intelligible that by less packing of the fodder when put into the silo, and extending the time of filling until the temperature rises to a point fatal to the bacteria, the resulting silage will be sweet and free from acidity; whilst sour silage is produced by at once consolidating, covering up, and weighting the grass fodder so as to prevent the temperature rising to the point fatal to the bacteria' (A. Voelcker, J. Roy. Agric. Soc. 20).

Two samples of sweet silage showed only a trace of acid, not exceeding in quantity that contained in ordinary fresh meadow grass:—

	Silage made from	
	Clover and rye grass mixed	Meadow grass
Moisture	75.80	74.40
*Albuminoids	2.53	2.56
Sugar and other carbohydrates soluble in water	1.43	2.99
Crude vegetable fibre	18.31	17.90
Mineral matter (ash)	1.93	2.15
	100.00	100.00
*Containing nitrogen	0.40	0.41
Volatile acids (calculated as acetic acid)	0.01	0.04
Non-volatile acids (calculated as lactic acid)	0.01	0.02

A sample of sour silage made from grass placed in a heavily weighted silo showed the following composition:—

Water	76.01
Soluble albuminoids	0.91
Insoluble albuminoids	1.78
Soluble carbohydrates	2.87
Crude fibre	15.82
Soluble mineral (ash)	1.63
Insoluble mineral matter (ash)	0.98
	100.00

Total nitrogen	0.43
Volatile acids (calculated as acetic acid)	0.19
Non-volatile acids (calculated as lactic acid)	1.24

This silo was provided with a tap at the bottom from which juice was drawn off from time to time. This drainage had a sp.gr. of 1.022, and contained, per imperial gallon:

	Grains
Albuminoids	1,008.56
Fixed acid (lactic acid)	516.42
Volatile acids (butyric and acetic acids)	476.70
*Carbohydrates and amides	1,528.42
Mineral matters (ash)	1,768.20
Water	64,701.70

70,000.00

*Containing non-albuminous nitrogen 35.84

The dry matter (dried at 100°) which was left on evaporation of its drainage contained:

*Albuminoids	20.90
Lactic acid	10.71
†Carbohydrates and amides	31.73
Mineral matter (ash)	36.66

100.00

*Containing nitrogen 3.34

†Containing nitrogen 0.51

The subject of changes during ensilage have been very carefully investigated both at Rothamsted by Lawes and Gilbert, and at Woburn by Voelcker. The results obtained present a striking similarity, and it will suffice if one set of tables (those of Dr. Voelcker) is referred to here, although the Experiments on Ensilage conducted at Rothamsted (Lawes and Gilbert) should also be read. The silo to which these figures relate was one made at Woburn in 1886, and was of the character generally termed 'sour.' It was weighted with stones in strong elm boxes to 112 lbs. per square foot, and was unprovided with any drain. The silo was closed on July 3 and opened on December 16, the contents being 'very fair,' although 'not really fine,' meadow grass. The numbers, in a condensed form, are given in the table, p. 337.

The main features shown in the table are as follows: The total loss due to fermentation, evaporation, &c., in making the silage was 7.29 p.c. on the fresh grass. Of this, 3½ p.c. consisted of water, so that the loss in dry matter was only about 4 p.c. The loss of total nitrogen when, as here, no drainage was allowed to flow away, is very slight; but the nitrogenous bodies have undergone considerable change from the albuminoid to the non-albuminoid condition, the fibre has been diminished, insoluble albuminoids have been lessened, and soluble albuminoids increased (Voelcker, J. Roy. Agric. Soc. 23, 410).

Since the nutritive value of food depends to a considerable extent on the albuminoid compounds contained in it, it becomes of importance from the economic point of view, to determine the quantity of such compounds in fresh green food and in silage. Kinch found that 55 p.c. of the total nitrogen present in the silage of grass was of a non-albuminoid nature, whilst in the original grass only 9 p.c. was of this

QUALITY AND COMPOSITION OF THE GRASS PUT INTO SILO, AND OF THE SILAGE PRODUCED.

Loss per 100 lbs. of fresh grass	7.29	3.27	+0.33	+0.32	+0.46	1.47	2.90	0.79	0.03	+0.12	0.06	+0.01	0.15	+0.16														

form. In the case of mangold leaves, Kellner found that of the total nitrogen present, 27.8 p.c. in the original leaves, 45.5 p.c. in the silage, and as much as 59.7 p.c. in silage preserved in stoppered jars, was non-albuminoid. Clifford Richardson, examining maize silage, found:

	Per cent. total nitrogen as non-albuminoid
Original stalks	21.2
Silage, No. 1	44.6
" No. 2	49.6
Dried fodder	15.6
Silage from young maize	53.3
" " older	47.1

These results with grass, mangolds, and maize show that in ensilage a large portion of the albuminoids are converted into non-albuminoid nitrogenous substances, whilst in the ordinary drying of fodder no such change seems to take place. This is made clear by a reference to Dr. Voelcker's table given above under the heading 'Quality and composition,' &c., where the woody fibre, as indeed the whole of the fibre, has been diminished, insoluble albuminoids are lessened, and the soluble albuminoids increased.

Ensilage is largely practised in Canada and in America for the sake of having a supply of 'green' fodder during the winter months, especially in Canada where the winter is long. In England, since the interest attaching to novelty has waned, it has gradually died out of practice, except as a resource for adoption in unusually wet seasons, when haymaking is impossible or is so long delayed as to threaten loss of the crops. In such circumstances those who possess the simple tackle necessary for putting up silage stacks in the open field have a material advantage over their neighbours. Otherwise, in a country in which roots are easily grown and preserved for winter use, and where the actual period of the year in which vegetation is suspended is comparatively short, it would seem preferable, having regard to the deterioration which occurs in ensilage, especially as regards albuminoids, to adhere to the more ordinary practice of hay-making.

The application of silage as fodder and its practical effects with stock have been carefully investigated both at Rothamsted and Woburn.

EPHEDRINE. Spehr (Chem. Soc. Abstr. 1892, 893) obtained an alkaloid which he called ephedrine from *Ephedra monostachya*, of very feeble physiological action, of the formula $C_{13}H_{16}NO$; m.p. 112°; volatilising at about 125°.

Nagai (Chem. Zeit. 1890, 441) isolated an alkaloid from the stems of *Ephedra vulgaris*, to which he also gave the name ephedrine; it was a powerful mydriatic, had the empirical formula $C_{10}H_{15}NO$, and yielded benzoic acid, monomethylamine, and oxalic acid on oxidation.

isoEphedrine he describes as obtained on heating normal ephedrine at 180° in sealed tubes with hydrochloric acid.

A similar alkaloid, with strong toxic and mydriatic properties, was isolated from other plants of the same genus by Merck, and provisionally termed ψ -ephedrine. Its physical and chemical characteristics were examined by Ladenburg, and Oelschlägel (Ber. 22, 1823); Miller (Arch. Pharm. 1902, 240, 481) could only obtain ψ -ephedrine from *Ephedra vulgaris*, and Flaecher (Arch. Pharm. 1904, 242, 380) has shown that Nagai's isoephedrine and the ψ -ephedrine of Ladenburg and Oelschlägel are identical.

Either base heated with hydrochloric acid gives an equilibrium mixture of both (Schmidt, *ibid.* 1908, 246, 210).

Ephedrine is completely converted into ψ -ephedrine on acetylation, the same acetyl derivative $C_{10}H_{14}ON(C_2H_5O)HCl$, m.p. 175°, $\alpha_D +97.6^\circ$, being formed from both bases, and yielding ψ -ephedrine on hydrolysis (Apoth. Zeit. 1910, 25, 677-678); while the alcohol produced from ψ -ephedrine by Hofmann's degradation is converted by repeated distillation into that from ephedrine (Emde, Arch. Pharm. 1907, 245, 662).

Ephedrine and ψ -ephedrine are optical isomerides, with the configurations shown below:

the reversible conversion with hydrochloric acid being due to racemisation of the right-hand portion of the molecule (Emde, Arch. Pharm. l.c.; Gadamer, *ibid.* 1908, 246, 566).

Fourneau (J. Pharm. Chim. 1904, 20, 481) describes the synthesis of four isomerides of ephedrine with varying physiological action. The crystallographic constants are given by Schwantke (Zeitsch. Kryst. Min. 1909, 46, 73).

Ephedrine hydrochloride (*ephedrinum hydrochloricum*) is readily soluble in water, and has a strong mydriatic action, 1-2 drops of a 10 p.c. solution producing in 40-60 minutes a marked dilation lasting 5-20 hours. It has been used in place of atropine and homatropine.

EPICARIN *v.* SYNTHETIC DRUGS.

EPICHLORHYDRINS *α*-epichlorhydrin

(*γ*-chlorpropylene oxide) $\text{C}_3\text{H}_5\text{OCl}$. Prepared by treating glycerol with phosphorus pentachloride or by heating the dichlorhydrins with hydrochloric acid (Berthelot, Ann. Chim. Phys. [3] 41, 299); by treating *α*- or *β*-dichlorhydrin with caustic potash (Reboul, Annalen. Spl. 1, 221; Tollens and Mündler, Zeitsch. Chem. 1871, 252). Glycerol is treated with hydrogen chloride at 120°-130°, and the product distilled *in vacuo*. The fraction boiling at 50°-120°, which contains the dichlorhydrins, is treated with strong caustic potash solution, and the product distilled *in vacuo*. The portion boiling below 75° is washed with water and distilled. The fraction boiling at 116°-118° is crude epichlorhydrin, and may be purified by redistillation *in vacuo* (Fauconnier, Bull. Soc. chim. ii. 50, 212). Mobile liquid with odour resembling that of chloroform; b.p. 116-6° (corr.); sp.gr. 1.2031 at 0°/4° (Thorpe, Chem. Soc. Trans. 1880, 206); insoluble in water. With sodium in ethereal solution epichlorhydrin yields allyl alcohol and the diallyl ether of glycerol (Tornøi, Ber. 1888, 1290; Kijner, J. Russ. Phys. Chem. Soc. 24, 31); by heating with alkyl iodides, chloriodohydrin alkyl ethers are produced (Paal, Ber. 1888, 2971); ammonia gas converts it into trichlorhydroxypropylamine (Fauconnier, Compt. rend. 107, 115); with potash in the presence of an alcohol, it yields the corresponding dialkyl ether of glycerol (Zunino, Atti. Real. Accad. Lincei, 1897, ii. 348; 1907, 9, i. 309); with phenols and sodium ethoxide, glyceryl diaryl ethers are formed; whilst with sodium hydroxide, glycide aryl ethers are produced (Boyd and Marle, Chem. Soc. Trans. 1908, 838; 1909, 1803; Zunino, Atti. Real. Accad. Lincei, 18, i. 254; Cohn and Plohn, Ber. 1907, 2597; Lindemann, *ibid.* 1891, 2145); concentrated nitric acid oxidises it to *β*-chlorlactic acid; alcoholic ammonia and ethylsodiummalonate convert it into chlorhydroxypropylmalonamide (Traube and Lehmann, Ber. 1899, 720). Haller and March have synthesised ketolactic acids and other unsaturated compounds by condensing epichlorhydrin with the sodium derivatives of benzoyl acetic esters, of acetone dicarboxylic ester and of acetylacetone (Compt. rend. 132, 1459; 136, 434; 137, 11, 1203). It has also been condensed with aniline (Fauconnier, *ibid.* 106, 605; 107, 250); with *p*-toluidine (Cohn and Friedländer, Ber. 1904, 3037); with prussic acid (Lespieau, Compt. rend. 127, 965), and with

salicylic acid (Lange, D. R. P. 184382; Chem. Soc. Abstr. 1906, i. 930). Organomagnesium compounds react with it to form substituted chlorhydrins of the type $\text{R-CH} \begin{cases} \text{CH}_2\text{OH} \\ \text{CH}_2\text{Cl} \end{cases}$ (Riedel, Chem. Zentr. 1907, i. 1607; D. R. P. 183361; Fourneau and Tiffeneau, Bull. Soc. chim. 1, [4] 1227). Epichlorhydrin has been used as a solvent for resins for photographic purposes (Phot. Korr. 1899, 2).

β-Epichlorhydrin (*β*-chlorpropylene oxide)

$\text{CH}_2\text{-CHCl-CH}_2$. Obtained together with the *α*-compound and other products by treating the chloriodohydrins formed by treating allyl alcohol with iodine monochloride, with dry sodium hydroxide (Bigot, Ann. Chim. Phys. 22 [6] 468). Liquid; b.p. 132°-134°. Phosphorus pentachloride converts it into *βγ*-dichloropropylene, and sodium amalgam into allyl alcohol.

Polymerides. $(\text{C}_3\text{H}_5\text{OCl})_2$. Obtained in the preparation of pyrazine bases by the distillation of glycerol with ammonium phosphate and ammonium chloride; by treating the high-boiling fractions with hydrochloric acid, it is obtained crystalline; m.p. 112°-113°; b.p. 232°-233°. Readily soluble in hot alcohol, sparingly soluble in water.

$(\text{C}_3\text{H}_5\text{OCl})_3$. Obtained by treating *α*-epichlorhydrin with hydrofluoric acid in a platinum dish. Yellow oil, soluble in alcohol, benzene, ether, or acetic acid. Dilute sulphuric acid at 200° converts it into a substance resembling cellulose (Paternò and Olivieri, Gazz. chim. ital. 24, i. 305; ii. 541).

Chlorbutylene oxide $\text{C}_4\text{H}_7\text{OCl}$. Obtained by treating a mixture of butenylglycerol and glacial acetic acid with hydrogen chloride; b.p. 125-5° (corr.) at 738 mm.; sp.gr. 1.098 at 15°/0 (Zikes, Monatsh. 6, 352).

EPINEPHRINE *v.* ADRENALINE; also SYNTHETIC DRUGS.

EPIRENAN *v.* SYNTHETIC DRUGS.

EPSOM SALTS. *Magnesium sulphate (v. MAGNESIUM).*

EQUILIBRIUM *v.* CHEMICAL AFFINITY.

ERBIUM. Sym. Er. At. wt. 167.7. A dark-grey powder; sp.gr. 4.77 at 15° (S. Meyer, Monatsh. 1899, 20, 793).

Sources.—Ytterbite (gadolinite), yttrant-alite, euxenite, xenotime.

The oxide of this metal belongs to the group of yttrium earths, forming with dysprosium and thulium the erbium sub-group, the salts of which are distinguished by their colour and by their characteristic absorption spectra in solution.

Separation and purification of the yttrium earths. The following methods have been employed in separating the closely related members of the yttrium earths:

1. *Fractional decomposition of nitrates* (Bahr and Bunsen, Annalen, 1866, 137, 1). The nitrates, heated until nitrous fumes are evolved, leave a vitreous residue of basic nitrates, the solutions of which, in hot water, slowly deposit, on cooling, small pink needles containing the greater proportion of the coloured erbium earths. The crystals are extracted with 3 p.c. nitric acid, the solution evaporated, the residue again heated, and the whole series of operations repeated many times. The erbium earths

accumulate in the less soluble basic salts, whilst the remaining yttrium earths, and any cerium earths which may be present, accumulate in the final mother liquors, and are not readily freed completely from the erbium earths. Further separation is effected by heating these nitrates from the final mother liquors so strongly that the residue consists of oxides mixed with insoluble basic nitrates. On extraction with water, the erbium compounds remain undissolved, and the operation is repeated till the more soluble yttrium salts no longer show absorption bands.

2. *Differences in the solubility of the oxides.*—The oxides are mixed with water and treated with an amount of nitric acid insufficient to convert the oxides into normal nitrates. The mixture becomes hot, and, after cooling, concentrated nitric acid is added until the product assumes a reddish tint. The precipitate is then digested with alcohol, which dissolves the normal nitrate, to the exclusion of the basic nitrates. The latter consist chiefly of erbium salts mixed with some ytterbium and scandium compounds, the more basic yttrium and cerite metals passing into solution. The final separation of erbium from ytterbium and scandium is effected by fractionally precipitating the basic nitrates by adding oxides to the solution of normal nitrates. In this operation ytterbium and scandium are precipitated as basic nitrates, while erbium remains dissolved (*v. Drossbach, Ber. 1902, 35, 2826*).

3. *Fractional precipitation by alkalis or aniline.*—The addition of ammonia to hot solutions of the salts of the yttrium group occasions the precipitation of basic salts which are easily filtered.

The neutral chloride dissolved in 50 p.c. alcohol is decomposed at 90° with alcoholic aniline, or the hydroxide is treated with aniline hydrochloride in aqueous solution (*Drossbach, Ber. 1896, 29, 2452*; *Mullmann and Baur, ibid. 1900, 33, 1748*; *1902, 35, 2382*; *Urban, Compt. rend. 1901, 132, 136*; *Krüss, Annalen, 1891, 265, 1*; *Zeitsch. anorg. Chem. 1893, 3, 108, 353, 407*).

4. *Fractionation with ammonium carbonate and acetic acid.*—The hydroxides of the yttrium group are moderately soluble in concentrated aqueous ammonium carbonate, and from this solution the earths may be fractionally precipitated by acetic acid (*Dennis and Dales, J. Amer. Chem. Soc. 1902, 24, 400*).

5. *Fractionation of oxalates, acetates, acetyl-acetonates, ethylsulphates* (*Urban, Ann. Chim. Phys. 1900, [7] 19, 184*; *Marc, Ber. 1902, 35, 2370*); *formates* (*K. A. Hofmann, ibid. 1908, 41, 308*); *ferrocyanides* (*Böhm, Die Darstellung der seltenen Erden*); *bromates* (*James, J. Amer. Chem. Soc. 1908, 30, 182*); *chromates* (*Krüss and Zoose, Zeitsch. anorg. Chem. 1893, 3, 92*).

Erbia (*erbium oxide*) Er_2O_3 . A pink powder obtained by heating the oxalate at 575°–845°; sp.gr. 8.64; sp.ht. 0.065.

The salts of erbium have a pink or reddish colour, a sweet, astringent taste, and their solutions exhibit characteristic absorption bands in the red, green, and blue regions of the spectrum. The wave lengths corresponding with the two most prominent bands are as follows: λ 522.5–523.5 and 647.5–651.5.

Unless ionic dissociation is repressed, dilute solutions of the various erbium salts exhibit identical absorption spectra (*Zeitsch. physikal. Chem. 1906, 56, 624*; *v. Purvis, Proc. Camb. Phil. Soc. 1903, 12, 202, 206*). The absorption bands undergo displacement when the solutions are placed in a magnetic field (*J. Becquerel, Compt. rend. 1907, 145, 1412*).

(For accounts of the flame, spark, and arc emission spectra, *v. Thalén, ibid. 1880, 91, 326*; *Exner and Haschek, Wien. Akad. Ber. 1899, 108, IIa, 1071, 1123*.)

Erbium salts exhibit signs of radio-activity (*Strong, Amer. Chem. J. 1909, 42, 147*).

Erbium sulphate $\text{Er}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$. Pink monoclinic crystals, separating from aqueous solution at 20°–25°; isomorphous with the corresponding yttrium, praseodymium, and neodymium salts (*Kraus, Zeitsch. Cryst. 1901, 34, 307*).

The double sulphates $\text{Er}_2(\text{SO}_4)_3 \cdot \text{K}_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$ and $\text{Er}_2(\text{SO}_4)_3 \cdot (\text{NH}_4)_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$, are readily soluble in cold water.

Erbium nitrate $\text{Er}(\text{NO}_3)_3 \cdot 5\text{H}_2\text{O}$. Large reddish crystals stable in air. When heated on platinum wire, the nitrate imparts an intense greenish colour to the flame, which, when viewed through the spectroscope, shows bright lines in the yellow-green and orange-blue regions of the spectrum. These bright lines correspond in position with the dark bands of the absorption spectrum.

Erbium formate $\text{Er}(\text{CHO}_2)_3 \cdot 2\text{H}_2\text{O}$. Crystallises from cold aqueous solution.

Erbium oxalate $\text{Er}_2(\text{C}_2\text{O}_4)_3 \cdot 10\text{H}_2\text{O}$ (*K. A. Hofmann, Ber. 1910, 43, 2631*) is a reddish, sparingly soluble microcrystalline powder.

Erbium platinumocyanide $\text{Er}_2[\text{Pt}(\text{CN})_4]_3 \cdot 21\text{H}_2\text{O}$, like the corresponding yttrium salt, crystallises in red prisms with a green metallic reflex.

G. T. M.

ERECTHIDIS OIL consists of a terpene $\text{C}_{10}\text{H}_{16}$, which boils at 175°, and at 18.5° has a sp.gr. of 0.838. This body absorbs a molecule of hydrochloric acid without the separation of a crystalline compound. The portion of the oil which boils above 200° also consists of a terpene (*Beilstein and Wiegand, Ber. 15, 2854*).

EREPSIN *v. Enzymes*, art. FERMENTATION.

ERGOT OF RYE. *Spurred rye*; *Ergota*; *Secale cornutum*. (*Ergot de seigle*, Fr.; *Mutterkorn*, Ger.) Ergot of rye consists of the compact mycelium or spawn, the nutritive organ, of the fungus *Claviceps purpurea* (Tulasne), developed within the palæa of the rye fruits. The same fungus grows upon the fruits of other members of the natural order Gramineæ, giving rise to less-known ergots, as, for instance, *ergot of wheat* or *ergot of oat*. The fungus is collected in the second or intermediate stage of its development, in which it remains dormant for many months. At this period it is noticeable projecting out of the heads of the rye as long, narrow, slightly arched grains of a purplish black colour and horny consistence. Ergot has been known for some three hundred years, and is an agent of great importance in medicine. Its chief action is that of a stimulant of the uterine muscles. It is employed in cases of insufficient contractile power, and as a remedy for uterine and other forms of hæmorrhage. (Further botanical and historical

particulars are given by Flückiger and Hanbury (Flück. a. Hanb. 740); Pereira, Mat. Med. 3rd ed. 2, 996; Cooke, Brit. Fungi, 772; Pharm. J. [3] 1, 702; Benti. a. Trim. 303; Stoddart, Pharm. J. [3] 10, 194; Wilson, *ibid.* [3] 6, 525, 545, and 564; Parsons, Rep. U.S. Commissioner Agriculture, 1880, 136; Holmes, Pharm. J. [3] 16, 684.)

Ergot when kept undergoes decomposition of a kind which affects materially its physiological activity. To prevent this, many methods of preservation have been suggested. These depend generally either upon removal of the oil by a solvent such as light petroleum, or by expression, or on the addition of some substance such as ether or benzoin which surrounds the drug with an antiseptic vapour (*v. Goble*, J. Pharm. Chim. [4] 17, 217; Ducros, Z. oesterr. Apoth. V. 1876, 8; Gionvié, *ibid.* 1876, 126; Perret, Bull. Gen. Thérap. 1882, 202; Moss, Pharm. J. [3] 16, 274).

Few articles of materia medica have been more studied chemically than ergot, but of the numerous more or less definite constituents which have been isolated, there were none that represented in a satisfactory manner the physiological activity of the drug, or at all events that were available to the therapist. Thus ergot is still administered in the form of aqueous or other extract more or less concentrated and freed from inactive constituents. Formulæ for these pharmaceutical preparations, which are liable generally to the same deteriorations on keeping as the drug itself, find their place in the various pharmacopœias. One of the most celebrated extracts of ergot, *ergotin* or *ergotine*, is that of the French pharmacist Bonjean (J. Pharm. Chim. 1843, 4, 107; Compt. rend. July 17, 1843). (For examples of others, *v. Long*, Med. Press Cir. 8, 435; Ronayne, *ibid.* 9, 267; Squibb, Proc. Amer. Pharm. Assoc. 1873, 957; Gerrard, Pharm. J. [3] 5, 805; 13, 235; Wernich, Y.-Book Ph. 1875, 349; Carles, J. Pharm. Chim. 1878, 28, 45; Active Principle of Ergot of Rye, Pharm. J. [3] 6, 942; 7, 4; Zellhoefer, Proc. Amer. Pharm. Assoc. 1877, 404; Yvon, Révue Méd. Nov. 15, 1879; Catillon, Y.-Book Ph. 1880, 305; Diehl, Pharm. J. [3] 12, 519; Hallberg, Amer. J. Pharm. 1883, 8; Conrad, Y.-Book Ph. 1883, 299; Denzel and Waeker, Arch. Pharm. [3] 22, 314; Clark, Pharm. J. [3] 16, 521; Engelmann, Y.-Book Ph. 1887, 276).

Vauquelin, in 1816, made a chemical analysis of ergot (Ann. Chim. Phys. 3, 337), and among other early investigators are Pettekofer, Rep. Pharm. 3, 65; Winkler (Christison on Poisons); Ludwig, Arch. Pharm. [2] 114, 193; Wiggers, Annalen, 1, 129; J. Pharm. Chim. 18, 525; Chevallier, Neuest. Entd. Mat. Med. 1837, 129. The results obtained by Wiggers, which were confirmed in their main points by Chevallier, may be taken to represent those researches. That observer finds 35 p.c. of *fixed oil*, after removal of which with ether an alcoholic extract of the residue is prepared, and this on evaporation and washing of the residue with water, leaves 1½ p.c. of a very active resinous substance to which the name *ergotine* was applied.

About the year 1865 Wenzell (Vierteljahresschrift prakt. Pharm. 14, 18) announced the discovery of three new compounds obtained from

ergot: two amorphous alkaloids, *ergotine* and *ebotine*, and a volatile acid with which they are combined, *ergotic acid*. This ergotine must not be confused either with pharmaceutical preparations such as Bonjean's ergotine or with indefinite substances like Wigger's ergotine. The research of Wenzell was confirmed and extended by Manassewitz (Pharm. Zeit. 6, 387), Hermann (Vierteljahresschrift prakt. Pharm. 18, 481; Neues Rep. Pharm. 20, 283), and Ganser (Arch. Pharm. 144, 195; Neues Rep. Pharm. 20, 301).

Tanret, in 1875 (Compt. rend. 81, 896; 86, 888; Ann. Chim. Phys. [5] 17, 493; J. Pharm. Chim. 26, 320), announced the discovery of an active crystalline alkaloid which he named *ergotinine* in order to distinguish it from the resinous ergotin of previous investigators. From the mother liquors of this base, Tanret obtained a further yield of alkaloid in an amorphous form. This was called *amorphous ergotinine*, since, in other respects, it closely resembled the crystalline product.

A further examination of ergot was conducted by Dragendorff and his pupils (Dragendorff and Podwissotzky, Pharm. J. [3] 6, 1001; Neuer. Jahresh. Pharm. 1877, 39; Podwissotzky, Y.-Book Ph. 1884, 87; Blumberg, Pharm. J. [3] 9, 23, 66, 147 and 598). Several substances were obtained and analysed, but their state of purity was not sufficient to characterise them as individual compounds.

Kobert (Chem. Zentr. 1885, 66) also announced the discovery of three new compounds in ergot, *cornutine*, *ergotic*, and *sphaclimic acids*. Tanret (J. Pharm. Chim. 11, 309), however, questioned the existence of these compounds, and came to the conclusion that cornutine is ergotinine more or less profoundly altered. It also appears probable that the numerous ergot substances investigated by Jacobj (Chem. Zentr. 1897, i. 483, 1059) are mixtures (Kraft, Arch. Pharm. 244, 366; Barger and Carr, Chem. Soc. Trans. 91, 338).

The following substances were isolated by Kraft (*l.c.*): a phytosterol, *ergosterol*, which was first noted in 1869 by Ludwig (Arch. Pharm. 137, 36), and subsequently investigated by Tanret (Compt. rend. 108, 98); two alkaloids: *ergotinine* and *hydroergotinine*, which is isomorphous with and more soluble than ergotinine; a crystalline δ-lactonic acid, *secalonic acid* C₁₄H₁₄O₆, m.p. 244°, and the corresponding hydroxy acid, and another acid formed from this by loss of carbon dioxide; *aminosecalon-sulphonic acid* (Kobert's ergotic acid)

betaine, choline, and mannitol.

Kraft's hydroergotinine, which corresponds to Tanret's amorphous ergotinine, was obtained in a high state of purity by Barger and Carr (*l.c.*) by recrystallising its salts. These investigators have given the name *ergotoxine* to this alkaloid.

To obtain ergotinine, the drug is extracted with 86 p.c. alcohol. The residue, after the removal of the spirit by distillation, separates into three parts: a fatty layer, an aqueous extract, and a resinous precipitate. The precipitate and the fatty layer are extracted with ether and the ethereal solution is shaken with dilute sulphuric acid which takes up the alkaloid as sulphate. The salts of the ergot

alkaloids are very slightly soluble in water and the slight solubility of the chloride and especially the bromide may be used as a means of purification. The residue left on evaporation of the alcoholic extract is treated with light petroleum to remove fat and oily matter; it is then dissolved in ethyl acetate and shaken with citric acid solution. Sodium bromide is added and the alkaloids are precipitated as hydrobromides. A rough separation of the ergotinine from the ergotoxine can be effected by the repeated shaking of the solution of the mixed hydrobromides in dilute caustic soda solution with ether. In this way the ergotinine is removed first. The base is then crystallised from alcohol, leaving ergotoxine in the mother liquor. Ergotinine crystals consist of long needles which, on heating, melt with decomposition about 220°, the exact point depending on the rate of heating. Analysis leads to the formula $C_{35}H_{49}O_6N_5$.

To prepare ergotoxine, the caustic liquor from which the ergotinine has been extracted is neutralised, rendered alkaline again with sodium carbonate and extracted with ether. The residue, after evaporation of the ether, together with that from the ergotinine mother liquors, is dissolved in 80 p.c. alcohol, and a slight excess of phosphoric acid in alcohol is added. After keeping for a few days, ergotoxine phosphate crystallises out and is recrystallised from alcohol. Obtained in this way, ergotoxine forms a light white powder which, when heated, softens at about 155° and gradually melts at 162°-164°. Analysis agrees with the formula $C_{35}H_{49}O_6N_5$. Ergotoxine can be converted by loss of water into ergotinine: for example, by boiling a solution of the former with methyl alcohol or by the action of acetic anhydride.

The colour reaction for ergotinine, described by Tanret, obtained by the addition of concentrated sulphuric acid to a solution of ergotinine in ether or in ethyl acetate, when a transitory orange colouration, changing to blue, appears; and also the colour reaction described by Keller, which occurs when anhydrous ferric chloride is added to ergotinine in concentrated sulphuric acid, in which case change of colour takes place from pale yellow to orange, crimson, green, and finally dark blue, are both given by ergotoxine and with the same intensity. Although ergotoxine is amorphous, it yields crystalline salts, whilst the salts from the crystalline ergotinine have only been obtained in an amorphous condition. Barger and Ewins (Chem. Soc. Trans. 97, 284) show that ergotoxine contains a carboxyl group and that ergotinine is its lactone (or lactam). On destructive distillation both ergotoxine and ergotinine yield a small quantity of isobutyrylformamide $CHMe_2 \cdot CO \cdot CO \cdot NH_2$.

All the physiological effects described as characteristic of ergot, the alkaloid ergotoxine produces in very small dosage: (a) the effects ascribed by Kobert to sphacelinic acid, and by Jacoby to sphacelotoxin, viz. ataxia, dyspnoea, salivation, gastro-intestinal irritation, and gangrene; and (b) the stimulant effect on plain-muscular organs—in particular the arteries and the uterus—and the subsequent selective sympathetic motor paralysis given by many ergot preparations (Barger and Dale, Bio-Chem. J. 2, 240).

Ergotinine, however, when uncontaminated

with ergotoxine, has apparently no physiological activity (Barger and Dale, Arch. Pharm. 244, 554).

In addition to the complex physiologically active alkaloid, ergotoxine, there are present in ergot other simpler bases possessing physiological action. Such bases are derived from amino-acids by the elimination of carbon dioxide and are generally formed in putrefaction. The first markedly active base of this class, *p*-hydroxyphenylethylamine, was isolated from the aqueous extract of ergot by Barger (Chem. Soc. Trans. 95, 1123). It is formed from tyrosine during putrefaction, but it appears to be present in fresh ergot and not merely to be formed by putrefaction. It is the chief pressor constituent of most aqueous ergot extracts but does not produce contraction of the isolated uterus of the non-pregnant cat. This substance is manufactured by Burroughs, Wellcome & Co. under the name 'tyramine.' Its physiological action has been described by Dale and Dixon (J. Physiol. 39, 25). A third active principle has been discovered in ergot by Barger and Dale (Chem. Soc. Trans. 97, 2592) and simultaneously by Kutscher (Zentr. Physiol. 24, 163). Barger and Dale proved this compound to be 4-β-aminoethylglyoxaline (β-iminazoylethyl-

amine) $\left. \begin{array}{l} CH=N \\ NH-CH \end{array} \right\} C \cdot CH_2 \cdot CH_2 \cdot NH_2$, a base previously obtained by the putrefaction of histidine (Ackermann, Zeitsch. physiol. Chem. 65, 504). Ackermann and Kutscher, however, consider it closely related but not identical with 4-β-aminoethylglyoxaline on account of differences in the physiological action of the two bases (Zeitsch. Biol. 54, 387). The physiological activity of this compound is very great, and the presence of this constituent accounts for the intense activity exhibited by some ergot extracts in producing contraction of the isolated non-pregnant uterus of the cat. A third active principle of this class has been found in ergot by Engeland and Kutscher (Zentr. Physiol. 24, 479). This is *agmatine* $NH_2 \cdot C(: NH) \cdot NH \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot NH_2$ which was previously discovered in herring roe by Kossel (Zeitsch. physiol. Chem. 66, 257). The action of this compound on the uterus is similar to that of 4-β-aminoethylglyoxaline.

The phytosterol in spurred rye, ergosterol, has the formula $C_{25}H_{40}O_2$. It loses a molecule of water at 105°, and melts at 165°. When anhydrous, it quickly absorbs moisture from the air. It is accompanied in ergot by a similar crystalline substance *fongisterol*

m.p. 144°, a lower homologue of ergosterol (Tanret, Compt. rend. 147, 75).

Other pure substances which have been isolated from ergot are: uracil and succinic acid (Engeland and Kutscher, Zentr. Physiol. 24, 589), isoamylamine (Barger and Dale, Proc. Physiol. Soc., May 15th, 1909), putrescine and cadaverine (Rieländer, Sitzungsber. Ges. Naturw. Marburg, No. 7, 1908), leucine and aspartic acid of which Vahlen's 'clavine' (Arch. exp. Path. Pharm. 55, 131) is chiefly composed (Barger and Dale, Bio-Chem. J. 2, 295).

Tanret (Compt. rend. 149, 222) discovered in ergot a new base containing sulphur *ergothionine*

m.p. 290° (decomp.), which occurs to the extent of 0.1 p.c.

Ergot oil is dark brown in colour with a slightly irritant taste. Examined by Rathje (Arch. Pharm. 246, 692), its percentage composition was found to be oleic acid, 68; hydroxy-oleic acid, 5; unsaponifiable matter, 0.35; inorganic matter, 0.2; alkaloid, 0.6; glycerol, 7.5.

Ergotism or ergot-poisoning has occurred from time to time owing to the use of flour contaminated with ergot, and on this account a chemical examination of flour or bread for ergot is sometimes required. The methods employed depend chiefly on the recognition of the colouring matter of the fungus (*v. Boettger*, Chem. Zentr. [3] 2, 624; E. Hoffmann, Pharm. Zeit. 23, 576, 726, and 742; Stoddart, Pharm. J. [3] 10, 194; Wolff, Pharm. Zeit. 23, 532, and 694; Petri, Zeitsch. anal. Chem. 18, 211; Poehl, Ber. 16, 1975; Palm, Zeitsch. anal. Chem. 22, 319; Lauek, Lands. Versuchs-Stat. 1893, 305).

(For a method of evaluation of ergot of rye, see Beekurts and Grothe, Zeitsch. anal. Chem. 1899, 125; and Musset, Chem. Zentr. 1899, ii. 323.) A. S.

ERGOTIC ACID *v.* ERGOT OF RYE.

ERGOTINE *v.* ERGOT OF RYE; also VEGETO-ALKALOIDS.

ERGOTININE *v.* ERGOT OF RYE; also VEGETO-ALKALOIDS.

ERICA B *v.* PRIMULINE.

ERICOLIN is found in several plants belonging to the order *Ericaceae*, especially in the herb of the marsh wild rosemary, *Ledum palustre* (Linn.) (Rochleder and Schwarz, Annalen, 84, 368), less abundantly in the common heath or ling, *Calluna vulgaris* (Salisb.) (Rochleder, *ibid.* 354), in *Rhododendron ferrugineum* (Linn.) (Schwarz, *ibid.* 361), and in the red bearberry, *Arctostaphylos Uva-ursi* (Spreng.) (Kawalier, Sitz. W. 9, 29).

To prepare it from *L. palustre*, the chopped leaves are thrown into boiling water and boiled for several hours. The filtrate obtained after adding basic lead acetate to the liquid is evaporated in a retort to one-third of its bulk. In Thal's modification of this process (Ber. 16, 1502), the liquid is concentrated *in vacuo*, the separated lead salt filtered off, and the liquid freed from lead by hydrogen sulphide. The filtrate is then evaporated to a syrup, and the ericolin dissolved out by anhydrous ether alcohol. The substance left on evaporating this solvent is repeatedly dissolved in a mixture of ether and alcohol till it no longer leaves any residue (Rochleder and Schwarz).

On heating the mother liquor obtained in the preparation of arbutin from the leaves of red bearberry with dilute hydrochloric or sulphuric acid, ericolin is deposited as a resinous precipitate, which may be purified by solution in alcohol and precipitation by water (Kawalier).

Rochleder and Schwarz, after deducting 10.6 p.c. ash, found ericolin to contain 51.71 p.c. carbon and 7.19 hydrogen, whence they deduced its formula to be $C_{31}H_{56}O_{31}$ (51.00 C and 7.00 H).

Thal (*l.c.*), after separating an admixed substance (containing 57.5 p.c. carbon and 7.29 hydrogen), which was insoluble in ether alcohol, from ericolin, assigned to the latter body the formula $C_{28}H_{24}O_3$, but subsequently altered it to $C_{28}H_{30}O_3$ to explain the decomposition equations of the substance. Ericolin, as prepared by Thal,

is a brown-yellow, odourless, hygroscopic, bitter substance decomposing even below 100°. It is decomposed by water. By extracting successively with benzene, chloroform, and a mixture of ether and alcohol, different substances go into solution; it appears that the ericolin is thus broken up into a sugar and ericinol. With dilute sulphuric acid warmed to 100°, a sugar and a resinous brown-yellow viscid mass, hydroericinol, are produced. An analysis of the latter body gave numbers corresponding with the formula $x(C_8H_{12}O_2)$, subsequently modified to $x(C_5H_{10}O_2)$.

The equations representing these decompositions are as follows:—

Power and Tutin, however, could not isolate ericinol by Thal's process, and they found that ericinol was identical with furfural (Chem. Zentr. 1907, i. 916).

Thal also isolated ericolin from *Calluna vulgaris* (Salisb.), and recognised it by the smell of ericinol in many *Ericaceae* and *Vaccinieae*.

Kanger extracted ericolin from the leaves of the cowberry (*Vaccinium vitis idaea*) by means of ether alcohol. It was then purified by precipitating foreign substances with lead acetate, and removing excess of the latter with sulphuretted hydrogen. The substance so obtained was of a resinous nature, completely soluble in ether alcohol, and corresponded with the composition $C_{16}H_{22}O_{10}$ (Chem. Zeit. 1903, 27, 794). Ericolin is probably not a chemical individual, but consists of a mixture of glucoside-like substances.

Ericolin is poisonous towards many micro-organisms, particularly those belonging to the colon group, but has no action on acid-fast bacilli. Twort (Proc. Roy. Soc. 1909, B, 81, 248) has used it as a medium for the isolation and culture of human tuberculous bacilli from sputum.

ERIGERON CANADENSE is an oil consisting of a terpene boiling at 176°, which, when pure, has sp.gr. 0.850–0.870, and an optical rotation +52°. It is soluble in an equal volume of alcohol, and rapidly resinifies. The commercial oil has sp.gr. 0.8549–0.8963; optical rotation, +28° 48' to 84° 20'; and b.p. 172°–178° (Kepler and Pancoast, Amer. J. Pharm. 75, 216).

According to Rabak (Pharm. Review, 1905, 23, 81; 1906, 326), the oil obtained from the fresh herb (0.66 p.c.) is of a bright-yellow colour with a peculiar odour like that of caraway. On exposure to air, it deposits crystals, and a brownish resinous mass is formed. The oil from the dried herb (0.26 p.c.) was darker in colour, had a powerful aromatic odour, and gave no crystals when exposed to air. It also differed from the fresh herb oil in sp.gr., optical rotation, and other characteristics. In all probability, the terpeneol found in erigeron oil is a decomposition product. The oil absorbs two molecules of hydrochloric acid to form a solid dihydrochloride $C_{10}H_{16} \cdot 2HCl$, melting at 47°–48° (Beilstein and Wiegand, Ber. 15, 2854; Wallach, Annalen, 227, 292).

ERIOGLAUCINE. The trade name of the dyestuff obtained by condensing benzaldehyde-*o*-sulphonic acid with ethylbenzylaminesul-

phonic acid (J. Soc. Chem. Ind. of Basle, Eng. Pat. 25128; Guelm and Schüle, *Annalen*, 299, 347).

ERUCIC ACID $C_{22}H_{42}O_2$. A homologue of acrylic acid obtained, together with oleic acid, by the saponification of the fixed oil of white mustard. It was found together with behenic acid by Goldschmidt (*Sitz. W.* 70, 451) in the oil expressed from black mustard, and by Fitz (Ber. 1871, 442) in the fat oil of grape seeds. It is best obtained by saponifying rape oil (from *Brassica campestris*, Linn.) with alcoholic potash, distilling off the alcohol and dissolving the acid liberated on the addition of sulphuric acid in three times its volume of 95 p.c. alcohol; on cooling to 0°, crystals of erucic acid separate out in an almost pure condition (Reimer and Will, Ber. 1886, 3320). It may be obtained by saponifying colza oil, freeing the erucic acid from arachidic acid by treatment with glacial acetic acid, in which the latter is insoluble (Ponzio, *Gazz. Chim. ital.* 1904, ii. 50). It is also present in cod liver oil (Bull. Ber. 1906, 3570).

Erucic acid crystallises in colourless needles, m.p. 34°; b.p. 281° at 30 mm. Heated with phosphorus oxychloride, it forms an anhydride $C_{44}H_{82}O_3$, an oil which may be crystallised in a freezing mixture. By treatment with nitrous acid, or better, by warming erucic acid with dilute nitric acid to the melting-point and then adding sodium nitrite, brassidic acid (brassic acid) is produced. This acid stands to erucic acid in the same relation as elaidic to oleic acid. Fused with potash, erucic acid yields aradic (arachidic) and acetic acids. Concentrated nitric acid converts erucic acid into brassilic acid ($C_{13}H_{24}O_4$), pelargonic acid, arachidic acid, and a small quantity of dinitrononane (Fileti and Ponzio, J. pr. Chem. [2] 48, 323), and concentrated sulphuric acid into behenolactone (Shukow and Schestakow, Chem. Zentr. 1908, ii. 1415). With hydriodic acid and amorphous phosphorus, it is converted into behenic acid (Goldschmidt, J. 1876, 579). On treatment with phosphorus triiodide, iodobehenic acid is obtained, which on treatment with alcoholic potash, yields *iso*-erucic acid, m.p. 54° (Ponzio, *l.c.*). Erucic acid is converted into behenic acid by heating with iodine in a sealed tube for 4 hours at 270° (Reyehler, Bull. Soc. chim. [3] 1, 296). When bromine is added to erucic acid under water, a dibromide $C_{22}H_{40}Br_2O_2$ is produced. It crystallises from alcohol in small white nodular crystals, m.p. 42°–43°, and is reduced to erucic acid by sodium amalgam in alcoholic solution. Its barium and lead salts ($(C_{22}H_{41}Br_2O_2)_2Ba$ and $(C_{22}H_{41}Br_2O_2)_2Pb$ are white, viscid, easily decomposable precipitates (Otto, *Annalen*, 127, 182; 135, 226). Erucic acid dibromide heated in sealed tubes to about 145° for 7–8 hours, with 4 or 5 mols. potassium hydroxide in alcoholic solution, yields the potassium salts of behenic acid
